- 3.5 Promote continuing awareness and involvement of personnel
- 3.6 Provide for periodic review and evaluation of overall energy management program

**29.2.1.1 Phase I: Management Commitment**

A commitment by the directors of a company to initiate and support a program is essential. An energy coordinator is designated, and an energy management committee is formed. The committee should include personnel representing major company activities utilizing energy. A plan is formulated to set up the programs with a commitment of funds and personnel. Realistic overall goals and guidelines in energy savings should be established based on overall information in the company records, projected activities, and future fuel costs and supply. A formal organization as described earlier is not an absolute requirement for the program; smaller companies will simply give the energy management coordination task to a staff member.

**29.2.1.1.1 Organizing for Energy Conservation Programs**

The most important organizational step that will affect the success of an energy management (EM) program is the appointment of one person who has full responsibility for its operation. Preferably that person should report directly to the top management position and be given substantial authority in directing technical and financial resources within the bounds set by the level of management commitment. It is difficult to stress enough the importance of making the position of plant energy manager a full-time job. Any diversion of interest and attention to other aspects of the business is bound to badly affect the EM program. One reason is that the greatest opportunity for energy cost control and energy efficiency gains is in improved operational and maintenance practices. Implementing and sustaining good

operational and maintenance procedures is an exceedingly demanding job and requires a constant attention and a dedication to detail that is rarely found in corporate business life. The energy manager should be energetic, enthusiastic, dedicated, and political.

The second step is the appointment of the plant EM committee. This should consist of one group of persons who are able to and have some motivation for cutting fuel and electric costs and a second group who have the technical knowledge or access to data needed for the program department managers or their assistants. Thus, the EM committees should include labor representatives, the maintenance department head, a manager of finance or data storage, some engineers, and a public relations person. The energy manager should keep up to date on the energy situation daily, convene the committee weekly, and present a definitive report to top management at least monthly and at other times when required by circumstance. It is suggested also that several subcommittees be broken out of the main committee to consider such important aspects as capital investments, employee education, operator-training programs, external public relations, and so on. The committee will define strategy, provide criticism, publish newsletters and press releases, carry out employee programs, argue for the acceptance of feasible measures before management, represent the program in the larger community, and be as supportive as possible to the energy coordinator. This group has the most to risk and the most to gain. They must defend their own individual interests against the group, but at the same time must cooperate in making the program successful and thus be eligible for rewards from top management for their good work and corporate success.

As the EM program progresses to the energy audit and beyond, it will be necessary to keep all employees informed as to its purposes, its goals, and how its operation will impact plant operations and employee routine, comfort, and job performance. The education should proceed through written and oral channels as best benefits the organizational structure. Newsletters, posters, and employee meetings have been used successfully.

In addition to general education about energy conservation, it may prove worthwhile to offer specialized courses for boiler, mechanical, and electrical equipment operators and other workers whose jobs can affect energy utilization in the plant. The syllabuses should be based on thermodynamic principles applied to the systems involved and given on an academic level consistent with the workers' backgrounds. Long-range attempts to upgrade job qualifications through such training can have very beneficial effects on performance. The courses can be given by community colleges, by private enterprises professional societies, or by in-house technical staff, if available.

The material presented here on organization is based on the presumption that a considerable management organization already exists and that sufficient technical and financial resources exist for support of the energy management program as outlined. Obviously, very small businesses cannot operate on this scale; however, we have found many small companies that have carried out effective energy management efforts.

#### *29.2.1.1.2 Setting Energy Conservation Goals*

It is entirely appropriate and perhaps even necessary to select an energy reduction goal for the first year of the program very early in the program. The purpose is to gain the advantage of the competitive spirit of those employees that can be aroused by a target goal. Unfortunately, the true potential for conservation and the investment costs required to achieve it are not known until the plant energy audit is completed and a detailed study made of the data. Furthermore, a wide variety of energy-use patterns exists even with a single industry.

However, looking at the experience of other industries that have set goals and met them can provide some useful guidance.

An excellent example of a long-term successful energy management program in a large industrial corporation is that of the 3M Company, headquartered in St. Paul, Minnesota.<sup>9</sup> 3M is a large, diversified manufacturing company with more than 50 major product lines; it makes some 50,000 products at over 50 different factory locations around the country. The corporate energy management objective is to use energy as efficiently as possible in all operations; the management believes that all companies have an obligation to conserve energy and all other natural resources.

Energy productivity at 3M improved 63% from 1973 to 2004. They saved over \$70 million in 2004 because of their energy management programs and saved a total of over \$1.5 billion in energy expenses from 1973 to 2004. From 1998 to 2004, they reduced their overall energy use by 27% in their worldwide operations.<sup>10</sup> Their program is staffed by three to six people who educate and motivate all levels of personnel on the benefits of energy management. The categories of programs implemented by 3M include conservation, maintenance procedures, utility operation optimization, efficient new designs, retrofits through energy surveys, and process changes.

Energy efficiency goals at 3M are set, and then the results are measured against a set standard to determine the success of the programs. The technologies that have resulted in the most dramatic improvement in energy efficiency include heat recovery systems, high-efficiency motors, variable-speed drives (VSDs), computerized facility management systems, steam-trap maintenance, combustion improvements, variable-air-volume systems, thermal insulation, cogeneration, waste-steam utilization, and process improvements. Integrated manufacturing techniques, better equipment utilization, and shifting to non-hazardous solvents have also resulted in major process improvements.

The energy management program at 3M has worked very well, but the company's management is not yet satisfied. They have historically set a goal of further improving energy efficiency at a rate of 2%–3%/year for the next 5 years. This goal has produced a 10%–15% reduction in energy use per pound of product or per square foot of building space. They expect to substantially reduce their emissions of waste gases and liquids, to increase the energy recovered from wastes, and to constantly increase the profitability of their operations. 3M continues to stress the extreme importance that efficient use of energy can have on their industrial productivity.

In 2010, 3M met their 20% goal of reducing energy use from 2005. Their new goal is a 15% reduction in energy use per pound of product by 2015.

### **29.2.1.2 Phase 2: Audit and Analysis**

#### *29.2.1.2.1 Energy Audit of Equipment and Facilities*

Historical data for the facility should be collected, reviewed, and analyzed. The review should identify gross energy uses by fuel types, cyclic trends, fiscal year effects, dependence on sales or workload, and minimum energy-use ratios. Historical data are graphed in a form similar to the one shown in Chapter 22. Historical data assist in planning a detailed energy audit and alert the auditors as to the type of fuel and general equipment to expect. A brief facility walk-through is recommended to establish the plant layout, major energy uses, and primary processes or functions of the facility.

The energy audit is best performed by an experienced or at least trained team, since visual observation is the principal means of information gathering and operational assessment. A team would have from three to five members, each with a specific assignment for the audit. For example, one auditor would check the lighting, another the HAVC system, another the equipment and processes, another the building structure (floor space, volume,

insulation, age, etc.), and another the occupancy use schedule, administration procedures, and employees' general awareness of energy management.

The objectives of the audit are to determine how, where, when, and how much energy is used in the facility. In addition, the audit helps to identify opportunities to improve the energy-use efficiency and its operations. Some of the problems encountered during energy audits are determining the rated power of equipment, determining the effective hours of use per year, and determining the effect of seasonal, climatic, or other variable conditions on energy use. Equipment ratings are often obscured by dust or grease (unreadable nameplates). Complex machinery may not have a single nameplate listing the total capacity, but several giving ratings for component equipment. The effect of load is also important because energy use in a machine operating at less than full load may be reduced along with a possible loss in operating efficiency.

The quantitative assessment of fuel and energy use is best determined by actual measurements under typical operational conditions using portable or installed meters and sensing devices. Such devices include light meters, ammeters, thermometers, air flowmeters, and recorders. In some situations, sophisticated techniques such as infrared scanning or thermography are useful. The degree of measurement and recording sophistication naturally depends on available funds and the potential savings anticipated. For most situations, however, nameplate and catalog information are sufficient to estimate power demand. Useful information can be obtained from operating personnel and their supervisors particularly as it relates to usage patterns throughout the day.

The first two columns of the form are self-explanatory. The third column is used for the rated capacity of the device (e.g., 5 kW). The sixth column is used if the device is operated at partial load. Usage hours (column 7) are based on all work shifts and are corrected to account for the actual operating time of the equipment. The last three columns are used to convert energy units to a common basis (e.g., MJ or Btu).

Data recorded in the field are reduced easily by the use of specialized software or spread sheets that provide uniform results and summaries in a form suitable for review or for further analysis. Computer analysis also provides easy modification of the results to reflect specific management reporting requirements or to present desired comparisons for different energy use, types of equipment, and so on.

#### 29.2.1.2.2 *In-Plant Metering*

Submetering reduces the work and time required for an energy audit; indeed, it does much more than that. Because meters are tools for assessing production control and for measuring equipment efficiency, they can contribute directly to energy conservation and cost containment. Furthermore, submetering offers the most effective way of evaluating the worth of an energy efficiency measure. Too many managers accept a vendor's estimate of fuel savings after buying a recuperator. They may scan the fuel bills for a month or two after the purchase to get an indication of savings—usually in vain—and then relax and accept the promised benefit without ever having any real indication that it exists. It may well be that, in fact, it does not yet exist. The equipment may not be adjusted correctly or it may be operated incorrectly, and there is no way of knowing without directly metering the fuel input. It is estimated that at least 2.5% waste is recoverable by in-plant metering.

Oil meters are just as effective as gas meters used in the same way and are even less expensive on an energy-flow basis. Electric meters are particularly helpful in monitoring the continued use of machines or lighting during shutdown periods and for evaluating the efficacy of lubricants and the machinability of feedstock. The use of in-plant metering can have its dark side too. The depressing part is the requirement for making periodic readings.

It does not stop even there. Someone must analyze the readings so that something can be done about them. If full use is to be made of the information contained in meter readings, it must be incorporated into the energy information portion of the management information system. At the very least, each subreading must be examined chronologically to detect malfunctions or losses of efficiency. Better still, a derived quantity such as average energy per unit of production should be examined.

#### 29.2.1.2.3 *A Special Case: Energy Audit of a Process*

In some manufacturing and process industries, it is of interest to determine the energy content of a product. This can be done by a variation of the energy audit techniques described earlier. Since this approach resembles classical financial accounting, it is sometimes called energy accounting. In this procedure, the energy content of the raw materials is determined in a consistent set of energy units. Then, the energy required for conversion to a product is accounted for in the same units. The same is done for energy in the waste streams and the by-products. Finally, the net energy content per unit produced is used as a basis for establishing efficiency goals.

In this approach, all materials used in the product or used to produce it are determined. Input raw materials used in any specific period are normally available from plant records. Approximations of specific energy content for some materials can be found in the literature or can be obtained from the U.S. Department of Commerce or other sources. The energy content of a material includes that due to extraction and refinement as well as an inherent heating value it would have as a fuel prior to processing. Consequently, nonfuel-type ores in the ground are assigned zero energy, and petroleum products are assigned their alternate value as a fuel prior to processing in addition to the refinement energy. The energy of an input metal stock would include the energy due to extraction, ore refinement to metal, and any milling operations.

Conversion energy is an important aspect of the energy audit, since it is under direct control of plant management. All utilities and fuels coming into the plant are accounted for. They are converted to consistent energy units (joules or Btu) using the actual data available on the fuels or using approximate conversions.

Electrical energy is assigned the actual fuel energy required to produce the electricity. This accounts for power conversion efficiencies. A suggested approach is to assume (unless actual values are available from your utility) that 10.8 MJ (10,200 Btu) is used to produce 3.6 MJ (1 kW h), giving a fuel conversion efficiency of  $3.6 / 10.8 = 0.33$  or 33%.

The energy content of process steam includes the total fuel and electrical energy required to operate the boiler as well as line and other losses. Some complexities are introduced when a plant produces both power and steam, since it is necessary to allocate the fuel used to the steam and power produced. One suggested way to make this allocation is to assume that there is a large efficient boiler feeding steam to a totally condensing vacuum turbine. Then, one must determine the amount of extra boiler fuel that would be required to permit the extraction of steam at whatever pressure while maintaining the constant load on the generator. The extra fuel is considered the energy content of the steam being extracted.

Waste disposal energy is that energy required to dispose of or treat the waste products. This includes all the energy required to bring the waste to a satisfactory disposal state. In a case where waste is handled by a contractor or some other utility service, it would include the cost of transportation and treatment energy.

If the plant has by-products or coproducts, then energy credit is allocated to them. A number of criteria can be used. If the by-product must be treated to be utilized or recycled

(such as scrap), then the credit would be based on the raw material less the energy expended to treat the by-product for recycle. If the by-product is to be sold, the relative value ratio of the by-product to the primary product can be used to allocate the energy.

#### 29.2.1.2.4 *Analysis of Audit Results and Identification of Energy Management Opportunities*

Often, the energy audit will identify immediate energy management opportunities, such as unoccupied areas that have been inadvertently illuminated 24 h/day, equipment operating needlessly, and so on. Corrective housekeeping and maintenance action can be instituted to achieve short-term savings with little or no capital investment.

An analysis of the audit data is required for a more critical investigation of fuel waste and identification of the potential for conservation. This includes a detailed energy balance of each process, activity, or facility. Process modification and alternatives in equipment design should be formulated, based on technical feasibility and economic and environmental impact. Economic studies to determine payback, return on investment, and net savings are essential before making capital investments.

#### 29.2.1.3 *Phase 3: Implementation and Submeters*

At this point, goals for saving energy can be established more firmly, and priorities set on the modification and alterations to equipment and the process: effective measurement and monitoring procedures are essential in evaluating progress in the energy management program. Routine reporting procedures between management and operations should be established to accumulate information on plant performance and to inform plant supervisors of the effectiveness of their operation. Time-tracking charts of energy use and costs can be helpful. Involving employees and recognizing their contributions facilitates the achievement of objectives. Finally, the program must be continually reviewed and analyzed with regard to established goals and procedures.

### 29.2.2 **Energy Audit Report**

Energy audits do not save money and energy for companies unless the recommendations are implemented. Audit reports should be designed to encourage implementation. The goal in writing an audit report should not be the report itself; rather, it should be to achieve implementation of the report recommendations and thus achieve increased energy efficiency and energy cost savings for the customer. In this section, the authors discuss their experience with writing industrial energy audit reports and suggest some ways to make the reports more successful in terms of achieving a high rate of the recommendations.<sup>11</sup>

- *Present information visually:* The authors present their client's energy-use data visually with graphs showing the annual energy and demand usage by month. These graphs give a picture of use patterns. Any discrepancies in use show up clearly.
- *Make calculation sections helpful:* The methodology and calculations used to develop specific energy management opportunity recommendations are useful in an audit report. Including the methodology and calculations gives technical personnel the ability to check the accuracy of one's assumptions and one's work. However, not every reader wants to wade through pages describing the methodology and showing the calculations. Therefore, the authors provide this information in a technical supplement to the audit report. Because this section is clearly labeled as the technical supplement, other readers are put on notice as to the purpose of this section.

- *Use commonly understood units:* When preparing the report, be sure to use units that the client will understand. Discussing energy savings in terms of Btu (British thermal units) may be meaningful only to the engineers and more technical readers. For management and operating personnel, kilowatt-hours (for electricity) or therms (for natural gas) are better units, because most energy bills use these units.
- *Explain your assumptions:* A major problem with many reports is the failure to explain the assumptions underlying the calculations. For example, when the authors use operating hours in a calculation, it is always carefully shown how the number was figured, for example, "Your facility operates from 7:30 a.m. to 8:00 p.m., 5 days a week, 51 weeks/year. Therefore, we will use 3188 h in our calculations."

When basic assumptions and calculations are shown, the reader can make adjustments if those facts change. In the example given, if the facility decided to operate 24 h/day, the reader would know where and how to make changes in operating hours, because that calculation had been clearly labeled.

The authors use one section of their report to list the standard assumptions and calculations. Thus, explanations for each of the recommendations do not have to be repeated. Some of the standard assumptions/calculations included in this section are operating hours, average cost of electricity, demand rate, off-peak cost of electricity, and the calculation of the fraction of air-conditioning load attributable to lighting.

- *Be accurate and consistent:* The integrity of a report is grounded in its accuracy. This does not just mean correctness of calculations. Clearly, inaccurate calculations will destroy a report's credibility, but other problems can also undermine the value of a report. Use the same terminology so that the reader is not confused. Make sure that the same values are used throughout the report. Do not use two different load factors for the same piece of equipment in different recommendations. This, for example, could happen if one calculated the loss of energy due to leaks from a compressor in one recommendation and the energy savings due to replacing the compressor motor with a high-efficiency motor in another recommendation.
- *Proofread the report carefully:* Typographical and spelling errors devalue an otherwise good product. With computer spell checkers, there is very little excuse for misspelled words. Nontechnical readers are likely to notice this type of error, and they will wonder if the technical calculations are similarly flawed.

### 29.2.2.1 Report Sections

The authors have found that the following report format meets their clients' needs and fits the authors' definition of a user-friendly report.

*Executive summary:* The audit report should start with an executive summary that basically lists the recommended energy conservation measures and shows the implementation cost and dollar savings amount. This section is intended for the readers who want to see only the bottom line. Although the executive summary can be as simple as a short table, the authors add some brief text to explain the recommendations and sometimes include other special information needed to implement the recommendations. They also copy the executive summary on colored paper so that it stands out from the rest of the report.

*Energy management plan:* Following the executive summary, some information is provided to the decision makers on how to set up an energy management program in their facility. The authors view this section as one that encourages implementation of the report, so every attempt is made to try to make it as helpful as possible.

*Energy action plan:* In this subsection, the authors describe the steps that a company should consider in order to start implementing the report's recommendations.

*Energy financing options:* The authors also include a short discussion of the ways that a company can pay for the recommendations. This section covers the traditional use of company capital, loans for small businesses, utility incentive programs, and the shared savings approach of the energy service companies.

*Maintenance recommendations:* The authors do not usually make formal maintenance recommendations in the technical supplement, because the savings are not often easy to quantify. However, in this section of the report, energy savings maintenance checklists are provided for lighting, heating/ventilation/air conditioning, and boilers.

*The technical supplement:* The technical supplement is the part of the report that contains the specific information about the facility and the audit recommendations. The authors' technical supplement has two main sections: one includes the report's assumptions and general calculations and the other describes the recommendations in detail, including the calculations and methodology. The authors sometimes include a third section that describes measures that were analyzed and determined not to be cost effective, or that have payback times beyond the client's planning horizon.

*Standard calculations and assumptions:* This section was briefly described earlier when the importance of explaining assumptions was discussed. Here, the reader is provided with the basis for understanding many of the authors' calculations and assumptions. Included is a short description of the facility: square footage (both air-conditioned and unconditioned areas); materials of construction; type and level of insulation; etc. If the authors are breaking the facility down into subareas, those areas are described, and each area is assigned a number that is then used throughout the recommendation section.

Standard values calculated in this section include operating hours, average cost of electricity, demand rate, off-peak cost of electricity, and the calculation of the fraction of air-conditioning load attributable to lighting. When a value is calculated in this section, the variable is labeled with an identifier that remains consistent throughout the rest of the report.

*Audit recommendations:* This section contains a discussion of each of the energy management opportunities the authors have determined to be cost effective. Each energy management recommendation (or EMR) that was capsulized in the executive summary is described in depth in this section.

Again, the authors try to make the EMRs user-friendly. To do this, the narrative discussion is placed at the beginning of a recommendation, and the technical calculations are left for the very end. In this manner, the authors allow the readers to decide for themselves whether they want to wade through the calculations.

Each EMR starts with a table that summarizes the energy, demand and cost savings, implementation cost, and simple payback period. Then follows a short narrative

section that provides some brief background information about the recommended measure and explains how it should be implemented at the facility in question. If the authors are recommending installation of more than one item (lights, motors, air-conditioning units, etc.), a table is often used to break down the savings by unit or by area.

The final section of each EMR is the calculation section. Here the authors explain the methodology that was used to arrive at the report's savings estimates. The equations are provided, and it is shown how the calculations are performed so that the clients can see what has been done. If they want to change the report's assumptions, they can. If some of the data the authors have used are incorrect, they can replace it with the correct data and recalculate the results. However, by placing the calculations away from the rest of the discussion rather than intermingling it, the authors do not scare off the readers who need to know the other information.

*Appendix:* The authors use an appendix for lengthy data tables. For example, there is a motor efficiency table that is used in several of the authors' EMRs. Instead of repeating it in each EMR, it is printed in the appendix. The authors also include a table showing the facility's monthly energy-use history and a table listing the major energy-using equipment. Similar to the calculation section of the EMRs, the appendix allows the authors to provide backup information without cluttering up the main body of the report.

---

## 29.3 Improving Industrial Energy Audits

### 29.3.1 Preventing Overestimation of Energy Savings in Audits

A frequent criticism of energy audits is that they overestimate the savings potential available to the facility. This section addresses several problem areas that can result in overly optimistic savings projections and suggests ways to prevent mistakes.<sup>12</sup> This possibility of overestimation concerns many of the people and organizations that are involved in some part of this energy audit process. It concerns utilities that do not want to pay incentives for demand-side management programs if the facilities will not realize the expected results in energy or demand savings. Overestimates also make clients unhappy when their energy bills do not decrease as much as promised. The problem multiplies when a shared savings program is undertaken by the facility and an energy service company. Here, the difference between the audit projections and the actual metered and measured savings may be so significantly different that either there are no savings for the facility or the energy service company makes no profit.

More problems are likely with the accuracy of the energy audits for industrial and manufacturing facilities than for smaller commercial facilities or even large buildings because the equipment and operation of industrial facilities are more complex. However, many of the same problems discussed here in terms of industrial and manufacturing facilities can occur in audits of large commercial facilities and office buildings. Based on the authors' auditing experience for industrial and manufacturing facilities over the last 5 years, it is possible to identify a number of areas where problems are likely to occur, and a number of these are presented and discussed. In addition, the authors have developed a few methods and approaches to dealing with these potential problems, and a few ways have been found to initiate energy

audit analyses that lead the authors to improved results. One of these approaches is to collect data on the energy-using equipment in an industrial or manufacturing facility and then to perform both an energy and a demand balance to help ensure that reasonable estimates of energy uses—and therefore, energy savings—are available for this equipment.

In addition, unfortunately, some analysts use the average cost of electricity to calculate energy savings. This can give a false picture of the actual savings and may result in overly optimistic savings predictions. This section also discusses how to calculate the correct values from the electricity bills and when to use these values. Finally, this section discusses several common energy savings measures that are frequently recommended by energy auditors. Some of these may not actually save as much energy or demand as expected, except in limited circumstances. Others have good energy-saving potential but must be implemented carefully to avoid increasing energy use rather than decreasing it.

### 29.3.2 Calculating Energy and Demand Balances

The energy and demand balances for a facility are an accounting of the energy flows and power used in the facility. These balances allow the energy analyst to track the energy and power inputs and outputs (uses) and see whether they match. A careful energy analyst should perform an energy-and-demand balance on a facility before developing and analyzing any EMRs.<sup>13</sup> In this way, the analyst can determine what the largest energy users are in a facility, can find out whether all—or almost all—energy uses have been identified, and can see whether more savings have been identified than are actually achievable. Making energy-use recommendations without utilizing the energy and demand balances is similar to making budget-cutting recommendations without knowing exactly where the money is currently being spent.

When the authors perform an energy survey (audit), all of the major energy-using equipment in the facility is inventoried. Then, the authors list the equipment and estimate its energy consumption and demand using the data gathered at the facility, such as nameplate ratings of the equipment and operating hours. The energy balance is developed by major equipment category, such as lighting, motors, HVAC, and air compressors. There is also a category called *miscellaneous* to account for loads that were not individually surveyed, such as copiers, electric typewriters, computers, and other plug loads. The authors typically allocate 10% of the actual energy use and demand to the *miscellaneous* category in the demand and energy balances. (For an office building instead of a manufacturing facility, this miscellaneous load might be 15%–20%.) Then, the energy and demand for each of the other categories is calculated.

#### 29.3.2.1 Lighting

The first major category analyzed is lighting, because this is usually the category in which the authors have the most confidence for knowing the actual demand and hours of use. Thus, they believe that the energy and demand estimates for the lighting system are the most accurate and can then be subtracted from the total actual use to let the authors continue to build up the energy and demand balance for the facility. The authors record the types of lamps and number of lamps used in each area of the facility and ask the maintenance person to show them the replacement lamps and ballasts used. With this lamp and ballast wattage data, together with a good estimate of the hours that the lights are on in the various areas, they can construct what they believe to be a fairly accurate description of the energy and demand for the lighting system.

### 29.3.2.2 Air Conditioning

There is generally no other “easy” or “accurate” category to work on, so the authors proceed to either air conditioning or motors. In most facilities, there will be some air conditioning, even if it is just for the offices that are usually part of the industrial or manufacturing facility. Many facilities—particularly in the hot and humid southeast—are fully air conditioned. Electronics, printing, medical plastics and devices, and many assembly plants are common ones seen to be fully air conditioned. Boats, metal products, wood products, and plastic pipe-manufacturing facilities are most often not air conditioned. Air-conditioning system nameplate data are usually available and readable on many units, and efficiency ratings can be found from published ARI data<sup>14</sup> or from the manufacturers of the equipment. The biggest problem with air conditioning is to get runtime data that will allow the author(s) of the report to determine the number of full-load equivalent operating hours for the air-conditioning compressors or chillers. From the authors’ experience in north and north-central Florida, about 2200–2400 h is used per year of compressor runtime for facilities that have air conditioning that responds to outdoor temperature. Process cooling requirements are much different and would typically have much larger numbers of full-load equivalent operating hours. With the equipment size, the efficiency data, and the full-load equivalent operating hours, it is possible to construct a description of the energy and demand for the air-conditioning system.

### 29.3.2.3 Motors

Turning next to motors, the authors begin looking at one of the most difficult categories to deal with in the absence of fully metered and measured load factors on each motor in the facility. In a 1-day plant visit, it is usually impossible to get actual data on the load factors for more than a few motors. Even then, that data are only good for the 1 day that it was taken. Very few energy-auditing organizations can afford the time and effort to make long-term measurements of the load factor on each motor in an industrial or manufacturing facility. Thus, estimating motor load factors becomes a critical part of the energy and demand balance, and also a critical part of the accuracy of the actual energy audit analysis. Motor nameplate data show the horsepower rating, the manufacturer, and sometimes the efficiency. If not, the efficiency can usually be obtained from the manufacturer, or from standard references such as the *Energy-Efficient Motor Systems Handbook*,<sup>15</sup> or from software databases such as MotorMaster produced by the Washington State Energy Office.<sup>16</sup> The authors inventory all motors over 1 hp and sometimes try to look at the smaller ones if there is enough time.

Motor runtime is another parameter that is very difficult to obtain. When the motor is used in an application where it is constantly on is an easy case. Ventilating fans, circulating pumps, and some process-drive motors are often in this class because they run for a known constant period of time each year. In other cases, facility operating personnel must help provide estimates of motor runtimes. With data on the horsepower, efficiency, load factor, and runtimes of motors, it is possible to construct a detailed table of motor energy and demands to use in the report’s balances. Motor load factors will be discussed further in a later section of this chapter.

### 29.3.2.4 Air Compressors

Air compressors are a special case of motor use with most of the same problems. Some help is available in this category because some air compressors have instruments showing the load factor and some have runtime indicators for hours of use. Most industrial

and manufacturing facilities will have several air compressors, and this may lead to some questions as to which air compressors are actually used and how many hours they are used. If the air compressors at a facility are priority-scheduled, it may turn out that one or more of the compressors are operated continuously, and one or two smaller compressors are cycled or unloaded to modulate the need for compressed air. In this case, the load factors on the larger compressors may be unity. Using these data on the horsepower, efficiency, load factor, and runtimes of the compressors, the authors develop a detailed table of compressor energy use and demand for the report's energy and demand balances.

#### **29.3.2.5 Other Process Equipment**

Specialized process equipment must be analyzed on an individual basis because it will vary tremendously depending on the type of industry or manufacturing facility involved. Much of this equipment will utilize electric motors and will be covered in the motor category. Other electrically powered equipment, such as drying ovens, cooking ovens, welders, and laser and plasma cutters, are nonmotor electric uses and must be treated separately. Equipment nameplate ratings and hours of use are necessary to compute the energy and demand for these items. Process chillers are another special class that are somewhat different from the comfort air-conditioning equipment, because the operating hours and loads are driven by the process requirements and not the weather patterns and temperatures.

#### **29.3.2.6 Checking the Results**

After the complete energy and demand balances are constructed for the facility, the authors check to see if the cumulative energy/demand for these categories plus the miscellaneous category is substantially larger or smaller than the actual energy usage and demand over the year. If it is, and it is certain that all of the major energy uses have been identified, the authors know that a mistake was made somewhere in their assumptions. As mentioned earlier, one area that has typically been difficult to accurately survey is the energy use by motors. Measuring the actual load factors is difficult on a 1-day walk-through audit visit, so the authors use the energy balance data to help estimate the likely load factors for the motors. This is done by adjusting the load factor estimates on a number of the motors to arrive at a satisfactory level of the energy and demand from the electric motors. Unless this is done, it is likely that the energy used by the motors will be overestimated and thus overestimate the energy savings from replacing standard motors with high-efficiency motors.

As an example, the authors performed an energy audit for one large manufacturing facility with a lot of motors. It was first assumed that the load factors for the motors were approximately 80%, based on what the facility personnel explained. Using this load factor gave a total energy use for the motors of over 16 million kW h/year and a demand of over 2800 kW. Because the annual energy use for the entire facility was just over 11 million kW h/year and the demand never exceeded 2250 kW, this load factor was clearly wrong. The authors adjusted the average motor load factor to 40% for most of the motors, which reduced the energy-use figure to 9 million kW h and the demand to just under 1600 kW. These values are much more reasonable with motors making up a large part of the electrical load of this facility.

After the energy/demand balances have been satisfactorily compiled, the authors use a graphics program to draw a pie chart showing the distribution of energy/demand between the various categories. This allows visual representation of which categories are

responsible for the majority of the energy use. It also makes it possible to focus the energy savings analyses on the areas of largest energy use.

### **29.3.3 Problems with Energy Analysis Calculations**

Over the course of performing 120 industrial energy audits, the authors have identified a number of problem areas. One lies with the method of calculating energy cost savings: whether to use the average cost of electricity or break the cost down into energy and demand cost components. Other problems include instances where the energy and demand savings associated with specific energy efficiency measures may not be fully realized or where more research should go into determining the actual savings potential.

#### ***29.3.3.1 On-Peak and Off-Peak Uses: Overestimating Savings by Using the Average Cost of Electricity***

One criticism of energy auditors is that they sometimes overestimate the dollar savings available from various energy efficiency measures. One way overestimation can result is when the analyst uses only the average cost of electricity to compute the savings. Because the average cost of electricity includes a demand component, using this average cost to compute the savings for companies who operate on more than one shift can overstate the dollar savings. This is because the energy cost during the off-peak hours does not include a demand charge. A fairly obvious example of this type of problem occurs when the average cost of electricity is used to calculate savings from installing high-efficiency security lighting. In this instance, there is no on-peak electricity use, but the savings will be calculated as if all the electricity was used on-peak.

The same problem arises when an energy efficiency measure does not result in an expected—or implicitly expected—demand reduction. Using a cost of electricity that includes demand in this instance will again overstate the dollar savings. Examples of energy efficiency measures that fall into this category are occupancy sensors, photosensors, and adjustable-speed drives (ASDs). Although all of these measures can reduce the total amount of energy used by the equipment, there is no guarantee that the energy use will only occur during off-peak hours. While an occupancy sensor will save lighting kW h, it will not save any kW if the lights come on during the peak load period. Similarly, an ASD can save energy use for a motor, but if the motor needs its full-load capability—as an air-conditioning fan motor or chilled-water pump motor might—during the peak load period, the demand savings may not be there. The reduced use of the device or piece of equipment on peak load times may introduce a diversity factor that produces some demand savings. However, even this savings will be overestimated by using the average cost of electricity in most instances.

On the other hand, some measures can be expected to provide their full demand savings at the time of the facility's peak load. Replacing 40 W T12 fluorescent lamps with 32 W T8 lamps will provide a verifiable demand savings because the wattage reduction will be constant at all times and will specifically show up during the period of peak demand. Shifting loads to off-peak times should also produce verifiable demand savings. For example, putting a timer or energy management system control on a constant-load electric drying oven to ensure that it does not come on until the off-peak time will result in the full demand savings. Using high-efficiency motors also seems like it would also produce verifiable savings because of its reduced kW load, but in some instances, there are other factors that tend to negate these benefits. This topic is discussed later.

To help solve the problem of overestimating savings from using the average cost of electricity, the authors divide their energy savings calculations into a demand savings and an energy savings. In most instances, the energy savings for a particular piece of equipment is calculated by first determining the demand savings for that equipment and then multiplying by the total operating hours of the equipment. To calculate the annual cost savings (CS), the following formula is used:

$$CS = [\text{Demand savings} \times \text{Average monthly demand rate} \times 12 \text{ months/year}] \\ + [\text{Energy savings} \times \text{Average cost of electricity without demand}]$$

If a recommended measure has no demand savings, then the energy cost savings is simply the energy savings times the average cost of electricity without demand (or off-peak cost of electricity). This procedure forces us to think carefully about which equipment is used on-peak and which is used off-peak.

To demonstrate the difference in savings estimates, consider replacing a standard 30 hp motor with a high-efficiency motor. The efficiency of a standard 30 hp motor is 0.901 and a high-efficiency motor is 0.931. Assume the motor has a load factor of 40% and operates 8760 h/year (three shifts). Assume also that the average cost of electricity is \$0.068/kW h (including demand), the average demand cost is \$3.79/kW/month, and the average cost of electricity without demand is \$0.053/kW h. The equation for calculating the demand of a motor is

$$D = HP \times LF \times 0.746 \times \frac{1}{Eff}$$

The savings on demand (or demand reduction) from installing a high-efficiency motor is

$$DR = HP \times LF \times 0.746 \times \left( \frac{1}{Eff_S} - \frac{1}{Eff_H} \right) \\ = 30 \text{ hp} \times 0.40 \times 0.746 \text{ kW/hp} \times \left( \frac{1}{0.901} - \frac{1}{0.931} \right) = 0.32 \text{ kW}$$

The annual energy savings (ES) is

$$ES = DR \times H = 0.32 \text{ kW} \times 8760 \text{ h/year} = 2803.2 \text{ kW h/year}$$

Using the earlier average cost of electricity, the cost savings (CS<sub>1</sub>) are calculated as

$$CS_1 = ES \times (\text{Average cost of electricity}) = 2803.2 \text{ kW h/year} \times 0.068/\text{kW h} = 190.62/\text{year}$$

Using the earlier recommended formula,

$$CS = [\text{Demand savings} \times \text{Average monthly demand rate} \times 12 \text{ months/year}] \\ \times [\text{Energy savings} \times \text{Average cost of electricity without demand}] \\ = (0.32 \text{ kW} \times 3.79/\text{month} \times 12 \text{ months/year}) + (2803.2 \text{ kW h/year} \times 0.053/\text{kW h}) \\ = (14.55 + 148.57)/\text{year} = 163.12/\text{year}$$

In this example, using the average cost to calculate the energy cost savings overestimates the cost savings by \$27.50/year, or 17%. Although the actual amount is small for one motor, if this error is repeated for all the motors for the entire facility as well as all other measures that reduce the demand component only during the on-peak hours, then the cumulative error in cost savings predictions can be substantial.

### **29.3.3.2 Motor Load Factors**

Many in the energy-auditing business started off assuming that motors ran at full load or near full load, and based their energy consumption analysis and energy savings analysis on that premise. Most books and publications that give a formula for finding the electrical load of a motor do not even include a term for the motor load factor. However, since experience soon showed the authors that few motors actually run at full load or near full load, they were left in a quandary about what load factor to actually use in calculations, because good measurements on the actual motor load factor are rarely to be had. A classic paper by Hoshide shed some light on the distribution of motor load factors from his experience.<sup>17</sup> In this paper, Hoshide noted that only about one-fourth of all three-phase motors run with a load factor greater than 60%, with 50% of all motors running at load factors between 30% and 60%, and one-fourth running with load factors less than 30%. Thus, those auditors who had been assuming that a typical motor load factor was around 70% or 80% had been greatly overestimating the savings from high-efficiency motors, adjustable-speed drives, high-efficiency belts, and other motor-related improvements.

The energy and demand balances discussed earlier also confirm that overall motor loads in most facilities cannot be anywhere near 70%–80%. The authors' experience in manufacturing facilities has been that motor load factors are more correctly identified as being in the 30%–40% range. With these load factors, one obtains very different savings estimates and economic results than when one assumes that a motor is operating at a 70% or greater load factor, as shown in the example earlier.

One place where the motor load factor is critical—but often overlooked—is in the savings calculations for ASDs. Many motor and ASD manufacturers provide easy-to-use software that will determine savings with an ASD if you supply the load profile data. Usually a sample profile is included that shows calculations for a motor operating at full load for some period of time and at a fairly high overall load factor—for example, around 70%. If the motor has a load factor of only 50% or less to begin with, the savings estimates from a quick use of one of these programs may be greatly exaggerated. If the actual motor use profile with the load factor of 50% is used, one may find that the ASD will still save some energy and money, but often not as much as it looks like when the motor is assumed to run at the higher load factor. For example, a 20 hp motor may have been selected for use on a 15 hp load to ensure that there is a “safety factor.” Thus, the maximum load factor for the motor would be only 75%. A typical fan or pump in an air-conditioning system that is responding to outside weather conditions may operate at its maximum load only about 10% of the time. Because that maximum load here is only 15 hp, the average load factor for the motor might be more like 40% and will not be even close to 75%.

### **29.3.3.3 High-Efficiency Motors**

Another interesting problem area is associated with the use of high-efficiency motors. In Hoshide's paper mentioned earlier, he notes that, in general, high-efficiency motors run at a faster full-load speed than standard-efficiency motors. This means that when a standard

motor is replaced by a high-efficiency motor, the new motor will run somewhat faster than the old motor in almost every instance. This is a problem for motors that drive centrifugal fans and pumps, because the higher operating speed means greater power use by the motor. Hoshide provides an example where he shows that a high-efficiency motor that should be saving about 5% energy and demand actually uses the same energy and demand as the old motor. This occurs because the increase in speed of the high-efficiency motor offsets the power savings by almost exactly the same 5% due to the cube law for centrifugal fans and pumps.

Few energy auditors ever monitor fans or pumps after replacing a standard motor with a high-efficiency motor; therefore, they have not realized that this effect has cancelled the expected energy and demand savings. Since Hoshide noted this feature of high-efficiency motors, the authors have been careful to make sure that their recommendations for replacing motors with centrifugal loads carry the notice that it will probably be necessary to adjust the drive pulleys or drive system so that the load is operated at the same speed to achieve the expected savings.

#### **29.3.3.4 Motor Belts and Drives**

The authors have developed some significant questions about the use of cogged and synchronous belts, and the associated estimates of energy savings. It seems fairly well accepted that cogged and synchronous belts do transmit more power from a motor to a load than if standard smooth V-belts are used. In some instances, this should certainly result in some energy savings. A constant-torque application like a conveyor drive may indeed save energy with a more efficient drive belt because the motor will be able to supply that torque with less effort. Consider also a feedback-controlled application, such as a thermostatically controlled ventilating fan or a level-controlled pump. In this case, the greater energy transmitted to the fan or pump should result in the task being accomplished faster than if less drive power were supplied, and some energy savings should exist. However, if a fan or a pump operates in a nonfeedback application—as is common for many motors—then there will not be any energy savings. For example, a large ventilating fan that operates at full load continuously without any temperature or other feedback may not use less energy with an efficient drive belt, because the fan may run faster as a result of the drive belt having less slip. Similarly, a pump that operates continuously to circulate water may not use less energy with an efficient drive belt. This is an area that needs some monitoring and metering studies to check the actual results.

Whether efficient drive belts result in any demand savings is another question. Because, in many cases, the motor is assumed to be supplying the same shaft horsepower with or without high-efficiency drive belts, a demand savings does not seem likely in these cases. It is possible that using an efficient belt on a motor with a constant-torque application that is controlled by an ASD might result in some demand savings. However, for the most common applications, the motor is still supplying the same load and thus would have the same power demand. For feedback-controlled applications, there might be a diversity factor involved so that the reduced operation times could result in some demand savings—but not the full value otherwise expected. Thus, using average cost electricity to quantify the savings expected from high-efficiency drive belts could well overestimate the value of the savings. Verification of the cases where demand savings are to be expected is another area where more study and data are needed.

### 29.3.3.5 Adjustable-Speed Drives

The authors would like to close this discussion with a return to ASDs because these are devices that offer a great potential for savings, but have far greater complexities than are often understood or appreciated. Fans and pumps form the largest class of applications where great energy savings is possible from the use of ASDs. This is a result again of the cube law for centrifugal fans and pumps where the power required to drive a fan or pump is specified by the cube of the ratio of the flow rates involved. According to the cube law, a reduction in flow to one-half the original value could now be supplied by a motor using only one-eighth of the original horsepower. Thus, whenever an air flow or liquid flow can be reduced, such as in a variable-air-volume system or with a chilled-water pump, there is a dramatic savings possible with an ASD. In practice, there are two major problems with determining and achieving the expected savings.

The first problem is the one briefly mentioned earlier, and that is determining the actual profile of the load involved. Simply using the standard profile in a piece of vendor's software is not likely to produce very realistic results. There are so many different conditions involved in fan and pump applications that taking actual measurements is the only way to get a good idea of the savings that will occur with an ASD. Recent papers have discussed the problems with estimating the loads on fans and pumps and have shown how the cube law itself does not always give a reasonable value.<sup>18–20</sup> The Industrial Energy Center at Virginia Polytechnic Institute and Virginia Power Company have developed an approach wherein they classify potential ASD applications into eight different groups and then estimate the potential savings from the analysis of each system and from measurements of that system's operation.<sup>21</sup> Using both an analytical approach and a few measurements allows them to get a reasonable estimate of the motor load profile and thus a reasonable estimate of the energy and demand savings possible.

The second problem is achieving the savings predicted for a particular fan or pump application. It is not sufficient to just identify the savings potential and then install an ASD on the fan or pump motor. In most applications, there is some kind of throttling or bypass action that results in almost the full horsepower still being required to drive the fan or pump most of the time. In these applications, the ASD will not save much, unless the system is altered to remove the throttling or bypass device and a feedback sensor is installed to tell the ASD what fraction of its speed to deliver. This means that in many air flow systems, the dampers or vanes must be removed so that the quantity of air can be controlled by the ASD changing the speed of the fan motor. In addition, some kind of feedback sensor must be installed to measure the temperature or pressure in the system to send a signal to the ASD or a PLC controller to alter the speed of the motor to meet the desired condition. The additional cost of the alterations to the system and the cost of the control system needed greatly change the economics of an ASD application compared to the case where only the purchase cost and installation cost of the actual ASD unit are considered.

For example, a dust collector system might originally be operated with a large 150 hp fan motor running continuously to pick up the dust from eight saws. However, because production follows existing orders for the product, sometimes only two, three, or four saws are in operation at a particular time. Thus, the load on the dust collector is much lower at these times than if all eight saws are in use. An ASD is a common recommendation in this case, but estimating the savings is not easy to begin with, and after the costs of altering the collection duct system and of adding a sophisticated control system to the ASD are considered, the bottom-line result is much different than the cost of the basic ASD with installation. Manual or automatic dampers must be added to each duct at a saw so that it can be shut off when the saw is

not running. In addition, a PLC for the ASD must be added to the new system, together with sensors added to each damper so that the PLC will know how many saws are in operation and therefore what speed to tell the ASD for the fan to run to meet the dust collection load of that number of saws. Without these system changes and control additions, the ASD itself will not save any great amount of energy or money. Adding them in might well double the cost of the basic ASD and double the payback time that may have originally been envisioned.

Similarly, for a water or other liquid flow application, the system piping or valving must be altered to remove any throttling or bypass valves, and a feedback sensor must be installed to allow the ASD to know what speed to operate the pump motor. If several sensors are involved in the application, then a PLC may also be needed to control the ASD. For example, putting an ASD on a chilled-water pump for a facility is much more involved, and much more costly, than simply cutting the electric supply lines to the pump motor and inserting an ASD for the motor. Without the system alterations and without the feedback control system, the ASD cannot provide the savings expected.

### **29.3.4 General Rules**

New energy auditors often do not have the experience to have engineering judgment about the accuracy of their analyses. That is, they cannot look at the result and immediately know that it is not within the correct range of likely answers. Because the authors' IAC program has a fairly steady turnover of students, they find the same type of errors cropping up over and over as draft audit reports are reviewed. To help new team members develop the engineering judgment that they will eventually gain through experience, the authors are developing "rules of thumb" for energy analyses. The rules of thumb are intended to provide a ballpark estimate of the expected results. For example, if the rule of thumb for the percentage for installing high-efficiency motors says that the savings range is 3%–5% of the energy use by the motors, then a student who comes up with a savings of 25% will immediately know that the calculations are wrong and will know to check the assumptions and data entry to see where the error lies. Without these rules of thumb, the burden for checking these results is shifted to the team leaders and program directors. Although this does not obviate the need for report review, it minimizes the likelihood that errors will occur. The authors suggest that other organizations who frequently utilize and train new energy auditors consider developing such rules of thumb for the major types of facilities or geographic areas that they audit.

Energy auditing is not an exact science, but a number of opportunities are available for improving the accuracy of the recommendations. Techniques that may be appropriate for small-scale energy audits can introduce significant errors into the analyses for large complex facilities. This chapter began by discussing how to perform an energy-and-demand balance for a company. This balance is an important step in doing an energy-use analysis, because it provides a check on the accuracy of some of the assumptions necessary to calculate savings potential. It also addressed several problem areas that can result in overly optimistic savings projections and suggested ways to prevent mistakes. Finally, several areas where additional research, analysis, and data collection are needed were identified. After this additional information is obtained, everyone can produce better and more accurate energy audit results.

#### **29.3.4.1 Decision Tools for Improving Industrial Energy Audits: OIT Software Tools**

The OIT—a program operated by the U.S. Department of Energy, Division of Energy Efficiency and Renewable Energy (EERE)—provides a series of computer software tools that can be obtained free from their website or by ordering a CD at no cost from them.

With the right know-how, these powerful tools can be used to help identify and analyze energy system savings opportunities in industrial and manufacturing plants. Although the tools are accessible at the U.S. DOE website for download, they also encourage users to attend a training workshop to enhance their knowledge and take full advantage of opportunities identified in the software programs. For some tools, advanced training is also available to help further increase expertise in their use.

#### **29.3.4.2 Decision Tools for Industry: Order the Portfolio of Tools on CD**

The Decision Tools for Industry CD contains the MotorMaster+ (MM+), Pump System Assessment Tool, Steam System Tool Suite, 3E Plus, and the new AIRMaster+ software packages described here. In addition, it includes MM+ training. The training walks the user through both the fundamentals and the advanced features of MM+ and provides examples for using the software to make motor purchase decisions. The CD can be ordered via e-mail from the EERE Information Center or by calling the EERE Information Center at 1-877-EERE-INF (877-337-3463).

##### *DOE industry tools*

- AIRMaster+
- Chilled Water System Analysis Tool (CWSAT)
- Combined Heat and Power Application Tool (CHP)
- Fan System Assessment Tool (FSAT)
- MotorMaster+ 4.0
- MotorMaster+ International
- NO<sub>x</sub> and Energy Assessment Tool (NxEAT)
- Plant Energy Profiler for the Chemical Industry (ChemPEP Tool)
- Process Heating Assessment and Survey Tool (PHAST)
- Pumping System Assessment Tool 2004 (PSAT)
- Steam System Tool Suite

##### *Other industry tools*

- ASDMaster: Adjustable-Speed Drive Evaluation Methodology and Application

**AIRMaster+:** AIRMaster+ provides comprehensive information on assessing compressed-air systems, including modeling existing and future system upgrades, and evaluating savings and effectiveness of energy efficiency measures.

**Chilled Water System Analysis Tool Version 2.0:** Use the CWSAT to determine energy requirements of chilled-water distribution systems and to evaluate opportunities for energy and cost savings by applying improvement measures. Provide basic information about an existing configuration to calculate current energy consumption and then select proposed equipment or operational changes for comparison. The results of this analysis will help the user quantify the potential benefits of chilled-water system improvements.

**Combined Heat and Power Application Tool:** The CHP Application Tool helps industrial users evaluate the feasibility of CHP for heating systems such as fuel-fired furnaces, boilers,

ovens, heaters, and heat exchangers. It allows the analysis of three typical system types: fluid heating, exhaust-gas heat recovery, and duct burner systems. Use the tool to estimate system costs and payback period, and to perform “what-if” analyses for various utility costs. The tool includes performance data and preliminary cost information for many commercially available gas turbines and default values that can be adapted to meet specific application requirements.

*Fan System Assessment Tool:* Use the FSAT to help quantify the potential benefits of optimizing fan system configurations that serve industrial processes. FSAT is simple and quick, and requires only basic information about the fans being surveyed and the motors that drive them. With FSAT, one can calculate the amount of energy used by one’s fan system, determine system efficiency, and quantify the savings potential of an upgraded system.

*MotorMaster+ 4.0:* An energy-efficient motor selection and management tool, MotorMaster+ 4.0 software, includes a catalog of over 20,000 AC motors. This tool features motor inventory management tools, maintenance log tracking, efficiency analysis, savings evaluation, energy accounting, and environmental reporting capabilities.

*MotorMaster+ International:* MotorMaster+ International includes many of the capabilities and features of MotorMaster+; however, now it can help evaluate repair/replacement options on a broader range of motors, including those tested under the Institute of Electrical and Electronic Engineers standard and those tested using International Electrical Commission methodology. With this tool, analyses can be conducted in different currencies, and it will calculate efficiency benefits for utility rate schedules with demand charges, edit and modify motor rewind efficiency loss defaults, and determine “best available” motors. The tool can be modified to operate in English, Spanish, and French.

*NO<sub>x</sub> and Energy Assessment Tool:* The NxEAT helps plants in the petroleum refining and chemical industries to assess and analyze NO<sub>x</sub> emissions and application of energy efficiency improvements. Use the tool to inventory emissions from equipment that generates NO<sub>x</sub> and then compare how various technology applications and efficiency measure affect overall costs and reduction of NO<sub>x</sub>. Perform “what-if” analyses to optimize and select the most cost-effective methods for reducing NO<sub>x</sub> from systems such as fired heaters, boilers, gas turbines, and reciprocating engines.

*Plant Energy Profiler for the Chemical Industry:* The ChemPEP Tool provides chemical plant managers with the information they need to identify savings and efficiency opportunities. The ChemPEP Tool enables energy managers to see overall plant energy use, identify major energy-using equipment and operations, summarize energy cost distributions, and pinpoint areas for more detailed analysis. The ChemPEP Tool provides plant energy information in an easy-to-understand graphical manner that can be very useful to managers.

*Process Heating Assessment and Survey Tool:* The PHAST provides an introduction to process heating methods and tools to improve thermal efficiency of heating equipment. Use the tool to survey process-heating equipment that uses fuel, steam, or electricity, and identify the most energy-intensive equipment. It can also help perform an energy (heat) balance on selected equipment (furnaces) to identify and reduce nonproductive energy use. Compare performance of the furnace under various operating conditions and test “what-if” scenarios.

*Pumping System Assessment Tool 2004:* The PSAT helps industrial users assess the efficiency of pumping system operations. The PSAT uses achievable pump performance data from Hydraulic Institute standards and motor performance data from the MotorMaster+ database to calculate potential energy and associated cost savings.

*Steam System Tool Suite:* In many industrial facilities, steam system improvements can save 10%–20% in fuel costs. To help tap into potential savings in typical industrial facilities, DOE offers a suite of tools for evaluating and identifying steam system improvements.

- *Steam System Assessment Tool (SSAT) Version 2.0.0:* The SSAT allows steam analysts to develop approximate models of real steam systems. Using these models, SSAT can be applied to quantify the magnitude—energy, cost, and emissions savings—of key potential steam improvement opportunities. SSAT contains the key features of typical steam systems. The enhanced and improved version includes features such as a steam demand savings project, a user-defined fuel model, a boiler stack loss worksheet for the SSAT fuels, a boiler flash steam recovery model, and improved steam trap models.
- *3E Plus, Version 3.2:* The program calculates the most economical thickness of industrial insulation for user input operating conditions. Calculations can be made using the built-in thermal performance relationships of generic insulation materials or supply conductivity data for other materials.
- *Steam Tool Specialist Qualification Training:* Industry professionals can earn recognition as Qualified Specialists in the use of the BestPractices Steam Tools. DOE offers an in-depth (2–1½)-day training session for steam system specialists, including 2 days of classroom instruction and a written exam. Participants who complete the workshop and pass the written exam are recognized by DOE as Qualified Steam Tool Specialists. Specialists can assist industrial customers in using the BestPractices Steam Tools to evaluate their steam systems.

*ASDMaster:* Adjustable-Speed Drive Evaluation Methodology and Application. This Windows® software program helps plant or operations professionals determine the economic feasibility of an ASD application, predict how much electrical energy may be saved by using an ASD, and search a database of standard drives. The package includes two 3.5 in. diskettes, a user's manual, and a user's guide. Please order from EPRI. For more information, see the ASDMaster website.

#### **29.3.4.3 Energy-Auditing Help from Industrial Assessment Centers**

The IACs, sponsored by the U.S. Department of Energy, EERE Division Industrial Technologies Program (ITP), provide eligible small- and medium-sized manufacturers with no-cost energy assessments. Additionally, the IACs serve as a training ground for the next generation of energy-savvy engineers.

Teams composed mainly of engineering faculty and students from the centers, located at 24 universities around the country, conduct energy audits or industrial assessments and provide recommendations to manufacturers to help them identify opportunities to improve productivity, reduce waste, and save energy. Recommendations from industrial assessments have averaged about \$55,000 in potential annual savings for each manufacturer.

As a result of performing these assessments, upper-class and graduate engineering students receive unique hands-on assessment training and gain knowledge of industrial process systems, plant systems, and energy systems, making them highly attractive to employers.

**FIGURE 29.5**

Industrial Assessment Center (IAC) locations, [http://www1.eere.energy.gov/manufacturing/tech\\_assistance/iacs\\_locations](http://www1.eere.energy.gov/manufacturing/tech_assistance/iacs_locations), and service areas. (From U.S. Department of Energy, Office of Industrial Technologies, Washington, DC, 2005, <http://www.energy.gov/eere/amo/industrial-assessment-centers-iacs>.)

To be eligible for an IAC assessment, a manufacturing plant must meet the following criteria:

- Within Standard Industrial Codes 20-39
- Generally be located within 150 miles of a host campus
- Gross annual sales below \$100 million
- Fewer than 500 employees at the plant site
- Annual energy bills more than \$100,000 and less than \$2.5 million
- No professional in-house staff to perform the assessment

Presently (2014), there are 26 schools across the country participating in the IAC Program. For additional information or to apply for an assessment, go to <http://www.energy.gov/eere/amo/industrial-assessment-centers-iacs> and click on one of the school names for contact information. A map of the IAC centers and their service areas is shown in Figure 29.5.

## 29.4 Industrial Electricity End Uses and Electrical Energy Management

### 29.4.1 Importance of Electricity in Industry

Electricity use in industry is primarily for electric drives, electrochemical processes, space heating, lighting, and refrigeration. Table 29.2 lists the relative importance of the use of electricity in the industrial sector. Timely data on industrial and manufacturing energy use are difficult to obtain, since its frequency of collection is only every 3 years, and then it takes EIA

**TABLE 29.2**

Manufacturing Electricity by End Use, 2006

	GW h	Percent Use
Machine drives (motors)	422,408	53.8
Electrochemical processes	60,323	10.1
Process heat	101,516	10.4
Facility HVAC (motors)	77,768	8.3
Facility lighting	58,013	6.5
Process cooling and refrigeration	60,389	6.0
On-site transportation (motors)	2,197	0.1
Other process	13,816	0.4
Other	45,000	
Total	8,40,787	100

Source: U.S. Department of Energy, Energy Information Agency, Manufacturing Energy Consumption Survey, 2006, Washington, DC, 2012.

another 3 years to process the results. In addition, it is only a sample survey, so the accuracy of the data is less than what would be optimal. However, it is better data than is available for most countries in the world. The most recent, detailed data on manufacturing energy end use (as of early 2013) are still the 2006 Manufacturing Energy Consumption Survey (MECS) data. Table 29.2 shows the electrical energy consumed for different end uses in 2006.

Because several of the categories mentioned earlier involve motor use, the total manufacturing energy use for motors is actually the sum of several categories:

Machine drives	50.5%
Facility HVAC	7.2%
Process cooling and refrigeration	9.3%
On-site transportation	0.1%
Total motors	67%

This gives the same results shown as the pie chart shown in [Figure 29.3](#).

### 29.4.2 Electric Drives

Electric drives of one type or another use 68% of industrial electricity. Examples include electric motors, machine tools, compressors, refrigeration systems, fans, and pumps. Improvements in these applications would have a significant effect on reducing industrial electrical energy.

Motor efficiency can be improved in some cases by retrofit (modifications, better lubrication, improved cooling, heat recovery), but generally requires purchasing of more efficient units. For motors in the sizes 1–200 hp, manufacturers today supply a range of efficiency. Greater efficiency in a motor requires improved design, more costly materials, and generally greater first cost. Losses in electric drive systems may be divided into four categories:

	Typical Efficiency (%)
Prime mover (motor)	10–95
Coupling (clutches)	80–99
Transmission	70–95
Mechanical load	1–90

**TABLE 29.3**

Typical Electric Motor Data (1800 rpm Motors)

Size (hp)	Full Load Efficiency (%)	
	1975	1993 (EPACT)
1	76	82.5–85.5
5	84	87.5–89.5
10	85	90.2–91.7
20	85	91.7–93.0
40	85	93.0–94.1
100	91	94.5–95.4
200	90	95.4–96.2

Each category must be evaluated to determine energy management possibilities. In many applications, the prime mover will be the most efficient element of the system. Table 29.3 shows typical induction motor data, illustrating the improvement in efficiency due to the 1992 Energy Policy Act. Note that both efficiency and power factor decrease with partial load operation, which means that motors should be sized to operate at or near full load ratings.

Manufacturers have introduced new high-efficiency electric motors in recent years. Many utilities offer rebates of \$5–\$20/hp for customers installing these motors.

### 29.4.3 Electrochemical Processes

Industrial uses of electrochemical processes include electrowinning, electroplating, electrochemicals, electrochemical machining, fuel cells, welding, and batteries.

A major use of electrolytic energy is in electrowinning—the electrolytic smelting of primary metals such as aluminum and magnesium. Current methods require on the order of 13–15 kW h/kg; efforts are under way to improve electrode performance and reduce this to 10 kW h/kg. Recycling now accounts for one-third of aluminum production; this requires only about 5% of the energy required to produce aluminum from ore.

Electrowinning is also an important low-cost method of primary copper production. Another major use of electrochemical processes is in the production of chlorine and sodium hydroxide from salt brine. Electroplating and anodizing are two additional uses of electricity of great importance. Electroplating is basically the electrodeposition of an adherent coating upon a base metal. It is used with copper, brass, zinc, and other metals. Anodizing is roughly the reverse of electroplating, with the workpiece (aluminum) serving as the anode. The reaction progresses inward from the surface to form a protective film of aluminum oxide on the surface.

Fuel cells are devices for converting chemical energy to electrical energy directly through electrolytic action. Currently, they represent a small use of energy, but research is directed at developing large systems suitable for use by electric utilities for small dispersed generation plants. Batteries are another major use of electrolytic energy, ranging in size from small units with energy storage in the joule or fractional joule capacity up to units proposed for electric utility use that will store  $18 \times 10^9$  J (5 MW h). Electroforming, etching, and welding are forms of electrochemical used in manufacturing and material shaping. The range of applications for these techniques stretches from microcircuits to aircraft carriers. In some applications, energy for machining is reduced, and reduction of scrap also saves energy. Welding has benefits in the repair and salvage of materials and equipment, reducing the need for energy to manufacture replacements.

#### **29.4.4 Electric Process Heat**

Electricity is widely used as a source of process heat due to ease of control, cleanliness, wide range in unit capacities (watts to megawatts), safety, and low initial cost. Typical heating applications include resistance heaters (metal sheath heaters, ovens, furnaces), electric salt bath furnaces, infrared heaters, induction and high-frequency resistance heating, dielectric heating, and direct arc electric furnaces.

Electric arc furnaces in the primary metals industry are a major use of electricity. Typical energy use in a direct arc steel furnace is about 2.0 kW h/kg. Electric arc furnaces are used primarily to refine recycled scrap steel. This method uses about 40% of the energy required to produce steel from iron ore using basic oxygen furnaces. Energy savings can be achieved by using waste heat to preheat scrap iron being charged to the furnace.

Glass making is another process that uses electric heat. An electric current flows between electrodes placed in the charge, causing it to melt. Electric motors constitute a small part of total glass production. Major opportunities for improved efficiency with electric process heat applications in general include improved heat transfer surfaces, better insulation, heat recovery, and improved controls.

#### **29.4.5 HVAC**

Heating, ventilating, and air conditioning (HVAC) is an important use of energy in the industrial sector. The environmental needs in an industrial operation can be quite different from residential or commercial operations. In some cases, strict environmental standards must be met for a specific function or process. More often, the environmental requirements for the process itself are not limiting, but space conditioning is a prerequisite for the comfort of production personnel. Chapters 22 and 23 have a more complete discussion of energy management opportunities in HVAC systems.

#### **29.4.6 Lighting**

Industrial lighting needs range from low-level requirements for assembly and welding of large structures (such as shipyards) to the high levels needed for the manufacture of precision mechanical and electronic components such as integrated circuits. Lighting uses about 20% of the U.S. electrical energy and 7% of all energy. Of all lighting energy, about 20% is industrial, with the balance being sizes of systems; energy management opportunities in industrial lighting systems are similar to those in residential/commercial systems (see Chapter 22).

#### **29.4.7 Electric Load Analysis**

The energy audit methodology is a general tool that can be used to analyze energy use in several forms and over a short or long period of time. Another useful technique, particularly for obtaining a short-term view of industrial electricity use, is an analysis based on the evaluation of the daily load curve. Normally, this analysis uses metering equipment installed by the utility and therefore available at the plant. However, special metering equipment can be installed if necessary to monitor specific process or building.

For small installations, both power and energy use can be determined from the kilowatt hour meter installed by the utility. Energy in kW h is determined by

$$E = (0.001)(K_h P_t C_t N) \text{ (kW h)} \quad (29.1)$$

where

$E$  is the electric energy used, kW h

$K_h$  is the meter constant, W h/revolution

$P_t$  is the potential transformer ratio

$C_t$  is the current transformer ratio

$N$  is the number of revolutions of the meter disk

(The value of  $K_h$  is usually marked on the meter.  $P_t$  and  $C_t$  are usually 1.0 for small installations.) To determine energy use, the meter would be observed during an operation and the number of revolutions of the disk counted. Then, the equation can be used to determine  $E$ .

To determine the average load over some period  $p$  (h), determine  $E$  as earlier for time  $p$  and then use the relation that

$$L = \frac{E}{p} \text{ (kW)} \quad (29.2)$$

where

$E$  is in kW h

$p$  is in h

$L$  is the load in kW

Larger installations will have meters with digital outputs or strip charts. Often, these will provide a direct indication of kW h and kW as a function of time. Some also indicate the reactive load (kVARs) or the power factor.

The first step is to construct the daily load curve. This is done by obtaining kW h readings each hour using the meter. The readings are then plotted on a graph to show the variation of the load over a 24 h period. Table 29.4 shows a set of readings obtained over a 24 h period in the XYZ manufacturing plant located in Sacramento, California, and operating one shift per day. These readings have been plotted in Figure 29.6.

Several interesting conclusions can be immediately drawn from this figure:

- The greatest demand for electricity occurs at 11:00.
- Through the lunch break, the third highest demand occurs.
- The ratio of the greatest demand to the least demand is approximately 3:1.
- Only approximately 50% of the energy used actually goes into making a product (54% on-shift use, 46% off-shift use).

When presented to management, these facts were of sufficient interest that a further study of electricity use was requested. Additional insight into the operation of a plant (and into the cost of purchase of electricity) can be obtained from the load analysis. Following a brief discussion of electrical load parameters, a load analysis for the XYZ company will be described.

**TABLE 29.4**

Kilowatt Hour Meter Readings for XYZ Manufacturing Company

Time Meter Read	Elapsed (kW h)	Notes Concerning Usage	Percentage of Total Usage (%)
1:00 (a.m.)	640

Any industrial electrical load consists of lighting, motors, chillers, compressors, and other types of equipment. The sum of the capacities of this equipment, in kW, is the *connected* load. The actual load at any point in time is normally less than the connected load since every motor is not turned on at the same time; only part of the lights may be on at any one time, and so on. Thus, the load is said to be diversified, and a measure of this can be found by calculating a *diversity factor*:

$$DV = \frac{(D_{m1} + D_{m2} + D_{m3} + \cdots)}{(D_{\max})} \quad (29.3)$$

where

$D_{m1}$ ,  $D_{m2}$ , and so on are the sum of maximum demand of individual loads in kW  
 $D_{\max}$  is the maximum demand of plant in kW

If the individual loads do not occur simultaneously (usually they do not), the diversity factor will be greater than unity. Typical values for industrial plants are 1.3–2.5.

**FIGURE 29.6**  
Daily load curve for XYZ company.

If each individual load operated to its maximum extent simultaneously, the *maximum* demand for power would be equal to the connected load, and the diversity factor would be 1.0. However, as pointed out earlier, this does not happen except for special cases. The demand for power varies over time as loads are added and removed from the system. It is usual practice for the supplying utility to specify a demand interval (usually 0.25, 0.5, or 1.0 h) over which it will calculate

$$D = \frac{E}{p} \text{ (kW)} \quad (29.4)$$

where

$D$  is the demand in kW

$E$  is the kW h used during  $p$

$p$  is the demand interval in h

The demand calculated in this manner is an average value, greater than the lowest instantaneous demand during the demand interval but less than the maximum demand during the interval.

Utilities are interested in *peak demand* since this determines the capacity of the equipment they must install to meet the customer's power requirements. This is measured by a demand factor, defined as

$$DF = \frac{D_{\max}}{CL} \quad (29.5)$$

where

$D_{\max}$  is the maximum demand in kW

$CL$  is the connected load in kW

The demand factor is normally less than unity; typical values range from 0.25 to 0.90.

Since the customer normally pays a premium for the maximum load placed on the utility system, it is of interest to determine how effectively the maximum load is used. The most effective use of the equipment would be to have the peak load occur at the start of the use period and continue unchanged throughout it. Normally, this does not occur, and a measure of the extent to which the maximum demand is sustained throughout the period (a day, month, or year) is given by the *hours use of demand*:

$$HUOD = \frac{E}{D_{\max}} \text{ (h)} \quad (29.6)$$

where

$HUOD$  is the hours use of demand in h

$E$  is the energy used in period  $p$ , in kW h

$D_{\max}$  is the maximum demand during period  $p$ , in kW

$p$  is the period over which  $HUOD$  is determined—for example, 1 day, 1 month, or 1 year ( $p$  is always expressed in h)

The *load factor* is another parameter that measures the plant's ability to use electricity efficiently. In effect, it measures the ratio of the average load for a given period of time to the maximum load that occurs during the same period. The most effective use results when the load factor is as high as possible once  $E$  or  $HUOD$  has been minimized (it is always less than 1). The load factor is defined as

$$LF = \frac{E}{(D_{\max})(p)} \quad (29.7)$$

where

$LF$  is the load factor (dimensionless)

$E$  is the energy used in period  $p$  in kW h

$D_{\max}$  is the maximum demand during period  $p$  in kW

$p$  is the period over which load factor is determined (e.g., 1 day, 1 month, or 1 year) in h

Another way to determine  $LF$  is from the relation

$$LF = \frac{HUOD}{p} \quad (29.8)$$

Still another method is to determine the average load,  $L$ —kW h/ $p$  during  $p$  divided by  $p$ —and then use the relation

$$LF = \frac{L}{D_{\max}} \quad (29.9)$$

These relations are summarized for convenience in Table 29.5.

Returning to the XYZ plant, the various load parameters can now be calculated. Table 29.6 summarizes the needed data and the results of the calculations. The most striking

**TABLE 29.5**

Summary of Load Analysis Parameters

Formulas	Definitions
$E = \frac{K_h P_t C_t N}{1000}$	$E$ = Electric energy used in period $p$ (kW h)
$L = \frac{E}{p}$	$E_{\max}$ = Maximum energy used during period $p$ (kW h)
$DV = \frac{(D_{m1} + D_{m2} + D_{m3})}{D_{\max}}$	$K_h$ = Meter constant (W h/revolution)
$D = \frac{E}{p}, D_{\max} = \frac{E_{\max}}{p}$	$P_t$ = Potential transformer ratio
$DF = \frac{D_{\max}}{CL}$	$C_t$ = Current transformer ratio
$HUOD = \frac{E}{D_{\max}}$	$N$ = Number of revolutions of the meter disk
$LF = \frac{E}{(D_{\max})(p)} = \frac{HUOD}{p} = \frac{L}{D_{\max}}$	$L$ = Average load (kW) $p$ = Period of time used to determine load, demand, electricity use, etc., normally 1 h, day, month, or year; measured in hours $DV$ = Diversity factor (dimensionless) $D_{\max}$ = Maximum demand in period $p$ (kW) $D_{m1}, D_{m2}, \dots$ = Maximum demand of individual load (kW) $D$ = Demand during period $p$ (kW) $DF$ = Demand factor for period $p$ (dimensionless) $CL$ = Connected load (kW) $HUOD$ = Hours use of demand during period $p$ (h) $LF$ = Load factor during period $p$ (dimensionless)

**TABLE 29.6**

Data for Load Analysis of XYZ Plant

$p = 24$ h
$E = 28,800$ kW h/day
$E_{\max} = 1850$ kW h
$CL = 2792$ kW
$D_{m1}, D_{m2}, \dots = 53, 62, 144, 80, 700, 1420$ kW

thing shown by the calculations is the hours use of demand, equal to 15.6. This is a surprise, since the plant is only operating one shift. The other significant point brought out by the calculations is the low load factor.

An energy audit of the facility was conducted, and the major loads were the evaluated number of energy management opportunities whereby both loads (kW) and energy use (kW h) could be reduced. The audit indicated that inefficient lighting (on about 12 h/day) could be replaced in the parking lot. General office lighting was found to be uniformly at 100 fc; by selective reduction and task lighting, the average level could be reduced to 75 fc or less. The air-conditioning load would also be reduced. Improved controls could be installed to automatically shut down lighting during off-shift and weekend hours (the practice had been to leave the lights on). Some walls and ceilings were selected for repainting to improve reflectance and reduced lighting energy. It was found that the air-conditioning chillers operated during weekends and off-hours; improved controls would prevent this. Also, the ventilation rates were found to be excessive and could be reduced. In the plant, compressed air system leaks, heat losses from plating tanks, and on-peak operation of the heat treat furnace represented energy and load management opportunities.

The major energy management opportunities were evaluated to have the following potential savings, with a total payback of 5.3 months, as shown in [Table 29.7](#). The average daily savings of electricity amounted to approximately 4400 kW h/day. This led to savings of \$80,000/year, with the cost of the modification being \$36,000.

This can be compared to the original situation ([Table 29.4](#)). See also [Figure 29.6](#), which shows the daily load curve after the changes have been made. The percentage of use on shift is now higher. Note that  $D_{\max}$  has been improved significantly (reduced by 13%); the *HUOD* has improved slightly (about 3% lower now); and the *LF* is slightly lower. Furthermore, improvements are undoubtedly still possible in this facility; they should be directed first at reducing nonessential uses, thereby reducing *HUOD*.

So far, the discussion has dealt entirely with power and has neglected the reactive component of the load. In the most general case, the apparent power in kV A that must be supplied to the load is the sum of the active power in kW and the *reactive power* in kVAR (the reader who is unfamiliar with these terms should refer to a basic electrical engineering text):

$$|S| = \sqrt{P^2 + Q^2} \quad (29.10)$$

where

$S$  is the apparent power in kV A

$P$  is the active power in kW

$Q$  is the reactive power in kVAR

In this notation, the apparent power is a vector of magnitude  $S$  and angle  $\theta$  where  $\theta$  is commonly referred to as the phase angle and given as

$$\theta = \tan^{-1} (\text{kVAR/kW}) \quad (29.11)$$

Another useful parameter is the *power factor*, given by

$$pf = \cos \theta \quad (29.12)$$

**TABLE 29.7**

Sample Calculations for XYZ Plant

$$\begin{aligned}
 1. D_{\max} &= \frac{E_{\max}}{p} = \frac{1850 \text{ kW h}}{1 \text{ h}} = 1850 \text{ kW} \\
 2. DV &= \frac{D_{m1} + D_{m2} + D_{m3} + \dots}{D_{\max}} = \frac{2459}{1850} = 1.33 \\
 3. DF &= \frac{D_{\max}}{CL} = \frac{1850}{2792} = 0.66 \\
 4. HOUD_{(\text{daily})} &= \frac{E}{D_{\max}} = \frac{28,800 \text{ kW h/day}}{1,850 \text{ kW}} = 15.6 \text{ h/day} \\
 5. LF_{(\text{daily})} &= \frac{HUOD}{p} = \frac{15.6}{24.0} = 0.65
 \end{aligned}$$

The load parameters after the changes were made can be found:

$$\begin{aligned}
 D_{\max} &= \frac{1850 - 235}{1 \text{ h}} = 1615 \text{ kW} \\
 HOUD &= \frac{24,400 \text{ kW h/day}}{1,615 \text{ kW}} = 15.1 \text{ h/day} \\
 LF &= \frac{15.1}{24} = 0.63
 \end{aligned}$$

**Calculated Savings**

	Savings	
	kW	kW h/year
More efficient parking lot lighting	16	67,000
Reduce office lighting	111	495,000
Office lighting controls to reduce off-shift use	—	425,000
Air-conditioning controls and smaller fan motor	71	425,000
Compressed air system repairs and reduction of heat losses from plating tanks	—	200,000
Shift heat treat oven off-peak	37	—
Totals	235	1,612,000
The revised electricity use was found to be	kW h	%
Preshift	4,400	18
On shift	14,400	59
Postshift	5,600	23
Totals	24,400	100

The power factor is also given by

$$pf = \frac{|P|}{|S|} \quad (29.13)$$

The power factor is always less than or equal to unity. A high value is desirable because it implies a small reactive component to the load (Figure 29.7). A low value means the reactive component is large.

The importance of the power factor is related to the reactive component of the load. Even though the reactive component does not dissipate power (it is stored in magnetic or electric fields), the switch gear and distribution system must be sized to handle the current required by the apparent power, or the vector sum of the active and reactive components. This results in a greater capital and operating expense. The operating expense is increased due to the standby losses that occur in supplying the reactive component of the load.

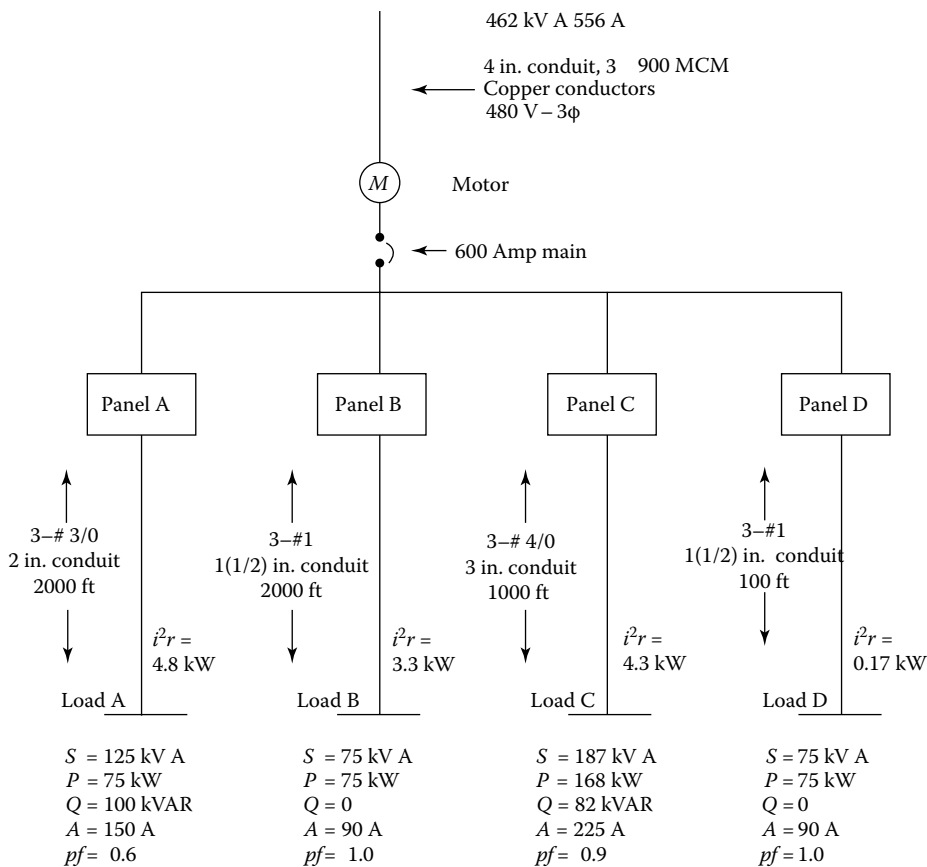

**FIGURE 29.7**  
Daily load curve for XYZ company after modifications.

The power factor can be improved by adding capacitors to the load to compensate for part of the inductive reactance. The benefit of this approach depends on the economics of each specific case and generally requires a careful review or analysis.

These points can be clarified with an example. Consider the distribution system shown in Figure 29.8. Four loads are supplied by a 600 A bus. Load A is a distant load that has a large reactive component and a low power factor ( $pf = 0.6$ ). To supply the active power requirement of 75 kW, an apparent power of 125 kV A must be provided, and a current of 150 A is required.

The size of the wire to supply the load is dictated by the current to be carried and voltage drop considerations. In this case, #3/0 wire that weighs 508 lb/1000 ft and has a resistance

**FIGURE 29.8**

Electrical diagrams for building 201, XYZ company.

of 0.062  $\Omega$ /1000 ft is used. Since the current in this conductor is 150 A, the power dissipated in the resistance of the conductor is

$$P = \sqrt{3}i^2r = (1.732)(150^2)(0.124) \text{ W}$$

$$P = 4.8 \text{ kW}$$

Similar calculations can be made for load B, which uses #1 wire, at 253  $\Omega$ /1000 ft and 0.12  $\Omega$ /1000 ft.

Now the effect of the power factor is visible. Although the active power is the same for both load A and load B, load A requires 150 A vs. 90 A for load B. The  $i^2r$  standby losses are also higher for load A as opposed to load B. The installation cost to service load B is roughly half that of load A, due to the long conduit run of load B compared to load D. For large loads that are served over long distances and operate continuously, consideration should be given to using larger wire sizes to reduce standby losses.

An estimate of the annual cost of power dissipated as heat in these conduit runs can be made if the typical operating hours of each load are known:

Load	Line Losses (kW)	Operating Hours/Year	kW h/Year
A	4.8	2000	9,600
B	3.3	2000	6,600
C	4.3	4000	17,200
D	0.17	2000	340
Total			33,740

At an average cost of 6¢/kW h (includes demand and energy costs), the losses in the distribution system alone are \$2022/year. Over the life of the facility, this is a major expense for a totally unproductive use of energy.

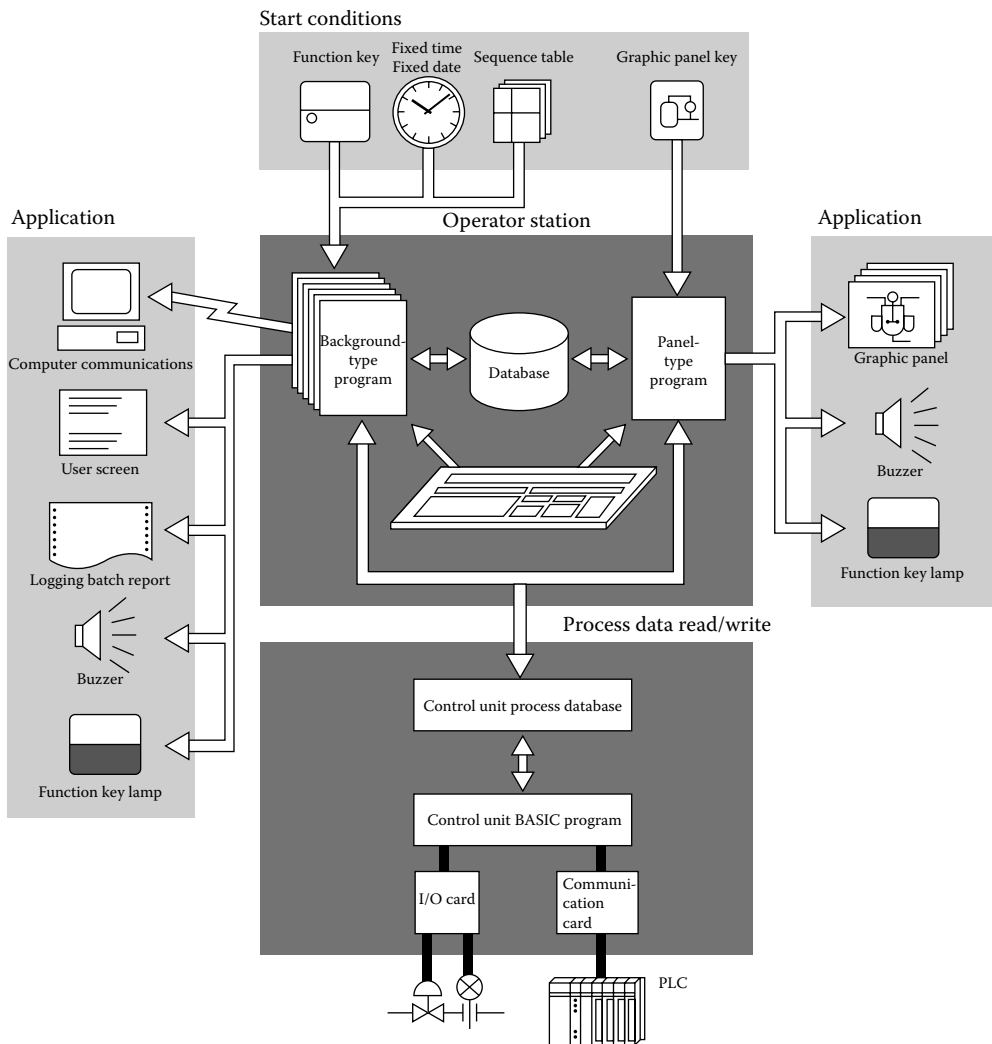

#### 29.4.8 Data Acquisition and Control Systems for Energy Management

Data acquisition is essential in energy management for at least three reasons: (1) baseline operational data are an absolute requirement for understanding the size and timing of energy demands for each plant, division, system, and component, and design of the energy management strategy; (2) continuing data acquisition during the course of the energy conservation effort is necessary to calculate the gains made in energy-use efficiency and to measure the success of the program; and (3) effective automatic control depends upon the accurate measurement of the controlled variables and the system operational data. More information on control systems can be found in Chapter 23.

With small, manually controlled systems, data acquisition is possible using indicating instruments and manual recording of data. With large systems, or almost any size automatically controlled system, manual data collection is impractical. The easy availability and the modest price of personal digital computers (PCs) and their present growth in speed and power as their price declines make them the preferred choice for data acquisition equipment. The only additions needed to the basic PC are the video monitor; a mass data storage device, analog-to-digital (A/D) interface cards; software for controlling the data sampling, data storage, and data presentation; and a suitable enclosure for protecting the equipment from the industrial environment.

That same computer is also suitable for use as the master controller of an automatic control system. Both functions can be carried on simultaneously, with the same equipment, with a few additions necessary for the control part of the system. These additional electronic components include multiplexers to increase the capacity of the A/D cards; direct memory access (an addition to the A/D boards), which speeds operation by allowing the data transfer to bypass the CPU and programmable logic controllers (PLCs); and digital input/output cards (I/Os), both used for controlling the equipment controllers. The most critical parts of either the data acquisition or the control system are the software. The hardware can be ordered off the shelf, but the software must be either written from scratch or purchased and modified for each particular system in order to achieve the reliable, high-performance operation that is desired. Although many proprietary program languages exist for the PCs and PLCs used for control purposes, BASIC is the most widely used. A schematic diagram of a typical data acquisition and control system is shown in [Figure 29.9](#).

A major application has been in the control of mechanical and electrical systems in commercial and industrial buildings. These have been used to control lighting, electric demand,

**FIGURE 29.9**  
Typical data acquisition and control system.

ventilating fans, thermostat setbacks, air-conditioning systems, and the like. These same computer systems can also be used in industrial buildings with or without modification for process control. Several manufactures of the computer systems will not only engineer and install the system but will maintain and operate it from a remote location. Such operations are ordinarily regional. For large systems in large plants, one may be able to have the same service provided in-plant. However, there are also many small stand-alone analog control systems that can be used advantageously for the control of simple processes. Examples of these are a temperature controller using a thermocouple output to control the temperature of a liquid storage tank; a level controller, which keeps the liquid level in a tank constant by controlling a solenoid valve; and an oxygen trim system for a small boiler, which translates the measurement of the oxygen concentration in the exhaust stream into the jack shaft position, which regulates the combustion air flow to the burner.

After installing a demand limiter on an electric arc foundry cupola, the manager was able to reduce the power level from 7100 to 4900 kW with negligible effect on the production time and no effect on product quality. The savings in demand charges alone were \$4400/month with an additional savings in energy costs.

#### **29.4.9 Web-Based Facility Automation Systems**

Of all recent developments affecting computerized energy management systems, the most powerful new technology to come into use in the last several years has been information technology, or IT. The combination of cheap, high-performance microcomputers, together with the emergence of high-capacity communication lines, networks, and the Internet, has produced explosive growth in IT and its application throughout the U.S. economy. Energy information and control systems have been no exception. IT- and Internet-based systems are the wave of the future. Almost every piece of equipment and almost every activity will be connected and integrated into the overall facility operation in the next several years.<sup>22</sup>

In particular, the future of DDC in facility automation systems (FASs) can be found on the web. Almost all FAS manufacturers see the need to move their products to the Internet. Tremendous economies of scale and synergies can be found there. Manufacturers no longer have to create the transport mechanisms for data to flow within a building or campus. They just need to make sure their equipment can utilize the network data paths already installed or designed for a facility. Likewise, with the software to display data to users, manufacturers that take advantage of presentation layer standards such as HTML and JAVA can provide the end user with a rich, graphical, and intuitive interface to their FAS using a standard web browser.

Owners will reap the benefits of Internet standards through a richer user interface, more competition among FAS providers, and the ability to use their IT infrastructure to leverage the cost of transporting data within a facility. Another area where costs will continue to fall in using Internet standards is the hardware required to transport data within a building or a campus. Off-the-shelf products such as routers, switches, hubs, and server computers make the FAS just another node of the IT infrastructure. Standard IT tools can be used to diagnose the FAS network, generate reports of FAS bandwidth on the intranet, and back up the FAS database.

The FAS of old relied heavily on a collection of separate systems that operated independently, and often with proprietary communication protocols that made expansion, modification, updating, and integration with other building or plant information and control systems very cumbersome, if not impossible. Today, the FAS is not only expected to handle all of the energy- and equipment-related tasks, but also to provide operating information and control interfaces to other facility systems, including the total facility or enterprise management system.

Measuring, monitoring, and maximizing energy savings is a fundamental task of all FAS and is the primary justification for many FAS installations. Improving facility operations in all areas, through enterprise information and control functions, is fast becoming an equally important function of the overall FAS or facility management system. The web provides the means to share information easier, quicker, and cheaper than ever before. There is no doubt that the web is having a huge impact on the FAS industry. The FAS of tomorrow will rely heavily on the web, TCP/IP, high-speed data networks, and enterprise-level connectivity. If it has not already been done, it is a good time for energy managers to get to know their IT counterparts at their facility, along with those in the accounting and maintenance departments. The future FAS will be here sooner than you think.<sup>23</sup>

#### **29.4.9.1 Energy Management Strategies for Industry**

Energy management strategies for industry can be grouped into three categories:

1. Operational and maintenance strategies
2. Retrofit or modification strategies
3. New design strategies

The order in which these are listed corresponds approximately to increased capital investment and increased implementation times. Immediate savings at little or no capital cost can generally be achieved by improved operations and better maintenance. Once these “easy” savings have been realized, additional improvements in efficiency will require capital investments.

#### **29.4.9.2 Electric Drives and Electrically Driven Machinery**

About 68% of industrial electricity use is for electrical motor-driven equipment. Integral horsepower ( $<0.75$  kW) motors are more numerous. Major industrial motor loads are, in order of importance, pumps, compressors, blowers, fans, and miscellaneous integral motor applications including conveyors, DC drives, machine tools, and fractional horsepower applications.

Numerous examples of pumping in industry can be observed. These include process pumping in chemical plants, fluid movement in oil refineries, and cooling water circulation. An example of compressors is in the production of nitrogen and oxygen, two common chemicals. Large amounts of electricity are used to drive the compressors, which supply air to the process.

The typical industrial motor is a polyphase motor rated at 11.2 kW (15 hp) and having a life of about 40,000 h. The efficiencies of electric motors have increased recently as a result of higher energy prices, conservation efforts, and new government standards (the Energy Policy Act). High-efficiency motors cost roughly 20%–30% more than standard motors, but this expense is quickly repaid for motors that see continuous use.

Most efficient use of motors requires that attention be given to the following:

*Optimum power:* Motors operate most efficiently at rated voltage. Three-phase power supplies should be balanced; an unbalance of 3% can increase losses 25%.<sup>1</sup>

*Good motor maintenance:* Provide adequate cooling, keep heat transfer surfaces and vents clean, and provide adequate lubrication. Improved lubrication alone can increase efficiency a few percentage points.

*Equipment scheduling:* Turn equipment off when not in use; schedule large motor operation to minimize demand peaks.

*Size equipment properly:* Match the motor to the load and to the duty cycle. Motors operate most efficiently at rated load.

*Evaluate continuous vs. batch processes:* Sometimes a smaller motor operating continuously will be more economical.

*Power factor:* Correct if economics dictate savings. Motors have the best power factor at rated load.

Retrofit or new designs permit use of more efficient motors. For motors up to about 10–15 kW (15–20 hp), there are variations in efficiency. Select the most efficient motor

for the job. Check to verify that the additional cost (if any) will be repaid by the savings that will accrue over the life of the installation.

In addition to reviewing the electric drive system, consider the power train and the load. Friction results in energy dissipation in the form of heat. Bearings, gears, and belt drives all have certain losses, as do clutches. Proper operation and maintenance can reduce energy wastage in these systems and improve overall efficiency.

Material shaping and forming, such as is accomplished with machine tools, requires that electrical energy be transformed into various forms of mechanical energy. The energy expenditure related to the material and to the depth and speed of the cut. By experimenting with a specific process, it is possible to establish cutting rates that are optimum for the levels of production required and are most efficient in terms of energy use. Motors are not the only part of the electric drive system that sustains losses. Other losses occur in the electric power systems that supply the motor. Electric power systems include substations, transformers, switching gear, distribution systems, feeders, power and lighting panels, and related equipment. Possibilities for energy management include the following:

*Use highest voltages that are practical:* For a given application, doubling the voltage cuts the required current in half and reduces the  $i^2r$  losses by a factor of 4.

*Eliminate unnecessary transformers:* They waste energy. Proper selection of equipment and facility voltages can reduce the number of transformers required and cut transformer losses. Remember, the customer pays for losses when the transformers are on his side of the meter. For example, it is generally better to order equipment with motors of the correct voltage, even if this costs more, than to install special transformers.

*Energy losses are an inherent part of electric power distribution systems:* This is primarily due to  $i^2r$  losses and transformers. The end-use conversion systems for electrical energy used in the process also contribute to energy waste. Proper design and operation of an electrical system can minimize energy losses and contribute to the reduction of electricity bills. Where long feeder runs are operated at near-maximum capacities, check to see if larger wire sizes would permit savings and be economically justifiable.

*The overall power factor of electrical systems should be checked for low power factor:* This could increase energy losses and the cost of electrical service, in addition to excessive voltage drops and increased penalty charges by the utility. Electrical systems studies should be made, and consideration should be given to power factor correction capacitors. In certain applications, as much as 10%–15% savings can be achieved in a poorly operating plant.

*Check load factors:* This is another parameter that measures the plant's ability to use electrical power efficiently. It is defined as the ratio of the actual kW h used to the maximum demand in kW times the total hours in the time period. A reduction in demand to bring this ratio closer to unity without decreasing plant output means more economical operation. For example, if the maximum demand for a given month (200 h) is 30,000 kWe and the actual kW h is  $3.6 \times 10^6$  kW h, the load factor is 60%. Proper management of operations during high-demand periods, which may extend only 15–20 min, can reduce the demand during that time without curtailing production. For example, if the 30,000 kWe could be reduced to 20,000 kWe, this would increase the load factor to about 90%. Such a reduction could amount to a \$20,000–\$50,000 reduction in the electricity bill.

*Reduce peak loads wherever possible:* Many nonessential loads can be shed during the demand peak without interrupting production. These loads would include such items as air compressors, heaters, coolers, and air conditioners. Manual monitoring and control is possible but is often impractical because of the short periods of time that are normally involved and the lack of centralized control systems. Automatic power demand control systems are available.

*Provide improved monitoring or metering capability, submeters, or demand recorders:* While it is true that meters alone will not save energy, plant managers need feedback to determine if their energy management programs are taking effect. Often, the installation of meters on individual processes or buildings leads to immediate savings of 5%–10% by virtue of the ability to see how much energy is being used and to test the effectiveness of corrective measures.

### 29.4.9.3 Fans, Blowers, and Pumps

Simple control changes are the first thing to consider with these types of equipment. Switches, time clocks, or other devices can ensure that they do not operate except when needed by the process. Heat removal or process mass flow requirements will determine the size of fans and pumps. Often, there is excess capacity, either as a result of design conservatism or because of process changes subsequent to the installation of equipment. The required capacity should be checked, since excess capacity leads to unnecessary demand charges and decreased efficiency.

For fans, the volume rate of air flow  $Q$  varies in proportion to the speed of the impeller:

$$Q = c_f N \text{ (m}^3\text{/s)} \quad (29.14)$$

where

$Q$  is the air flow, m<sup>3</sup>/s

$c_f$  is a constant, m<sup>3</sup>/r

$N$  is the fan speed, r/s

The pressure developed by the fan varies as the square of the impeller speed. The important rule, however, is that the power needed to drive the fan varies as the cube of the speed:

$$P = P_c N^3 \text{ (W)} \quad (29.15)$$

where

$P$  is the input power, W

$P_c$  is a constant, W s<sup>3</sup>/r<sup>3</sup>

The cubic law of pumping power indicates that if the air flow is to be doubled, eight (2<sup>3</sup>) times as much power must be supplied. Conversely, if the air flow is to be cut in half, only one-eighth (1/2<sup>3</sup>) as much power must be supplied. Air flow (and hence power) can be reduced by changing pulleys or installing smaller motors.

Pumps follow laws similar to fans, the key being the cubic relationship of power to the volume pumped through a given system. Small decreases in flow rate, such as might be obtained with a smaller pump or gotten by trimming the impeller, can save significant amounts of energy.

VSDs are another technique for reducing process energy use. VSDs permit fans, blowers, and pumps to vary speed depending on process requirements. This can lead to significant savings on noncontinuous processes. Recent improvements in solid-state electronics have caused the price of VSDs to drop substantially. This is another technology that is supported by utility rebates in many areas.

#### 29.4.9.4 Air Compressors

Compressed air is a major energy use in many manufacturing operations. Electricity used to compress air is converted into heat and potential energy in the compressed air stream. Efficient operation of compressed air systems therefore requires the recovery of excess heat where possible, as well as the maximum recovery of the stored potential energy.

Efficient operation is achieved in these ways:

*Select the appropriate type and size of equipment for the duty cycle required:* Process requirements vary, depending on flow rates, pressure, and demand of the system. Energy savings can be achieved by selecting the most appropriate equipment for the job. The rotary compressor is more popular for industrial operations in the range of 20–200 kW, even though it is somewhat less efficient than the reciprocal compressor. This has been due to lower initial cost and reduced maintenance. When operated at partial load, reciprocating units can be as much as 25% more efficient than rotary units. However, newer rotary units incorporate a valve that alters displacement under partial load conditions and improves efficiency. Selection of an air-cooled vs. a water-cooled unit would be influenced by whether water or air was the preferred medium for heat recovery.

*Proper operation of compressed air systems can also lead to improved energy utilization:* Obviously, air leaks in lines and valves should be eliminated. The pressure of the compressed air should be reduced to a minimum. The percentage saving in power required to drive the compressor at a reduced pressure can be estimated from the fan laws described previously. For example, suppose the pressure were reduced to one half the initial value. Since pressure varies as the square of the speed, this implies the speed would be 70.7% of the initial value. Since power varies as the cube of the speed, the power would now be  $0.707^3 = 35\%$  of the initial value. Of course, this is the theoretical limit; actual compressors would not do as well, and the reduction would depend on the type of compressor. Measurements indicate that actual savings would be about half the theoretical limit; reducing pressure 50% would reduce brake horsepower about 30%. To illustrate this point further, for a compressor operating at  $6.89 \times 10^5 \text{ N/m}^2$  (100 psi) and a reduction of the discharge pressure to  $6.20 \times 10^5 \text{ N/m}^2$  (90 psi), a 5% decrease in brake horsepower would result. For a 373 kW (500 hp) motor operating for 1 year, the 150,000 kW h savings per year would result in about \$9000/year in electric power costs.

*The intake line for the air compressor should be at the lowest temperature available:* This normally means outside air. The reduced temperature of air intake results in a smaller volume of air to be compressed. The percentage horsepower saving relative to a 21°C (70°F) intake air temperature is about 2% for each 10°F drop in temperature. Conversely, input power increases by about 2% for each 10°F increase in intake air temperature.

*Leakage is the greatest efficiency offender in compressed air systems:* The amount of leakage should be determined and measures should be taken to reduce it. If air leakage in a plant is more than 10% of the plant demand, a poor condition exists. The amount of leakage can be determined by a simple test during off-production hours (when air-using equipment is shut down) by noting the time that the compressor operates under load compared with the total cycle. This indicates the percentage of the compressor's capacity that is used to supply the plant air leakage. Thus, if the load cycle compared with the total cycle were 60 s compared with 180 s, the efficiency would be 33%, or 33% of the compressor capacity is the amount of air leaking in  $\text{m}^3/\text{min}$  ( $\text{ft}^3/\text{min}$ ).

*Recover heat where feasible:* There are sometimes situations where water-cooled or air-cooled compressors are a convenient source of heat for hot water, space heating, or process applications. As a rough rule of thumb, about  $300 \text{ J}/\text{m}^3 \text{ min}$  of air compressed ( $\sim 10 \text{ Btu}/\text{ft}^3 \text{ min}$ ) can be recovered from an air-cooled rotary compressor.

*Substitute electric motors for air motor (pneumatic) drives:* Electric motors are far more efficient. Typical vane air motors range in size from 0.15 to 6.0 kW (0.2–8 hp), cost \$300–\$1500, and produce 1.4–27 N m (1–20 ft lb) of torque at  $620 \text{ kN}/\text{m}^2$  (90 psi) air pressure. These are used in manufacturing operations where electric motors would be hazardous, or where light weight and high power are essential. Inefficiency results from air system leaks and the need (compared to electric motors) to generate compressed air as an intermediate step in converting electric to mechanical energy.

*Review air usage in paint spray booths:* In paint spray booths and exhaust hoods, air is circulated through the hoods to control dangerous vapors. Makeup air is constantly required for dilution purposes. This represents a point of energy rejection through the exhaust air.

Examination should be made of the volumes of air required in an attempt to reduce flow and unnecessary operation. Possible mechanisms for heat recovery from the exhaust gases should be explored using recovery systems.

#### **29.4.9.5 Electrochemical Operations**

Electrochemical processes are an industrial use of electricity, particularly in the primary metals industry, where it is used in the extraction process for several important metals. Energy management opportunities include the following:

*Improve design and materials for electrodes:* Evaluate loss mechanisms for the purpose of improving efficiency.

*Examine electrolysis and plating operations for savings:* Review rectifier performance, heat loss from tanks, and the condition of conductors and connections.

Welding is another electrochemical process. Alternating current welders are generally preferable when they can be used, since they have a better power factor, better demand characteristics, and more economical operation.

Welding operations can also be made more efficient by the use of automated systems, which require 50% less energy than manual welding. Manual welders deposit a bead only 15%–30% of the time the machine is running. Automated processes, however, reduce the

no-load time to 40% or less. Different welding processes should be compared in order to determine the most efficient process. Electroslag welding is suited only for metals over 1 cm (0.5 in.) thick but is more efficient than other processes.

Two other significant applications of electrolysis of concern to industry are batteries and corrosion. Batteries are used for standby power, transportation, and other applications. Proper battery maintenance and improved battery design contribute to efficient energy use.

Corrosion is responsible for a large loss of energy-intensive metals every year and thus indirectly contributes to energy wastage. Corrosion can be prevented and important economies realized, by use of protective films, cathodic protection, and electroplating or anodizing.

#### **29.4.9.6 Electric Process Heat and Steam Systems**

In as much as approximately 40% of the energy utilized in industry goes toward the production of process steam, it presents a large potential for energy misuse and fuel waste from improper maintenance and operation. Even though electrically generated steam and hot water is a small percentage of total industrial steam and hot water, the electrical fraction is likely to increase as other fuels increase in price. This makes increased efficiency even more important. Examples are as follows:

*Steam leaks from lines and faulty valves result in considerable losses:* These losses depend on the size of the opening and the pressure of the steam, but can be very costly. A hole 0.1 ft in diameter with steam at 200 psig can bleed \$1000–\$2000 worth of steam (500 GJ) in a year.

*Steam traps are major contributors to energy losses when not functioning properly:* A large process industry might have thousands of steam traps, which could result in large costs if they are not operating correctly. Steam traps are intended to remove condensate and noncondensable gases while trapping or preventing the loss of steam. If they stick open, orifices as large as 6 mm (0.25 in.) can allow steam to escape. Such a trap would allow 1894 GJ/year (2000 MBtu/year) of heat to be rejected to the atmosphere on a  $6.89 \times 10^5$  N/m (100 psi) pressure steam line. Many steam traps are improperly sized, contributing to an inefficient operation. Routine inspection, testing, and a correction program for steam valves and traps are essential in any energy program and can contribute to cost savings.

*Poor practice and design of steam distribution systems can be the source of heat waste up to 10% or more:* It is not uncommon to find an efficient boiler or process plant joined to an inadequate steam distribution system. Modernization of plants results from modified steam requirements. The old distribution systems are still intact, however, and can be the source of major heat losses. Large steam lines intended to supply units no longer present in the plant are sometimes used for minor needs, such as space heating and cleaning operations, that would be better accomplished with other heat sources.

Steam distribution systems operating on an intermittent basis require a start-up warming time to bring the distribution system into proper operation. This can extend up to 2 or 3 h, which puts a demand on fuel needs. Not allowing for proper ventilating of air can also extend the start-up time. In addition, condensate return can be facilitated if it is allowed to drain by gravity into a tank or receiver and is then pumped into the boiler feed tank.

*Proper management of condensate return:* Proper management can lead to great savings. Lost feedwater must be made up and heated. For example, every 0.45 kg (1 lb) of steam that must be generated from 15°C feedwater instead of 70°C feedwater requires an additional  $1.056 \times 10^5$  J (100 Btu) more than 1.12 MJ (1063 Btu) required or a 10% increase in fuel. A rule of thumb is that a 1% fuel saving results for every 5°C increase in feedwater temperature. Maximizing condensate recovery is an important fuel laying procedure.

*Poorly insulated lines and valves due either to poor initial design or a deteriorated condition:* Heat losses from a poorly insulated pipe can be costly. A poorly insulated line carrying steam at 400 psig can lose ~1000 GJ/year ( $10^9$  Btu/year) or more per 30 m (100 ft) of pipe. At steam costs of \$2.00/GJ, this translates to a \$2000 expense/year.

*Improper operation and maintenance of tracing systems:* Steam tracing is used to protect piping and equipment from cold weather freezing. The proper operation and maintenance of tracing systems will not only ensure the protection of traced piping but also saves fuel. Occasionally, these systems are operating when not required. Steam is often used in tracing systems, and many of the deficiencies mentioned earlier apply (e.g., poorly operating valves, insulation, leaks).

*Reduce losses in process hot water systems:* Electrically heated hot water systems are used in many industrial processes for cleaning, pickling, coating, or etching components. Hot or cold water systems can dissipate energy. Leaks and poor insulation should be repaired.

#### **29.4.9.7 Electrical Process Heat**

Industrial process heat applications can be divided into four categories: direct-fired, indirect-fired, fuel, or electric. Here we shall consider electric direct-fired installations (ovens, furnaces) and indirect-fired (electric water heaters and boilers) applications. Electrical installations use metal sheath resistance heaters, resistance ovens or furnaces, electric salt bath furnaces, infrared heaters, induction and high-frequency resistance heaters, dielectric heaters, and direct arc furnaces. From the housekeeping and maintenance point of view, typical opportunities would include the following:

*Repair or improve insulation:* Operational and standby losses can be considerable, especially in larger units. Remember that insulation may degrade with time or may have been optimized to different economic criteria.

*Provide finer controls:* Excessive temperatures in process equipment waste energy. Run tests to determine the minimum temperatures that are acceptable, then test instrumentation to verify that it can provide accurate process control and regulation.

*Practice heat recovery:* This is an important method, applicable to many industrial processes as well as HVAC systems and so forth. It is described in more detail in the next section.

#### **29.4.9.8 Heat Recovery**

Exhaust gases from electric ovens and furnaces provide excellent opportunities for heat recovery. Depending on the exhaust gas temperature, exhaust heat can be used to raise steam or to preheat air or feedstocks. Another potential source of waste-heat recovery is

the exhaust air that must be rejected from industrial operations in order to maintain health and ventilation safety standards. If the reject air has been subjected to heating and cooling processes, it represents an energy loss inasmuch as the makeup air must be modified to meet the interior conditions. One way to reduce this waste is through the use of heat wheels or similar heat exchange systems.

Energy in the form of heat is available at a variety of sources in industrial operations, many of which are not normally derived from primary heat sources. Such sources include electric motors, crushing and grinding operations, air compressors, and drying processes. These units require cooling in order to maintain proper operation. The heat from these systems can be collected and transferred to some appropriate use such as space heating or water heating.

The heat pipe is gaining wider acceptance for specialized and demanding heat transfer applications. The transfer of energy between incoming and outgoing air can be accomplished by banks of these devices. A refrigerant and a capillary wick are permanently sealed inside a metal tube, setting up a liquid-to-vapor circulation path. Thermal energy applied to either end of the pipe causes the refrigerant to vaporize. The refrigerant vapor then travels to the other end of the pipe, where thermal energy is removed. This causes the vapor to condense into liquid again, and the condensed liquid then flows back to the opposite end through the capillary wick.

Industrial operations involving fluid flow systems that transport heat such as in chemical and refinery operations offer many opportunities for heat recovery. With proper design and sequencing of heat exchangers, the incoming product can be heated with various process steams. For example, proper heat exchanger sequence in preheating the feedstock to a distillation column can reduce the energy utilized in the process.

Many process and air-conditioning systems reject heat to the atmosphere by means of wet cooling towers. Poor operation can contribute to increased power requirements.

*Water flow and airflow should be examined to see that they are not excessive:* The cooling tower outlet temperature is fixed by atmospheric conditions if operating at design capacity. Increasing the water flow rate or the air flow will not lower the outlet temperature.

*The possibility of utilizing heat that is rejected to the cooling tower for other purposes should be investigated:* This includes preheating feedwater, heating hot water systems, space heating, and other low-temperature applications. If there is a source of building exhaust air with a lower wet bulb temperature, it may be efficient to supply this to a cooling tower.

#### **29.4.9.9 Power Recovery**

Power recovery concepts are an extension of the heat recovery concept described earlier. Many industrial processes have pressurized liquid and gaseous streams at 150°C–375°C (300°F–700°F) that present excellent opportunities for power recovery. In many cases, high-pressure process stream energy is lost by throttling across a control valve.

The extraction of work from high-pressure liquid streams can be accomplished by means of hydraulic turbines (essentially diffuser-type or volute-type pumps running backward). These pumps can be either single or multistage. Power recovery ranges from 170 to 1340 kW (230–1800 hp). The lower limit of power recovery approaches the minimum economically justified for capital expenditures at present power costs.

#### 29.4.9.10 Heating, Ventilating, and Air-Conditioning Operation

The environmental needs in an industrial operation can be quite different from those in a residential or commercial structure. In some cases, strict environmental standards must be met for a specific function or process. More often, the environmental requirements for the process itself are not severe; however, conditioning of the space is necessary for the comfort of operating personnel, and thus large volumes of air must be processed. Quite often, opportunities exist in the industrial operation where surplus energy can be utilized in environmental conditioning. A few suggestions follow:

*Review HVAC controls:* Building heating and cooling controls should be examined and preset.

*Ventilation, air, and building exhaust requirements should be examined:* A reduction of air flow will result in a savings of electrical energy delivered to motor drives and additionally reduce the energy requirements for space heating and cooling. Because pumping power varies as the cube of the air flow rate, substantial savings can be achieved by reducing air flows where possible.

*Do not condition spaces needlessly:* Review air-conditioning and heating operations, seal off sections of plant operations that do not require environmental conditioning, and use air-conditioning equipment only when needed. During nonworking hours, the environmental control equipment should be shut down or reduced. Automatic timers can be effective.

*Provide proper equipment maintenance:* Ensure that all equipment is operating efficiently. (Filters, fan belts, and bearings should be in good condition.)

*Use only equipment capacity needed:* When multiple units are available, examine the operating efficiency of each unit and put operations in sequence in order to maximize overall efficiency.

*Recirculate conditioned (heated or cooled) air where feasible:* If this cannot be done, perhaps exhaust air can be used as supply air to certain processes (e.g., a paint spray booth) to reduce the volume of air that must be conditioned.

For additional energy management opportunities in HVAC systems, see Chapter 23.

#### 29.4.9.11 Lighting

Industrial lighting needs range from low-level requirements for assembly and welding of large structures (such as shipyards) to the high levels needed for the manufacture of precision mechanical and electronic components (e.g., integrated circuits). There are four basic housekeeping checks that should be made:

*Is a more efficient lighting application possible?* Remove excessive or unnecessary lamps.

*Is relamping possible?* Install lower-wattage lamps during routine maintenance.

*Will cleaning improve light output?* Fixtures, lamps, and lenses should be cleansed periodically.

*Can better controls be devised?* Eliminate turning on more lamps than necessary. For modification, retrofit, or new design, consideration should be given to the spectrum of high-efficiency lamps and luminaries that are available. For example, high-pressure sodium lamps are finding increasing acceptance for industrial use, with savings of nearly a factor of five compared to incandescent lamps. See Chapter 22 for additional details.

#### 29.4.9.12 New Electrotechnologies

Electricity has certain characteristics that make it uniquely suitable for industrial processes. These characteristics include electricity's suitability for timely and precise control, its ability to interact with materials at the molecular level, the ability to apply it selectively and specifically, and the ability to vary its frequency and wavelength so as to enhance or inhibit its interaction with materials. These aspects may be said to relate to the *quality* of electricity as an energy form. It is important to recognize that different forms of energy have different qualities in the sense of their ability to perform useful work. Thus, although the Btu content of two energy forms may be the same, their ability to transform materials may be quite different.

New electrotechnologies based on the properties of electricity are now finding their way into modern manufacturing. In many cases, the introduction of electricity reduces manufacturing costs, improves quality reduces pollution, or has other beneficial results. Some examples include the following:

Microwave heating	Ion nitriding
Induction heating	Infrared drying
Plasma processing	UV drying and curing
Magnetic forming	Advanced finishes
RF drying and heating	Electron beam heating

Microwave heating is a familiar technology that exhibits the unique characteristics of electricity described earlier. First, it is useful to review how conventional heating is performed to dry paint, anneal a part, or remove water. A source of heat is required, along with a container (oven, furnace, pot, etc.) to which the heat is applied. Heat is transferred from the container to the workpiece by conduction, radiation, convection, or a combination of these. There are certain irreversible losses associated with heat transfer in this process. Moreover, since the container must be heated, more energy is expended than is really required. Microwave heating avoids these losses due to the unique characteristics of electricity.

*Timely control:* There is no loss associated with the warm-up or cooldown of ovens. The heat is applied directly when needed.

*Molecular interaction:* By interacting at the molecular level, heat is deposited directly in the material to be heated, without having to preheat an oven, saving the extra energy required for this purpose and avoiding the losses that result from heat leakage from the oven.

*Selective application:* By selectively applying heat only to the material to be heated, parasitic losses are avoided. In fact, the specificity of heat applied this way can improve quality by not heating other materials.

*Selective wavelength and frequency:* A microwave frequency is selected that permits the microwave energy to interact with the material to be heated, and not with other materials. Typically, the frequency is greater than 2000 MHz.

Microwave heating was selected for this discussion, but similar comments could be made about infrared, ultraviolet (UV), dielectric, induction, or electron beam heating. In each case, the frequency or other characteristics of the energy form are selected to provide the unique performance required.

UV curing (now used for adhesive and finishes) is another example. The parts to be joined or coated can be prepared and the excessive adhesive removed without fear of pre-hardening. Then, the UV energy is applied, causing the adhesive to harden.

Induction heating is another example. It is similar to microwave heating except that the energy is applied at a lower frequency. Induction heating operates on the principle of inducing electric currents to flow in materials, heating them by the power dissipated in the material. The method has several other advantages. In a conventional furnace, the workpiece has to be in the furnace for a sufficient time to reach temperature. Because of this, some of the material is oxidized and lost as scale. In a typical high-temperature gas furnace, this can be 2% of the throughput. Additional product is scrapped as a result of surface defects caused by uneven heating and cooling. This can amount to another 1% of throughput. Induction heating can reduce these losses by a factor of four.

The fact that electricity can be readily controlled and carries with it a high information content through digitization or frequency modulation also offers the potential for quantum improvements in efficiency. A slightly different example is the printing industry.

Today, the old linotype technology has been replaced by electronic processes. The lead melting pots that used to operate continuously in every newspaper plant have been removed, eliminating a major energy use and an environmental hazard. Books, magazines, and newspapers can be written composed and printed entirely by electronic means. Text is processed by computer techniques. Camera-ready art is prepared by computers directly or prepared photographically and then optically scanned to create digital images. The resulting electronic files can be used in web offset printing by an electronic photochemical process. The same information can be transmitted electronically, via satellite, to a receiving station at a remote location where a high-resolution fax machine reconstitutes the image. This method is being used to simultaneously and instantaneously distribute advertising copy to multiple newspapers, using a single original. Previously, to insert an advertisement in 25 newspapers, 25 sets of photographic originals would have to be prepared and delivered, by messenger, air express, or mail, to each newspaper.

Some of the other applications of the new electrotechnologies include RF drying of plywood veneers, textiles, and other materials; electric infrared drying for automobile paint and other finishes; electric resistance melting for high-purity metals and scrap recovery; and laser cutting of wood, cloth, and other materials.

#### **29.4.9.13 General Industrial Processes**

The variety of industrial processes is so great that detailed specific recommendations are outside the scope of this chapter. Useful sources of information are found in trade journals, vendor technical bulletins, and manufacturers' association journals. These suggestions are intended to be representative, but by no means do they cover all possibilities.

*In machining operations, eliminate unnecessary operations and reduce scrap:* This is so fundamental from a purely economic point of view that it will not be possible to find significant improvements in many situations. The point is that each additional operation and each increment of scrap also represent a needless use of energy. Machining itself is not particularly energy intensive. Even so, there are alternate technologies that can not only save energy but reduce material wastage as well. For example, powder metallurgy generates less scrap and is efficient if done in induction-type furnaces.

*Use stretch forming:* Forming operations are more efficient if stretch forming is used. In this process, sheet metal or extrusions are stretched 2%–3% prior to forming, which makes the material more ductile so that less energy is required to form the product.

*Use alternate heat treating methods:* Conventional heat treating methods such as carburizing are energy intensive. Alternate approaches are possible. For example, a hard surface can be produced by induction heating, which is a more efficient energy process. Plating, metallizing, flame spraying, or cladding can substitute for carburizing, although they do not duplicate the fatigue strengthening compressive skin of carburization or induction hardening.

*Use alternative painting methods:* Conventional techniques using solvent-based paints require drying and curing at elevated temperature. Powder coating is a substitute process in which no solvents are used. Powder particles are electrostatically charged and attracted to the part being painted so that only a small amount of paint leaving the spray gun misses the part and the overspray is recoverable. The parts can be cured rapidly in infrared ovens, which require less energy than standard hot air systems. Water-based paints and high-solids coatings are also being used and are less costly than solvent-based paints. They use essentially the same equipment as the conventional solvent paint spray systems so that the conversion can be made at minimum costs. New water-based emulsion paints contain only 5% organic solvent and require no afterburning. High-solids coatings are already in use commercially for shelves, household fixtures, furniture, and beverage cans, and require no afterburning. They can be as durable as conventional finishes and are cured by either conventional baking or UV exposure.

*Substitute for energy-intensive processes such as hot forging:* Hot forging may require a part to go through several heat treatments. Cold forging with easily wrought alloys may offer a replacement. Lowering the preheat temperatures may also be an opportunity for savings. Squeeze forging is a relatively new process in which molten metal is poured into the forging die. The process is nearly scrap free, requires less press power, and promises to contribute to more efficient energy utilization.

Movement of materials through the plant creates opportunities for saving energy. Material transport energy can be reduced by the following methods:

*Combining processes or relocate machinery to reduce transport energy:* Sometimes merely relocating equipment can reduce the need to haul materials.

*Turning off conveyors and other transport equipment when not needed:* Look for opportunities where controls can be modified to permit shutting down of equipment not in use.

*Using gravity feeds wherever possible:* Avoid unnecessary lifting and lowering of products.

#### **29.4.9.14 Demand Management**

The cost of electrical energy for medium-to-large industrial and commercial customers generally consists of two components. The first component is the *energy charge*, which is based on the cost of fuel to the utility, the average cost of amortizing the utility generating plant, and on the operating and maintenance costs experienced by the utility.

Energy costs for industrial users in the United States are typically in the range of \$0.05–\$0.10/kW h.

The second component is the *demand charge*, which reflects the investment cost the utility must make to serve the customer. Besides the installed generating capacity needed, the utility also provides distribution lines, transformers, substations, and switches whose cost depends on the size of the load being served. This cost is recovered in a demand charge, which typically is \$2–\$10/kW month.

Demand charges typically account for 10%–50% of the bill, although wide variations are possible depending on the type of installation. Arc welders, for example, have relatively high demand charges, since the installed capacity is great (10–30 kW for a typical industrial machine) and the energy use is low.

From the utility's point of view, it is advantageous to have its installed generating capacity operating at full load as much of the time as possible. To follow load variations conveniently, the utility operates its largest and most economical generating units continuously to meet its base load and then brings smaller (and generally more expensive) generating units online to meet peak load needs.

Today, consideration is being given to time-of-day or *peak load pricing* as a means of assigning the cost of operating peak generating capacity to those loads that require it. See Chapter 18 for a discussion of utility pricing strategies. From the viewpoint of the utility, *load management* implies maintaining a high capacity factor and minimizing peak load demands. From the customer's viewpoint, *demand management* means minimizing electrical demands (both on- and off-peak) so as to minimize overall electricity costs.

Utilities are experimenting with several techniques for load management. Besides rate schedules that encourage the most effective use of power, some utilities have installed remotely operated switches that permit the utility to disconnect nonessential parts of the customer's load when demand is excessive. These switches are actuated by a radio signal, through the telephone lines, or over the power grid itself through a harmonic signal (ripple frequency) that is introduced into the grid.

Customers can control the demand of their loads by any of several methods:

- Manually switching off-loads ("load shedding")
- Use of timers and interlocks to prevent several large loads from operating simultaneously
- Use of controllers and computers to control loads and minimize peak demand by scheduling equipment operation
- Energy storage (e.g., producing hot or chilled water during off-peak hours and storing it for use on-peak)

Demand can be monitored manually (by reading a meter) or automatically using utility-installed equipment or customer-owned equipment installed in parallel with the utility meter. For automatic monitoring, the basic approach involves pulse counting.

The demand meter produces electronic pulses, the number of which is proportional to demand in kW. Demand is usually averaged over some interval (e.g., 15 min) for calculating cost. By monitoring the pulse rate electronically, a computer can project what the demand will be during the next demand measurement interval and can then follow a preestablished plan for shedding loads if the demand set point is likely to be exceeded.

Computer control can assist in the dispatching of power supply to the fluctuating demands of plant facilities. Large, electrically based facilities are capable of forcing large power demands during peak times that exceed the limits contracted with the utility or cause penalties in increased costs. Computer control can even out the load by shaving peaks and filling in the valleys, thus minimizing power costs. In times of emergency or fuel curtailment, operation of the plant can be programmed to provide optimum production and operating performance under prevailing conditions. Furthermore, computer monitoring and control provide accurate and continuous records of plant performance.

It should be stressed here that many of these same functions can be carried out by manual controls, time clocks, microprocessors, or other inexpensive devices. Selection of a computer system must be justified economically on the basis of the number of parameters to be controlled and the level of sophistication required. Many of the benefits described here can be obtained in some types of operations without the expense of a computer.

---

## 29.5 Thermal Energy Management in Industry

### 29.5.1 Importance of Fuel Use and Heat in Industry

The U.S. manufacturing sector depends heavily on fuels for the conversion of raw materials into usable products. Industry uses a wide range of fuels, including natural gas, petroleum, coal, and renewables. The petroleum forms used include distillate fuel oil, residual fuel oil, gasoline, LPG, and others. How efficiently energy is used, its cost, and its availability consequently have a substantial impact on the competitiveness and economic health of the U.S. manufacturers. More efficient use of fuels lowers production costs, conserves limited energy resources, and increases productivity. Efficient use of energy also has positive impacts on the environment—reductions in fuel use translate directly into decreased emissions of pollutants such as sulfur oxides, nitrogen oxides, particulates, and greenhouse gases (e.g., carbon dioxide).

From [Figure 29.10](#), it can be seen that fuel use in manufacturing is just over 70% of the total energy used in manufacturing on an end-use basis. [Figure 29.11](#) shows the percentage of each fuel used for boiler fuel and process heat combined. Of this total, 53% is used for boiler fuel, and 47% for direct process heating. Thus, there is a huge potential for energy management and energy efficiency improvement related to the use of fuels and thermal energy in industry. Section 29.5 discusses the use of improved and new equipment and technology to accomplish some of these reductions in energy use and cost.

*Energy efficiency* can be defined as the effectiveness with which energy resources are converted into usable work. Thermal efficiency is commonly used to measure the efficiency of energy conversion systems such as process heaters, steam systems, engines, and power generators. Thermal efficiency is essentially the measure of the efficiency and completeness of fuel combustion, or, in more technical terms, the ratio of the net work supplied to the heat supplied by the combusted fuel. In a gas-fired heater, for example, thermal efficiency is equal to the total heat absorbed divided by the total heat supplied; in an automotive engine, thermal efficiency is the work done by the gases in the cylinder divided by the heat energy of the fuel supplied.<sup>1</sup>

**FIGURE 29.10**

Manufacturing energy consumption by fuel (end-use data). (From U.S. Department of Energy, Energy Information Agency, Manufacturing Energy Consumption Survey, 2006, Washington, DC, 2012.)

**FIGURE 29.11**

Manufacturing energy use for boiler fuel and process heating end-use basis. (From U.S. Department of Energy, Energy Information Agency, Manufacturing Energy Consumption Survey, 1998, Washington, DC, 2002.)

Energy efficiency varies dramatically across industries and manufacturing processes, and even between plants manufacturing the same products. Efficiency can be limited by mechanical, chemical, or other physical parameters, or by the age and design of equipment. In some cases, operating and maintenance practices contribute to lower-than-optimum efficiency. Regardless of the reason, less-than-optimum energy efficiency implies that not all of the energy input is being converted to useful work—some is released as lost energy. In the manufacturing sector, these energy losses amount to several quadrillion Btus (quadrillion British thermal units, or quads) and billions of dollars in lost revenues every year.

Typical thermal efficiencies of selected energy systems and industrial equipment<sup>23</sup> are provided in the following table:

Power generation	25%–44%
Steam boilers (natural gas)	80%
Steam boilers (coal and oil)	84%–85%
Waste-heat boilers	60%–70%
Thermal cracking (refineries)	58%–61%
EAF steelmaking	56%
Paper drying	48%
Kraft pulping	60%–69%
Distillation column	25%–40%
Cement calciner	30%–70%
Compressors	10%–20%
Pumps and fans	55%–65%
Motors	90%–95%

Boiler losses represent energy lost due to boiler inefficiency. In practice, boiler efficiency can be as low as 55%–60% or as high as 90%. The age of the boiler, maintenance practices, and fuel type are contributing factors to boiler efficiency. It is assumed that the greater losses are in steam pipes (20%), with small losses incurred in other fuel transmission lines (3%) and electricity transmission lines (3%). Losses in steam pipes and traps have been reported to be as high as from 20% to 40%. A conservative value of 20% was used for steam distribution losses in this study.<sup>1</sup>

### 29.5.2 Boiler Combustion Efficiency Improvement

Boilers and other fuel-fired equipment, such as ovens and kilns, combust fuel with air for the purpose of releasing chemical energy as heat. For an industrial boiler, the purpose is to generate high-temperature and high-pressure steam to use directly in a manufacturing process or to operate other equipment such as steam turbines to produce shaft power. As shown earlier in [Figure 29.11](#), the predominant boiler fuel is natural gas. The efficiency of any combustion process is dependent on the amount of air that is used in relation to the amount of fuel and how they are mixed. Air is about 20% oxygen, so approximately 5 units of air must be brought into the boiler for every 1 unit of oxygen that is needed. Controlling this air–fuel mixture, and minimizing the amount of excess air while still obtaining safe mixing of the air and fuel, is key to ensuring a high combustion efficiency in the boiler.<sup>24</sup>

#### 29.5.2.1 Combustion Control

The stoichiometric equation for the combustion of methane, the principal constituent of natural gas, with air is

The stoichiometric equation is the one representing the exact amount of air necessary to oxidize the carbon and hydrogen in the fuel to carbon dioxide and water vapor. However,

it is necessary to provide more than the stoichiometric amount of air since the mixing of fuel and air is imperfect in the real combustion chamber. Thus, the combustion equation for hydrocarbon fuels becomes

Note that for a given fuel, nothing in the equation changes except the parameter  $\phi$ , the equivalence ratio, as the fuel–air ratio changes.

As  $\phi$  is increased beyond the optimal value for good combustion, the stack losses increase, and the heat available for the process decreases. As the equivalence ratio increases for a given flue temperature and a given fuel, more fuel must be consumed to supply a given amount of heat to the process.

The control problem for the furnace or boiler is to provide the minimum amount of air for good combustion over a wide range of firing conditions and a wide range of ambient temperatures. The most common combustion controller uses the ratio of the pressure drops across orifices, nozzles, or venturis in the air and fuel lines. Since these meters measure volume flow, a change in the temperature of combustion air with respect to fuel, or vice versa, will affect the equivalence ratio of the burner. Furthermore, since the pressure drops across the flowmeters are exponentially related to the volume flow rates, control dampers must have very complicated actuator motions. All the problems of ratio controllers are eliminated if the air is controlled from an oxygen meter. These are now coming into more general use as reasonably priced, high-temperature oxygen sensors become available. It is possible to control to any set value of percentage oxygen in the products; that is,

$$\%O_2 = \frac{\phi - 1}{((x + y/2)/(x + y/4)) + 4.76\phi - 1} \quad (29.18)$$

Figure 29.12 is a nomograph from the Bailey Meter Company<sup>32</sup> that gives estimates of the annual dollar savings resulting from the reduction of excess air to 15% for gas-, oil-, or coal-fired boilers with stack temperatures from 300°F to 700°F. The fuel savings are predicted on the basis that as excess air is reduced, the resulting reduction in mass flow of combustion gases results in reduced gas velocity and thus a longer gas residence time in the boiler. The increased residence time increases the heat transfer from the gases to the water. The combined effect of lower exhaust gas flows and increased heat exchange effectiveness is estimated to be 1.5 times greater than that due to the reduced mass flow alone.

As an example, assume the following data pertaining to an oil-fired boiler. Entering the graph at the top abscissa with 6.2%  $O_2$ , we drop to the oil fuel line and then horizontally to the 327°C (620°F) flue gas temperature line. Continuing to the left ordinate, we can see that 6.2%  $O_2$  corresponds to 37.5% excess air. Dropping vertically from the intersection of

**FIGURE 29.12**

Nomograph for estimating savings from the adjustment of burners. (From Dukelow, S.G., Bailey Meter Company, Wickliffe, OH, 1974. With permission.)

the flue gas temperature line and the excess air line, we note a 3.4% total fuel savings. Fuel costs are as follows:

Burner capacity	63 GJ/h ( $60 \times 10^6$ Btu/h)
Annual operating hours	6,200
Fuel cost	\$0.38/L (\$1.44/gal)
Heating value fuel	42.36 MJ/L (152,000 Btu/gal)
Percent O <sub>2</sub> in exhaust gases	6.2%
Stack temperature	327°C (620°F)

$$10^9 \text{ J/GJ (} 10^6 \text{ Btu/million Btu)} \times \frac{\$0.38/\text{L}}{74,236,500 \text{ J/L}} \left( \frac{1.44/\text{gal}}{152,000 \text{ Btu/gal}} \right) \\ = \$8.96/\text{GJ (} 9.48/\text{million Btu)}$$

Continuing the vertical line to intersect the \$2.50/million Btu and then moving to left ordinate show a savings of \$140,000/year for 8000 h of operation,  $100 \times 10^6$  Btu/h input, and \$5.00/million Btu fuel cost. Adjusting that result for the assumed operating data,

$$\text{Annual savings} = \frac{6,200}{8,000} \times \frac{60 \times 10^6}{100 \times 10^6} \times \frac{9.48}{5.00} \times \$140,000 = \$123,430/\text{year}$$

This savings could be obtained by installing a modern oxygen controller, an investment with approximately a 1-year payoff, or from heightened operator attention with frequent flue gas testing and manual adjustments. Valuable sources of information concerning fuel conservation in boilers and furnaces are given by the DOE/OIT website.

### 29.5.2.2 Waste-Heat Management

Waste heat as generally understood in industry is the energy rejected from any process to the atmospheric air or to a body of water. It may be transmitted by radiation, conduction, or convection, but often it is contained in gaseous or liquid streams emitted to the environment. Almost 50% of all fuel energy used in the United States is transferred as waste heat to the environment, causing thermal pollution as well as chemical pollution of one sort or another. It has been estimated that half of that total may be economically recoverable for useful heating functions.

What must be known about waste-heat streams in order to decide whether they can become useful? Here is a list along with a parallel list of characteristics of the heat load that should be matched by the waste-heat supply.

Waste-heat supply
Quantity
Quality
Temporal availability of supply
Characteristics of fluid
Heat load
Quantity required
Quality required
Temporal availability of load
Special fluid requirements

Let us examine the particular case of a plant producing ice-cream cones. All energy quantities are given in terms of 15.5°C reference temperature. Sources of waste heat include the following:

- Products of combustion from 120 natural gas jets used to heat the molds in the carousel-type baking machines. The stack gases are collected under an insulated hood and released to the atmosphere through a short stack. Each of six machines emits 236.2 m<sup>3</sup>/h of stack gas at 160°C. Total source rate is 161,400 kJ/h or 3874 MJ/day for a three-shift day.
- Cooling water from the jackets, intercoolers, and aftercoolers of two air compressors used to supply air to the pneumatic actuators of the cone machines; 11.36 L/min of water at 48.9°C is available. This represents a source rate of 96 MJ/h. The compressors run an average of 21 h/production day. Thus, this source rate is 2015 MJ/day.
- The water chillers used to refrigerate the cone batter make available—at 130°F—264 MJ/h of water heat. This source is available to heat water to 48.9°C using desuperheaters following the water chiller compressors. The source rate is 6330 MJ/day.
- At 21.2°C, 226 m<sup>3</sup>/min of ventilating air is discharged to the atmosphere. This is a source of rate of less than 22.2 MJ/h or 525 MJ/day.

Uses for waste heat include the following:

- For cleanup operations during 3 h of every shift or during 9 of every 24 h, 681 L/h of hot water at 82.2°C is needed. Total daily heat load is 4518 MJ.
- Heating degree-days total in excess of 3333 annually. Thus, any heat available at temperatures above 21.1°C can be utilized with the aid of runaround systems during the 5(1/2)-month heating season. Estimated heating load per year is 4010 GJ.
- Total daily waste heat available—12.74 GJ/day.
- Total annual waste heat available—3.19 TJ/year.
- Total annual worth of waste heat (at \$5.00/GJ for gas)—\$15,893.
- Total daily heat load—this varies from a maximum of 59.45 GJ/day at the height of the heating season to the hot water load of 4.52 GJ/day in the summer months.

Although the amount of waste heat from the water chillers is 40% greater than the load needed for hot water heating, the quality is insufficient to allow its full use, since the hot water must be heated to 82°C and the compressor discharge is at a temperature of 54°C.

However, the chiller waste heat can be used to preheat the hot water. Assuming 13°C supply water and a 10°C heat exchange temperature approach, the load that can be supplied by the chiller is

$$\frac{49 - 13}{82 - 13} \times 4.52 = 2.36 \text{ GJ/day}$$

Since the cone machines have an exhaust gas discharge of 3.87 GJ/day at 160°C, the remainder of the hot water heating load of 2.17 GJ/day is available. Thus, a total saving of 1129 GJ/year in fuel is possible with a cost saving of \$5645 annually based on \$5.00/GJ gas. The investment costs will involve the construction of a common exhaust heater for the cone machines, a desuperheater for each of the three water chiller compressors, a gas-to-liquid

**FIGURE 29.13**

Heat balance on steam boiler.

heat exchanger following the cone-machine exhaust heater, and possibly an induced draft fan following the heat exchanger, since the drop in exhaust gas temperature will decrease the natural draft due to hot-gas buoyancy.

It is necessary to almost match four of four characteristics. Not exactly, of course, but the closer means thermodynamic availability of the waste heat. Unless the energy of the waste stream is sufficiently hot, it will be impossible to even transfer it to the heat load, since spontaneous heat transfer occurs only from higher to lower temperature.

The quantity and quality of energy available from a waste-heat source or for a heat load are studied with the aid of a heat balance. Figure 29.13 shows the heat balance for a steam boiler. The rates of enthalpy entering or leaving the system fluid streams must balance with the radiation loss rate from the boiler's external surfaces. Writing the first law equation for a steady-flow-steady-state process

$$\dot{q}_L = \dot{m}_f h_f + \dot{m}_a h_a + \dot{m}_c h_c - \dot{m}_s h_s - \dot{m}_g h_g \quad (29.19)$$

and referring to the heat-balance diagram, one sees that the enthalpy flux  $\dot{m}_g h_g$ , leaving the boiler in the exhaust gas stream, is a possible source of waste heat. A fraction of that energy can be transferred in a heat exchanger to the combustion air, thus increasing the enthalpy flux  $\dot{m}_a h_a$  and reducing the amount of fuel required. The fraction of fuel that can be saved is given in the equation

$$\frac{\dot{m}_f \dot{m}_{f'}}{\dot{m}_f} = 1 - \left[ \frac{K_1 - (1 + \phi) \bar{C}_p T_g}{K_1 - (1 + \phi) \bar{C}'_p T'_g} \right] \quad (29.20)$$

where the primed values are those obtained with waste-heat recovery.  $K_1$  represents the specific enthalpy of the fuel-air mixture,  $h_f + \phi h_a$ , which is presumed to be the same with or without waste-heat recovery,  $\phi$  is the molar ratio of air to fuel, and  $\bar{C}_p$  is the specific heat averaged over the exhaust gas components. Figure 29.14, which is derived from

**FIGURE 29.14**

Heat balance for a simple continuous steel tube furnace.

Equation 29.20, gives possible fuel savings from using high-temperature flue gas to heat the combustion air in industrial furnaces.

It should be pointed out that the use of recovered waste heat to preheat combustion air, boiler feedwater, and product to be heat treated confers special benefits not necessarily accruing when the heat is recovered to be used in another system. The preheating operation results in less fuel being consumed in the furnace, and the corresponding smaller air consumption means even smaller waste heat being ejected from the stacks.

Table 29.8 shows heat balances for a boiler with no flue gas–heat recovery, with a feedwater preheater (economizer) installed and with an air preheater, respectively.

It is seen that air preheater alone saves 6% of the fuel and the economizer saves 9.2%. Since the economizer is cheaper to install than the air preheater, the choice is easy to make for an industrial boiler. For a utility boiler, both units are invariably used in series in the exit gas stream.

Table 29.9 is an economic study using 2005 prices for fuel, labor, and equipment. At that time, it was estimated that a radiation recuperator fitted to a fiberglass furnace would cost \$820,200 and effect a savings of \$90,435/year, making for a payoff period of approximately 2.8 years. This assumes of course that the original burners, combustion control system, and so on could be used without modification.

At this point, we can take some time to relate waste-heat recovery to the combustion process itself. We can first state categorically that the use of preheated combustion air improves combustion conditions and efficiency at all loads and in a newly designed installation permits a reduction in size of the boiler or furnace. It is true that the increased mixture temperature that accompanies air preheat results in some narrowing of the mixture stability limits, but in all practical furnaces, this is of small importance.

In many cases, low-temperature burners may be used for preheated air, particularly if the air preheat temperature is not excessive and if the fuel is gaseous. However, the higher volume flow of preheated air in the air piping may cause large enough increases in pressure drop to require a larger combustion air fan. Of course, larger diameter air piping can prevent the increased pressure drop, since air preheating results in reduced quantities of fuel and combustion air. For high preheat temperatures, alloy piping, high-temperature insulation, and water-cooled burners may be required. Since many automatic combustion-control systems sense volume flows of air and/or fuel, the correct control settings will

**TABLE 29.8**

Heat Balances for a Steam Generator

Case	Input Streams				Output Streams			
	Name	Temperature (°C)	Flow Rate	Energy	Name	Temperature (°C)	Flow Rate	Energy
Without economizer or air preheater	Natural gas	26.7	3,611 m <sup>3</sup> /h	134.78 GJ/h	Steam	185.6	45,349 kg/h	126.23
	Air	26.7	35,574 m <sup>3</sup> /h	560.32 MJ/h	Flue gas	372.2	41,185 m <sup>3</sup> /h	19.49

	Condensate water	82.2	41,277 kg/h	12.21 GJ/h	Blowdown	185.6	2,994 kg/h	2.36

**TABLE 29.9**

Cost–Fuel Savings Analysis of a Fiberglass Furnace Recuperator

Operation	Continuous
Fuel input	19.42 GJ/h
Fuel	No. 3 fuel oil
Furnace temperature	1482°C
Flue gas temperature entering recuperator	1204°C
Air preheat (at burner)	552°C
Fuel savings = 37.4%	
$Q = 7.26 \text{ GJ/h}$ or $173.6 \text{ L/h}$ of oil	
Fuel cost savings estimation	
Per GJ = \$5.00	
Per hour = \$36.30	
Per year (8,000 h) = \$290,435	
Cost of recuperator	\$421,400
Cost of installation, related to recuperator	\$398,800
Total cost of recuperator installation	\$820,200
Approximate payback time	2.82 years

change when preheated air is used. Furthermore, if air preheat temperature varies with furnace load, then the control system must compensate for this variation with an auxiliary temperature-sensing control. On the other hand, if control is based on the oxygen content of the flue gases, the control complications arising from gas volume variation with temperature is obviated. This is the preferred control system for all furnaces, and only cost prevents its wide use in small installations. Burner operation and maintenance for gas burners is not affected by preheating, but oil burners may experience accelerated fuel coking and resulting plugging from the additional heat being introduced into the liquid fuel from the preheated air. Careful burner design, which may call for water cooling or for shielding the fuel tip from furnace radiation, will always solve the problems. Coal-fired furnaces may use preheated air up to temperatures that endanger the grates or burners. Again, any problems can be solved by special designs involving water cooling if higher air temperatures can be obtained and/or desired.

The economics of waste-heat recovery today range from poor to excellent depending upon the technical aspects of the application as detailed earlier, but the general statement can be made that, at least for most small industrial boilers and furnaces, standard designs and/or off-the-shelf heat exchangers prove to be the most economic. For large systems, one can often afford to pay for special designs, construction, and installations. Furthermore, the applications are often technically constrained by material properties and space limitations and, as shall be seen later, always by economic considerations. For further information on heat exchangers, see Chapter 29.

### 29.5.2.3 Heating, Ventilating, and Air Conditioning

HVAC, while not usually important in the energy-intensive industries, may be responsible for the major share of energy consumption in the light manufacturing field, particularly in high-technology companies and those engaged primarily in assembly.

Because of air pollution from industrial processes, many HVAC systems require 100% outside ventilating air. Furthermore, ventilating air requirements are often much in excess of

those in residential and commercial practice. An approximate method for calculating the total heat required for ventilating air in kJ per heating season is given by

$$\begin{aligned} E_v \text{ (kJ)} &= 60 \times 24 \text{ (min/day)} \times (1.2 \times 0.519) \text{ (kJ/m}^3\text{K)} \times \text{SCMM} \times \text{DD} \\ &= 896.8 \times \text{SCMM} \times \text{DD} \end{aligned} \quad (29.21)$$

where

SCMM is the standard cubic meter per minute of total air entering plant including unwanted infiltration

DD is the heating degree-days (°C)

This underestimates the energy requirement, because degree-days are based on 18.33°C reference temperature, and indoor temperatures are ordinarily held 1.6°–3.9° higher. For a location with 3333 degree-days, each year the heating energy given by Equation 29.13 is about 17% low.

Savings can be effected by reducing the ventilating air rate to the actual rate necessary for health and safety and by ducting outside air into direct-fired heating equipment such as furnaces, boilers, ovens, and dryers. Air infiltration should be prevented through a program of building maintenance to replace broken windows, doors, roofs, and siding, and by campaigns to prevent unnecessary opening of windows and doors.

Additional roof insulation is often economic, particularly because thermal stratification makes roof temperatures much higher than average wall temperatures. Properly installed vertical air circulators can prevent the vertical stratification and save heat loss through the roof. Windows can be double glazed, storm windows can be installed, or windows can be covered with insulation. Although the benefits of natural lighting are eliminated by this measure, it can be very effective in reducing infiltration and heat transfer losses.

Waste heat from ventilating air itself, from boiler and furnace exhaust stacks, and from air-conditioning refrigeration compressors can be recovered and used to preheat make-up air. Consideration should also be given to providing spot ventilation in hazardous locations instead of increasing general ventilation air requirements.

As an example of the savings possible in ventilation air control, a plant requiring 424.5 CMM outside air flow is selected. A gas-fired boiler with an energy input of 0.0165 GJ is used for heating and is supplied with room air.

$$\text{Combustion air} = \frac{16.5 \times 10^6}{37,281} \times \frac{12}{60} = 88.52 \text{ CMM}$$

for a fuel with 37,281 kJ/m<sup>3</sup> heating value and an air fuel ratio of 12 m<sup>3</sup> air/m<sup>3</sup> fuel. The number of annual degree-days was 3175.

A study showed that the actual air supplied through infiltration and air handlers was 809 m<sup>3</sup>/min. An outside air duct was installed to supply combustion air for the boiler, and the actual ventilating air supply was reduced to the required 424 m<sup>3</sup>/min. The fuel saving that resulted using Equation 29.21 was

$$896.8(809 - 424)3175 = 1096.2 \text{ GJ}$$

worth \$5482 in fuel at \$5.00/GJ for natural gas.

#### **29.5.2.4 Modifications of Unit Processes**

The particular process used for the production of any item affects not only the cost of production but also the quality of the product. Since the quality of the product is critical in customer acceptance and therefore in sales, the unit process itself cannot be considered a prime target for the energy conservation program. That does not say that one should ignore the serendipitous discovery of a better and cheaper way of producing something. Indeed, one should take instant advantage of such a situation, but that clearly is the kind of decision that management could make without considering energy conservation at all.

#### **29.5.2.5 Optimizing Process Scheduling**

Industrial thermal processing equipment tends to be quite massive compared to the product treated. Therefore, the heat required to bring the equipment to steady-state production conditions may be large enough to make start-ups fuel intensive. This calls for scheduling this equipment so that it is in use for as long periods as can be practically scheduled. It also may call for idling the equipment (feeding fuel to keep the temperature close to production temperature) when it is temporarily out of use. The fuel rate for idling may be between 10% and 40% of the full production rate for direct-fired equipment. Furthermore, the stack losses tend to increase as a percentage of fuel energy released. It is clear that overfrequent start-ups and long idling times are wasteful of energy and add to production costs. The hazards of eliminating some of that waste through rescheduling must not be taken lightly. For instance, a holdup in an intermediate heating process can slow up all subsequent operations and make for inefficiency down the line. The breakdown of a unit that has a very large production backlog is much more serious than that of one having a smaller backlog. Scheduling processes in a complex product line is a very difficult exercise and perhaps better suited to a computerized PERT program than to an energy conversation engineer. That does not mean that the possibilities for saving through better process scheduling should be ignored. It is only a warning to move slowly and take pains to find the difficulties that can arise thereby.

A manufacturer of precision instruments changed the specifications for the finishes of over half of his products, thereby eliminating the baking required for the enamel that had been used. He also rescheduled the baking process for the remaining products so that the oven was lighted only twice a week instead of every production day. A study is now proceeding to determine if electric infrared baking will not be more economic than using the gas-fired oven.

#### **29.5.2.6 Cogeneration of Process Steam and Electricity**

In-plant (or on-site) electrical energy cogeneration is nothing new. It has been used in industries with large process steam loads for many years, both in the United States and in Europe. It consists of producing steam at a higher pressure than required for process use, expanding the high-pressure steam through a backpressure turbine to generate electrical energy and then using the exhaust steam as process steam. Alternatively, the power system may be a diesel engine that drives an electrical generator. The diesel engine exhaust is then stripped of its heat content as it flows through a waste-heat boiler where steam is generated for plant processes. A third possibility is operation of a gas turbine generator to supply electric power and hot exhaust gases, which produce process steam in a waste-heat boiler. As will be seen later, the ratio of electric power to steam-heat rate varies markedly

from one of these types of systems to the next. In medium-to-large industrial plants, the cogeneration of electric power and process steam is economically feasible provided certain plant energy characteristics are present. In small plants or in larger plants with small process steam loads, cogeneration is not economic because of the large capital expenditure involved. Under few circumstances is the in-plant generation of electric power economic without a large process steam requirement. A small industrial electric plant cannot compete with an electric utility unless the generation required in-plant exceeds the capacity of the utility. In remote areas where no electric utility exists, or where its reliability is inferior to that of the on-site plant, the exception can be made.

Cogeneration if applied correctly is not only cost effective, but also fuel conserving. That is, the fuel for the on-site plant is less than that used jointly by the utility to supply the plant's electric energy and that used on-site to supply process steam. Figures 29.15 and 29.16 illustrate the reasons for and the magnitude of the savings possible. However, several conditions must be met in order that an effective application is possible. First, the ratio of process steam heat rate to electric power must fall close to these given in the following table:

Heat Engine Type	$E_{\text{steam}}/E_{\text{elect}}$
Steam turbine	2.3
Gas turbine	4.0
Diesel engine	1.5

The table is based upon overall electric plant efficiencies to 30%, 20%, and 40% respectively, for steam turbine, gas turbine, and diesel engine. Second, it is required that the availability

**FIGURE 29.15**

Steam plant schematic before adding electrical generation.

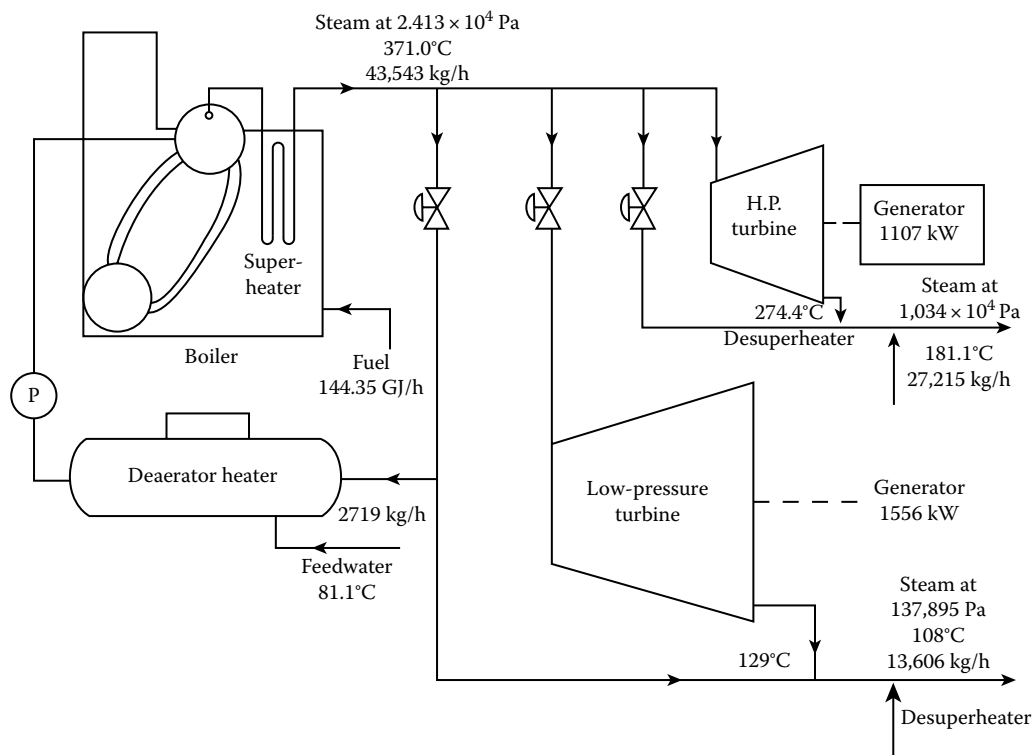

FIGURE 29.16

Steam plant schematic after installing electrical generation.

of the steam load coincides closely with the availability of the electric load. If these temporal availabilities are out of phase, heat storage systems will be necessary, and the economy of the system altered. Third, it is necessary to have local electric utility support. Unless backup service is available from your utility, the cost of building in redundancy is too great. This may be the crucial factor in some cases. The subject of cogeneration and the available technology is covered in Chapter 32.

### 29.5.2.7 Commercial Options in Waste-Heat Recovery Equipment

The equipment that is useful in recovering waste heat can be categorized as heat exchangers, heat storage systems, combination heat storage–heat exchanger systems, and heat pumps.

Heat exchangers certainly constitute the largest sales volume in this group. They consist of two enclosed flow paths and a separating surface that prevents mixing, supports any pressure difference between the fluids of the two fluids, and provides the means through which heat is transferred from the hotter to the cooler fluid. These are ordinarily operated at steady-state steady-flow condition. The fluids may be gases, liquids, condensing vapors, or evaporating liquids, and occasionally fluidized solids. For more information, see Chapter 29.

Radiation recuperators are high-temperature combustion-air preheaters used for transferring heat from furnace exhaust gases to combustion air. As seen in Figure 29.17, they

**FIGURE 29.17**  
Metallic radiation recuperator.

consist of two concentric cylinders, the inner one as a stack for the furnace and the concentric space between the inner and outer cylinders as the path for the combustion air, which ordinarily moves upward and therefore parallel to the flow of the exhaust gases. With special construction materials, these can handle 1355°C furnace gases and save as much as 30% of the fuel otherwise required. The main problem in their use is damage due to overheating for reduced air flow or temperature excursions in the exhaust gas flow.

Convective air preheaters are corrugated metal or tubular devices that are used to preheat combustion air in the moderate temperature range (121°C–649°C) for ovens, furnaces, boilers, and gas turbines, or to preheat ventilating air from sources as low in temperature as 21°C. [Figures 29.18](#) and [29.19](#) illustrate typical construction. These are often available in modular design so that almost any capacity and any degree of effectiveness can be obtained by multiple arrangements. The biggest problem is keeping them clean.

Economizer is the name traditionally used to describe the gas-to-liquid heat exchanger used to preheat the feedwater in boilers from waste heat in the exhaust gas stream. These often take the form of loops, spiral, or parallel arrays of finned tubing through which the feedwater flows and over which the exhaust gases pass. They are available in modular form to be introduced into the exhaust stack or into the breeching. They can also be used in reverse to heat air or other gases with waste heat from liquid streams.

A more recent development is the use of condensing economizers that are placed in the exhaust stream following high-temperature economizers. They are capable of extracting

**FIGURE 29.18**  
Air preheater.

**FIGURE 29.19**  
Ceramic tube recuperator.

**FIGURE 29.20**  
Heat pipe recuperator.

an additional 6%–8% of the fuel input energy from the boiler exhaust gases. However, they are used only under certain restricted conditions. Obviously, the cooling fluid must be at a temperature below the dew point of the exhaust stream. This condition is often satisfied when boilers are operated with 100% make-up water. A second, less restrictive condition is that the flue gases be free of sulfur oxides. This is normally the case for natural gas-fired boilers. Otherwise, the economizer tubes will be attacked by sulfurous and/or sulfuric acid. Acid corrosion can be slowed down markedly by the use of all-stainless steel construction, but the cost of the equipment is increased significantly.

Heat-pipe arrays are often used for air-to-air heat exchangers because of their compact size. Heat-transfer rates per unit area are quite high. A disadvantage is that a given heat pipe (i.e., a given internal working substance) has a limited temperature range for efficient operation. The heat pipe transfers heat from the hot end by evaporative heating and at the cold end by condensing the vapor. Figure 29.20 is a sketch of an air preheater using an array of heat pipes.

Waste-heat boilers are water-tube boilers, usually prefabricated in all but the largest sizes, used to produce saturated steam from high-temperature waste heat in gas streams. The boiler tubes are often finned to keep the dimensions of the boiler smaller. They are often used to strip waste heat from diesel engine exhausts, gas turbine exhausts, and pollution control incinerators or afterburners. Figure 29.21 is a diagram of the internals of a typical waste-heat boiler. Figure 29.22 is a schematic diagram showing a waste-heat boiler for which the evaporator is in the form of a finned-tube economizer. Forced water circulation is used giving some flexibility in placing the steam drum and allowing the use of smaller tubes. It also allows the orientation of the evaporator to be either vertical or horizontal. Other advantages of this design are the attainment of high boiler efficiencies, a more compact boiler, less cost to repair or retube, the ability to make superheated steam using the first one or more rows of downstream tubes as the superheater, and the elimination of thermal shock, since the evaporator is not directly connected to the steam drum.

Heat storage systems, or regenerators, once very popular for high-temperature applications, have been largely replaced by radiation recuperators because of the relative simplicity of the latter. Regenerators consist of twin flues filled with open ceramic checkerwork.

**FIGURE 29.21**  
Waste-heat boiler.

The high-temperature exhaust of a furnace flowing through one leg of a swing valve to one of the flues heated the checkerwork, while the combustion air for the furnace flowed through the second flue in order to preheat it. When the temperatures of the two masses of checkerwork were at proper levels, the swing valve was thrown and the procedure was continued, but with reversed flow in both flues. Regenerators are still used in some glass- and metal-melt furnaces, where they are able to operate in the temperature range  $1093^{\circ}\text{C}$ – $1649^{\circ}\text{C}$ . It should be noted that the original application of the regenerators was to achieve the high-melt temperatures required with low-heating-value fuel.

A number of ceramic materials in a range of sizes and geometric forms are available for incorporation into heat storage units. These can be used to store waste heat in order to remedy time discrepancies between source and load. A good example is the storage of solar energy in a rock pile so that it becomes available for use at night and on cloudy days. Heat storage, other than for regenerators in high-temperature applications, has not yet been used a great deal for waste-heat recovery but will probably become more popular as more experience with it accumulates.

Combination heat storage unit–heat exchangers called heat wheels are available for waste-heat recovery in the temperature range  $0^{\circ}\text{C}$ – $982^{\circ}\text{C}$ . The heat wheel is a porous flat cylinder that rotates within a pair of parallel ducts, as can be observed in [Figure 29.23](#). As the hot gases flow through the matrix of the wheel, they heat one side of it, which then gives up that heat to the cold gases as it passes through the second duct. Heat-recovery

**FIGURE 29.22**

**FIGURE 29.23**  
Heat wheel.

efficiencies range to 80% in low- and moderate-wire matrix of the same material. In the high-temperature range, the material is ceramic. In order to prevent cross-contamination of the fluid streams, a purge section, cleared by fresh air, can be provided. If the matrix of the wheel is covered with a hygroscopic material, latent heat as well as sensible heat can be recovered. Problems encountered with heat wheels include freeze damage in winter, seal wear, and bearing maintenance in high-temperature applications.

The heat pump is a device operating on a refrigeration cycle that is used to transfer energy from a low-temperature source to a higher-temperature load. It has been highly developed as a domestic heating plant using energy from the air or from well but has not been used a great deal for industrial applications. The COP (or the ratio of heat delivered to work input) for an ideal Carnot refrigeration cycle equals  $T_H/(T_H - T_L)$ , where  $T_H$  is the load temperature and  $T_L$  is the source temperature. It is obvious that when the temperature difference  $T_H - T_L$  becomes of the order of  $T_H$ , the heat could be derived almost as cheaply from electric resistance heating. However, for efficient refrigeration machines and a small temperature potential to overcome, the actual COP is favorable to moderate-cost waste energy. The heat pump can be used to transfer waste heat from and to any combination of liquid, gas, and vapor.

---

## **29.6 Role of New Equipment and Technology in Industrial Energy Efficiency**

### **29.6.1 Industrial Energy Savings Potential**

The beginning of this chapter mentioned several studies of industrial energy efficiency that showed that a 20% reduction could be accomplished in a relatively easy and cost-effective manner. The purpose of this section is to provide the equipment, technology, and operational changes that could lead to industrial energy savings on the order of 20% or more.

### **29.6.2 The U.S. DOE Energy-Loss Study and the NAM Efficiency and Innovation Study**

The most recent major study on the potential for improving energy efficiency in industry was conducted for the U.S. Department of Energy, OIT, for their ITP in December 2004. This study was called the "Energy Use, Loss and Opportunities Analysis: U.S. Manufacturing and Mining."<sup>1</sup> This study was then used by NAM together with the Alliance to Save Energy to produce a report on the "Efficiency and Innovation in U.S. Manufacturing Energy Use."<sup>3</sup> Both the U.S. DOE/OIT and NAM conclude that there is a significant opportunity for reducing industrial energy use by 20%.

As stated in the NAM report

[i]ndustry's best R&D options for reducing energy costs were summarized in a study sponsored by the U.S. DOE. This study identifies energy efficiency opportunities that yield energy, economic and environmental benefits, primarily for large volume, commodity/process industries. Opportunities were prioritized to reflect the magnitude of potential savings, broadness of suitability across industries, and feasibility to implement. In total, these energy-saving opportunities represent 5.2 quadrillion Btu—21% of primary energy consumed by the manufacturing sector. These savings equate to almost \$19 billion for manufacturers, based on 2004 energy prices and consumption volumes.

**TABLE 29.10**

Best Opportunities for Future Industrial Energy Savings

Type of Opportunity	Total Energy Savings		Total Cost Savings	
	(trillion Btu)	% of Total	(\$mill.)	% of Total
<i>Top R&amp;D opportunities for energy savings in commodity/process manufacturing; initiatives that provide the largest energy and dollar savings</i>

Table 29.10 summarizes these leading opportunities. An expanded version of this information appears in [Table 29.11](#).

### 29.6.3 The ACEEE Fan and Pump Study

In April 2003, the ACEEE released a report on their study “Realizing Energy Efficiency Opportunities in Industrial Fan and Pump Systems.” They concluded that fans and pumps account for more than a quarter of industrial electricity consumption and that optimization of the operation of these fans and pumps could achieve electricity savings ranging from 20% to well over 50% of this category of use.<sup>10</sup> This report says that most optimization projects involve greater engineering costs than equipment costs, but the average payback for a good optimization project is about 1.2 years, with the cost of saved energy on the order of \$0.012/kW h. In addition, these estimates do not account for productivity gains known to exist at many of the plant sites, which are sometimes as much as two to five times the energy savings.

This ACEEE report contains some excellent data on motor systems end use that is very difficult to find in general. Their data show that 40% of industrial motor use is for fans and pumps. Because the MECS data from EIA show that about 68% of electric use in industry is motors, this leads to the fraction of industrial electric use from fans and pumps to be  $(0.68) \times (0.4) = 0.32$ , or 32%. The end-use data from ACEEE are reproduced in [Table 29.12](#).

To see the final impact of this estimate of industrial energy savings, now apply the ACEEE estimates of 20%–50% savings on fan and pump energy to the 32% fraction of fan and pump contribution to the total industrial electricity use. Thus, the overall savings are in the range  $(0.2) \times (0.32) = 6.4\%$  to  $(0.5) \times (0.32) = 16\%$ . Just this opportunity alone could result in achieving over half of the 20% savings contained in the U.S. DOE/OIT study.

[Table 29.13](#) presents the ACEEE estimates of the relative magnitude of electricity consumed by fans and pump systems for the important industries on a national basis.

#### 29.6.4 The LBL/ACEEE Study of Emerging Energy-Efficient Industrial Technologies

In October 2000, ACEEE released a report of a study it did in conjunction with staff from Lawrence Berkeley Laboratories (LBL), where they identified 175 emerging energy-efficient technologies, and honed this list down to 32 technologies that had a high likelihood of success and a high energy savings.<sup>25</sup> An interesting aspect of this study is that it shows that the United States is not running out of technologies to improve energy efficiency and economic and environmental performance, and will not run out in the future. The study shows that many of the technologies have important nonenergy benefits, ranging from reduced environmental impact to improved productivity. Several technologies have reduced capital costs compared to the current technology used by those industries. Nonenergy benefits such as these are frequently a motivating factor in bringing this kind of technology to market.

The LBL/ACEEE list of 32 most beneficial technologies is shown in [Table 29.14](#).

**TABLE 29.14**

Technologies with High Energy Savings and a High Likelihood of Success

Technology	Code	Total Energy Savings	Likelihood of Success	Recommended Next Steps
Efficient cell retrofit designs	Alum-2	High	High	Demo
Advanced lighting technologies	Lighting-1	High	High	Dissemination, demo
Advance ASD designs	Motorsys-1	High	High	R&D

## 29.7 Conclusion

Energy is the lifeblood of industry; it is used to convert fuels to thermal, electric, or motive energy to manufacture all the products of daily life. Using this energy efficiently is a necessity to keep industries competitive, clean, and at their peak of productivity. Energy management programs that improve the operational efficiency and the technological efficiency of industry are critical to the long-term success of industry and manufacturing in the United States. One important result in this area has been a recognition

that the United States is not running out of technologies to improve industrial energy efficiency, productivity, and environmental performance, and it is not going to run out in the foreseeable future. A substantial opportunity to the country's industrial energy use by over 20% is currently available using better operational procedures and using improved equipment in industrial plants. These savings to industry are worth almost \$19 billion at 2004 energy prices. With crude oil prices edging toward \$70 in late summer 2005, this dollar savings amount should be substantially higher. It is time to capture the benefits of this opportunity.

### 30.1 Pinch Technology in Theory

Many industrial processes require that heat be added to and removed from streams within the process. This is notably the case in the chemical process industry. Raw materials are heated or cooled to the appropriate reaction temperature. Heat may be added or removed to carry out the reaction at the specified condition of temperature and pressure. The product separation is achieved by heat addition (to a reboiler in a distillation column) and removal (from a condenser of the distillation column). The product may be heated or cooled to the correct temperature for storage and transportation. Thus, at all times heat is either added or removed to a variety of process streams by utilities or by heat exchange between process streams. In an integrated plant this is normally achieved with a *heat exchanger network* (HEN). A large fraction of the capital cost of many chemical process plants is attributed to heat recovery networks.

The aim of a designer is to synthesize a near optimal configuration for a process. This indicates that a proper trade-off between the capital invested and the operating cost of the plant should be achieved. The capital cost depends on the type, number, and size of units utilized to satisfy the design objectives. A substantial part of the operating cost usually depends upon the utilities consumed. To reduce these costs, the process designer should

aim for an economic combination having near the theoretical minimum number of heat exchanger units and aim to recover the maximum possible heat with them. An obvious way to recover heat is by exchanging it between hot process streams that need to be cooled and cold process streams that need to be heated, in addition to the heating and cooling utilities. Furthermore, the designer should also investigate the operability of the final design.

These objectives can be achieved by synthesizing a good heat exchanger network. However, a very large number of alternatives exist. Because of this, it will be highly rewarding to synthesize quickly and systematically the best possible alternatives. It is now possible to do this with the aid of “pinch technology.”

Pinch technology refers to a large and growing set of methods for analyzing process energy requirements in order to find economically optimal and controllable designs. Considerable development has taken place in pinch technology during the last three decades, mainly due to the efforts of Linnhoff and co-workers. Pinch technology has proved to be effective and is successfully applied to process integration<sup>1</sup> that encompasses overall plant integration and includes heat exchanger networks, heat and power integration or cogeneration, and thermal integration of distillation columns. To date, there are more than 65 concepts used by this technology. However, due to the limited scope of this chapter, only the most important concepts are discussed here.

Industrial applications of this technology include capital cost reduction, energy cost reduction, emissions reduction, operability improvement, and yield improvement for both new process design and revamp process design. Imperial Chemical Industries (ICI) where this technology was first developed reported an averaged energy saving of about MM\$11/year, (about 30%) in processes previously thought optimized.<sup>2</sup> The payback time was typically in the order of 12 months. Union Carbide showed even better results.<sup>3</sup> Studies conducted by Union Carbide in nine projects showed an average savings of 50% with an average payback period of 6 months. BASF reports energy savings of 25% obtained by application of pinch technology to their Ludwigshafen site in Germany.<sup>4</sup> Over a period of 3 years about 150 projects were undertaken by BASF. Fraser and Gillespie<sup>5</sup> reported energy savings of 10% with a payback period of 2 years by applying pinch technology to the Caltex Refinery situated in Milnerton, South Africa. The energy consumption before the study was 100 MW for the whole refinery. A newsfront article in *Chemical Engineering*<sup>6</sup> gives more details about the experience of various companies in using pinch technology and the benefits obtained.

### 30.1.1 Fundamental Principles and Basic Concepts

Pinch technology is based on thermodynamic principles. Hence, in this section we will review the important thermodynamic principles and some basic concepts.

#### 30.1.1.1 Temperature-Enthalpy Diagram

Whenever there is a temperature change occurring in a system, the enthalpy of the system will change. If a stream is heated or cooled, then the amount of heat absorbed or liberated can be measured by the amount of the enthalpy change. Thus,

$$Q = \Delta H \quad (30.1)$$

For sensible heating or cooling at constant pressure where  $CP = mc_p$ ,

$$\Delta H = CP\Delta T \quad (30.2)$$

For latent heating or cooling

$$\Delta H = m\lambda \quad (30.3)$$

If we assume that the temperature change for latent heating or cooling is  $1^\circ\text{C}$ , then

$$CP = m\lambda \quad (30.4)$$

Equation 30.2 enables us to represent a heating or cooling process on a temperature-enthalpy diagram. The abscissa is the enthalpy and the ordinate is the temperature. The slope of the line is  $(1/CP)$ . Figure 30.1a shows a cold stream being heated from  $20^\circ\text{C}$  to  $80^\circ\text{C}$  with  $CP = 2.0 \text{ kW}/^\circ\text{C}$ .

As enthalpy is a relative function, the stream can be drawn anywhere on the enthalpy scale as long as it is between its starting and target temperatures and has the same enthalpy change. Figure 30.1b shows such a case. Thus, one of the important advantages of representing a stream on the temperature-enthalpy plot is that the stream can be moved horizontally between the same temperature intervals. Figure 30.1c shows two different streams in the same temperature interval.

Two streams can be easily added on the temperature-enthalpy plot to represent a composite of the two streams. Figure 30.2 shows how to obtain the composite of two streams on this plot. This feature will be used in later sections to predict the minimum utility requirement for multistream problems.

A heat exchanger is represented by two heat curves on the temperature-enthalpy diagram as shown in Figure 30.3. This figure also shows how we will represent heat exchangers in a grid diagram form and the conventional form. In the grid diagram form, the hot stream goes from left to right and the cold stream goes from right to left. If the flow

**FIGURE 30.1**

is counter-current in the exchanger, then the temperature will decrease from left to right. The exchanger is represented by two circles connected by a vertical line. The advantages of the grid diagram will become apparent when we discuss the design of heat exchanger networks. The exchanger has a temperature difference at the hot end and another at the cold end of the heat exchanger. The smaller of these two temperature differences is called  $\Delta t_{\min}$ .

### 30.1.1.2 Second Law of Thermodynamics and Exergy Analysis

According to the Second Law of Thermodynamics, heat can be transferred from a higher temperature to a lower temperature only. Design of low-temperature processes uses exergy analysis that is based on this law.

### 30.1.1.3 Some Definitions

A *match* between a hot and a cold stream indicates that heat transfer is taking place between the two streams. A match between two streams is physically achieved via a heat exchanger *unit*. The number of heat exchanger units impacts the plot plan and determines the piping and the foundation cost.

For reasons of fouling, mechanical expansion, size limitation, cleaning, improved heat transfer coefficients, and so on, most process heat exchangers are shell-and-tube type with 1 shell pass and 2 tube passes. Often what appears as a single match between two streams in a heat exchanger network representation is actually installed as several 1–2 exchangers in series or parallel. The term *shell* will be used to represent a single 1–2 shell-and-tube heat exchanger. See Chapter 41 for more discussion on 1–2 shell-and-tube heat exchangers.

## 30.1.2 Software

Pinch technology is a mature state-of-the-art technology for process integration and design. While various programs have been written by different researchers at various universities, only a handful of commercial programs are available. Table 30.1 shows the commercially available programs for process integration.

## 30.1.3 Heat Exchanger Network Design Philosophy

This section discusses the design philosophy of pinch technology.

### 30.1.3.1 Optimization Variables

The objective of the heat exchanger network synthesis problem is to design a network that meets an economic criterion such as minimum total annualized cost. The total annualized cost is the sum of the annual operating cost (which consists mainly of energy costs) and annualized capital cost. The capital cost of a network primarily depends on the total surface area, the number of shells, and the number of units that will be installed. The capital cost

will also depend on the individual type of heat exchangers and their design temperature, pressure, and material of construction.

If we include the pressure drop incurred in a heat exchanger, then the capital and operating cost of the pumps will also have to be taken into account. We will limit the scope of this chapter by not including stream pressure drop constraints.

Figure 30.4 shows the various variables that affect the optimization of a heat exchanger network. To make the network operable or flexible, extra cost may be incurred. This cost may be in the form of added equipment, use of extra utilities, or use of additional area on some of the exchangers in the network.

From this discussion, it is clear that the synthesis of heat exchanger networks is a multi-variable optimization problem. The design can never violate the laws of thermodynamics. Hence, the philosophy adopted in pinch technology is to establish targets for the various optimization variables based on thermodynamic principles. These targets set the boundaries and constraints for the design problem. Further, targets help us identify the various trade-offs between the optimization parameters. They help us in obtaining a bird's-eye view of the solution space and identify the optimal values of the optimization parameters.

**FIGURE 30.4**  
Optimization variables in the design of heat exchanger networks.

**FIGURE 30.5**

Effects of  $\Delta t_{\min}$  on the energy, area, units, and shells required for a heat exchange system. (a) Small  $\Delta t_{\min}$ ; (b) large  $\Delta t_{\min}$ .

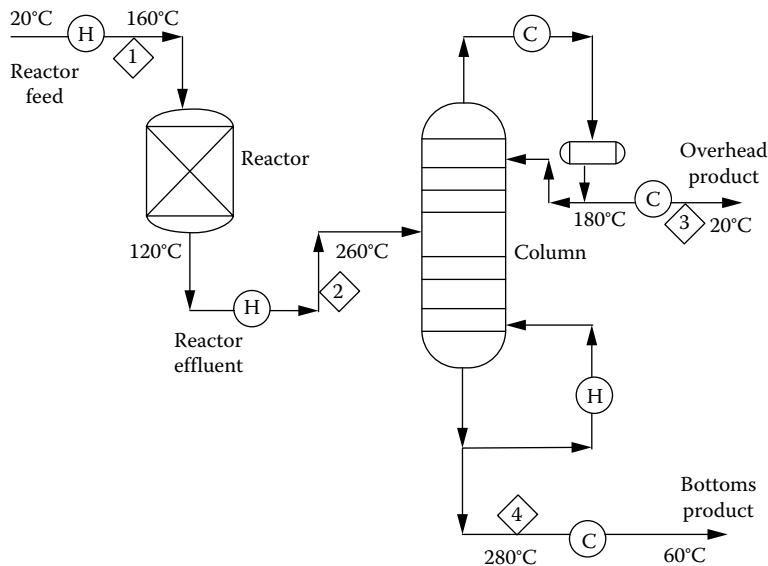

Once the optimal values are identified, design the network at these values. This approach will always lead to an optimal design.

To understand the interaction between the different optimization variables consider the heat curves with a small  $\Delta t_{\min}$  for a simple two-stream system shown in Figure 30.5a. Three different sections can be easily identified on this diagram. Section 1 represents the cold utility requirement, Section 2 represents the process–process heat exchange, and Section 3 represents the hot utility requirement. From this set of heat curves we can calculate the utility requirements for the system, and for each section we can calculate the area required as we know the duty for each section and the terminal temperatures. Further, we can deduce that each section will require one unit. We can use Bell's method<sup>7</sup> to estimate the number of shells required for each unit that represents the different sections. In Section 2, two shells will be required. The heat curves for the hot and cold streams establish targets for energy, area, units, and shells. These are the major components that contribute towards the annualized cost of the network.

Now for the same system, let us increase the  $\Delta t_{\min}$ . The new set of heat curves is shown in Figure 30.5b. The preceding exercise can now be repeated to obtain targets for energy, area, units, and shells. When we increase the value of  $\Delta t_{\min}$ , the utility requirement will increase and the total network area required will be decreased. The number of units for this system remains the same, but the number of shells required will decrease. Section 2 now only requires one shell. Thus, as the value of  $\Delta t_{\min}$  increases, the utility cost increases and the capital cost decreases. This indicates that  $\Delta t_{\min}$  is the single variable that fixes the major optimization variables shown in Figure 30.4. Hence, we can reduce the multivariable optimization problem to a single-variable optimization problem. This single variable is  $\Delta t_{\min}$ . At the optimum value of  $\Delta t_{\min}$ , the other optimization variables—that is, number of shells, number of units, total network area requirement, and the hot and cold utility requirements—will also be optimal. For a multistream problem the same conclusion can be easily derived. Hence, for the multistream problem optimization discussed in the next sections, we will develop methods to optimize the value of  $\Delta t_{\min}$ .

### 30.1.4 Design Problem

Consider an illustrative plant flowsheet shown in Figure 30.6. The feed is heated to the reaction temperature. The reactor effluent is further heated, and the products are separated in a distillation column. The reboiler and condenser use external utilities for control purposes. The overhead and bottoms products are cooled and sent for further processing. We shall use this problem to illustrate the concepts of pinch technology.

**FIGURE 30.6**  
A typical plant flowsheet.

**TABLE 30.2**

Stream Data for the Flowsheet in Figure 30.6

Stream Number	Stream Name	Stream No.	$T_s$ (°C)	$T_t$ (°C)	CP (kW/°C)
1	Reactor feed	1	20	160	40
2	Reactor effluent	2	120	260	60
3	Overhead product	3	180	20	45
4	Bottoms product	4	280	60	30

Table 30.2 lists the starting and target temperatures of all the streams involved in the flowsheet. It also shows the CP values. While pressure drop constraints on the individual streams determine the film heat transfer coefficients, we shall not take into account this constraint. Instead, we use (unrealistically) the same heat transfer coefficient value of  $1 \text{ kW/m}^2 \text{ K}$  for all streams. Our objective is to design an optimum heat exchanger network for this process using the economics outlined in Table 30.3. Further, let  $\Delta t_{\min}$  denote the minimum temperature difference between any hot stream and any cold stream in any exchanger in the network. It is desired that the final network should be able to control the target temperature of all the streams at the design temperature.

### 30.1.5 Targets for Optimization Parameters

#### 30.1.5.1 Energy Targets

##### 30.1.5.1.1 Composite Curves

Let us plot the heat curves for all the hot streams on the  $T$ - $H$  diagram (see Figure 30.7). We can divide the diagram into a number of temperature intervals, defined by the starting and target temperatures for all the streams. Between two adjacent temperatures we

**TABLE 30.3**

**FIGURE 30.7**  
Construction of the hot composite curve.

can calculate the total heat content of all the streams that are present in this temperature interval. For example, between 180°C and 60°C, the sum total of the heat available is calculated as

$$\Delta H = (T_3 - T_2) \sum_j CP_j$$
$$\Delta H_2 = (180 - 60)(40 + 30) = 8400 \text{ kW} \tag{30.5}$$

A composite curve that represent the heat content of all the hot streams is obtained by summing the heat available in each of these temperature intervals as shown in Figure 30.7.

**FIGURE 30.8**

Composite curves for the flowsheet in Figure 30.9.

Similarly, a composite curve for all the cold streams can be obtained. These two composite curves can be used as the heat curves for the whole process.

To obtain the energy target, fix the hot composite curve and move the cold composite curve horizontally till the shortest vertical distance between the two curves is equal to the value of  $\Delta t_{\min}$ . The overshoot of the cold composite curve is the minimum hot utility requirement and the overshoot of the hot composite curve is the minimum cold utility requirement.<sup>8</sup> For  $\Delta t_{\min} = 30^\circ\text{C}$ , the minimum hot utility requirement is 4750 kW and the cold utility requirement is 4550 kW (see Figure 30.8).

#### 30.1.5.1.2 The Problem Table

The preceding procedure for obtaining the energy targets using composite curves is time-consuming and clumsy. An alternative method based on thermodynamic principles is developed. Hohmann<sup>8</sup> called it the feasibility table. Linnhoff and Flower<sup>9</sup> independently developed the problem table. The problem table algorithm is easy and involves no trial and error.

The algorithm consist of the following steps:

- Select a value of  $\Delta t_{\min}$ . Since we have already established the targets using composite curves for  $\Delta t_{\min} = 30^\circ\text{C}$ , we shall use that value here.
- Convert the actual terminal temperatures into interval temperatures as follows:  
For the hot streams:  $T_{\text{int}} = T_{\text{act}} - \Delta t_{\min}/2$   
For the cold streams:  $T_{\text{int}} = T_{\text{act}} + \Delta t_{\min}/2$

where

$T_{\text{int}}$  is the interval temperature

$T_{\text{act}}$  is the actual stream temperature

The interval temperatures now have the allowance for  $\Delta t_{\min}$ . This modification guarantees that for a given  $T_{\text{int}}$ , the actual temperature difference between the hot and cold stream will always be greater than or equal to  $\Delta t_{\min}$ .

- All the interval temperatures for both the hot and cold streams are sorted in descending order and the duplicate intervals are removed (see Table 30.4).
- For each interval, an enthalpy balance is made. The enthalpy balance for interval  $i$  is calculated using the following equation:

$$\Delta H_i = (T_{\text{int},i} - T_{\text{int},i+1}) \left( \sum_j^{N_{\text{streams}}} \text{CP}_{cj} - \sum_j^{N_{\text{streams}}} \text{CP}_{hj} \right) \quad (30.6)$$

where

$\Delta H_i$  is the net heat surplus or deficit in interval  $i$

$\text{CP}_c$  is the mass specific heat of a cold stream

$\text{CP}_h$  is the mass specific heat of a hot stream

For the example problem this calculation is shown in Table 30.5. With each interval the enthalpy balance will indicate that there is either heat deficit or surplus or the interval is in heat balance. A heat surplus is negative and a heat deficit is positive.

The Second Law of Thermodynamics only allows us to cascade heat from a higher temperature to a lower temperature. Thus, a heat deficit from any interval can be satisfied in two possible ways—by using an external utility or by cascading the surplus heat from a higher temperature interval. If no external utility is used, the heat cascade column of Table 30.5 can be constructed. All intervals in this heat cascade have negative heat flows. This is thermodynamically impossible in any interval (it would mean heat flowing from lower to higher temperature). To correct this situation, we take the largest negative flow in the cascade and supply that amount of external hot utility at the highest temperature interval. This modification will make the heat cascade feasible (i.e., none of the intervals will have negative heat flows). The amount of external heat supplied to the first interval is minimum amount of hot utility required. The surplus heat in the last interval is the minimum amount of cold utility required.

**TABLE 30.4**

Hot utility–275	0								0	4750
275–265	1		■			10	60	600	–600	4150
265–175	2		■		■	90	30	2700	–3300	1450
175–165	3	■			■	10	70	700	–4000	750
165–135	4	■		■		30	25	750	–4750	0
135–45	5		■	■		90	–35	–3150	–1600	3150
45–35	6		■	■	■	10	–5	–50	–1550	3200
35–5	7	■		■		30	–45	–1350	–200	4550
5–Cold utility	8			■						4550

For the example under consideration, the minimum hot utility required is 4750 kW and the minimum cold utility required is 4550 kW. These are the same targets obtained from the composite curves. It is clear, however, that the problem table algorithm is an easier, quicker, and more exact method for setting the energy targets. One can easily set up a spreadsheet to implement the problem table algorithm. Further, once the energy targets are obtained, the composite curves can be easily drawn to visualize the heat flows in the system. It should be noted that the absolute minimum utility targets for a fixed flowsheet are determined by the case of  $\Delta t_{\text{min}} = 0$ .

### 30.1.5.2 Capital Cost Targets

To find the optimal value of  $\Delta t_{\text{min}}$  ahead of design, we need to set the targets for the capital and energy costs. As seen before, the capital cost target for a given  $\Delta t_{\text{min}}$  depends on the total area of the network, the number of shells required in the network, and the number of units required in the network. We will now establish these targets.

#### 30.1.5.2.1 Target for Minimum Total Area for the Network

The composite curves can be divided into different enthalpy intervals at the discontinuities in the hot and cold composite curves. Between any two adjacent enthalpy intervals, if the hot streams in that interval transfer heat only to the cold streams in that interval and vice versa, then we say that vertical heat transfer takes place along the composite curves.<sup>10</sup> This mode of heat transfer models the pure countercurrent heat exchange.

The equation for establishing the minimum area target is based on a complex network called the “spaghetti” network. This network models the vertical heat transfer on the composite curves. In this network, for any enthalpy interval defined by the discontinuities in the composite curves, each hot stream is split into the number of cold streams in that enthalpy interval. Each cold stream in the enthalpy interval is also split into the number of hot streams in that interval. A match is made between each

FIGURE 30.9

Enthalpy intervals for area targeting and the spaghetti network that mimics vertical heat transfer.

hot stream and each cold stream. Figure 30.9 shows this network. The area target is obtained by the following equation:

$$A_{\min} = \sum_i^{N_{\text{intervals}}} \frac{1}{\Delta T_{\text{LMTD}i}} \left( \sum_j^{N_{\text{streams}}} \frac{q_j}{h_j} \right)_i \quad (30.7)$$

where

$A_{\min}$  is the total minimum area for the network

$\Delta T_{\text{LMTD}i}$  is the  $\Delta T_{\text{LMTD}}$  for enthalpy interval  $i$

$q_j$  is the heat content of stream  $j$  in enthalpy interval  $i$

$h_i$  is the film plus fouling heat transfer coefficient of stream  $j$  in enthalpy interval  $i$

The equation gives a minimum total surface area for any system where the process streams have uniform heat transfer coefficients. Townsend and Linnhoff<sup>10</sup> claim that for non uniform heat transfer coefficients the equation gives an useful approximation of the minimum area, with errors being typically within 10%.

#### 30.1.5.2.2 Minimum Number of Units Target

The minimum number of units is given by<sup>11</sup>:

$$u = N + L - s \quad (30.8)$$

where

$u$  is the number of units including heaters and coolers

$N$  is the number of streams including utilities

$L$  is the number of loops

$s$  is the number of separate networks

**FIGURE 30.10**

Loops and independent subnetworks in a heat exchanger network.

A loop is a closed path through the network, and its effect is to increase the number of units. For a network to have the minimum number of units, the number of loops should be zero. Figure 30.10 shows a loop on the grid diagram. Normally for a given stream system, only a single network exists and if the number of loops is assumed to be zero, then the equation can be reduced to<sup>8</sup>

$$u = N - 1 \quad (30.9)$$

Figure 30.10 illustrates the occurrence of independent networks. The total network consists of two independent subnetworks. Thus, for the system shown in this figure,  $N = 5$ ,  $L = 1$ ,  $s = 2$ , and  $u = 4$ .

#### 30.1.5.2.3 Target for Minimum Number of Shells

Trivedi et al.<sup>12</sup> have developed a method for estimating the total number of shells required for the heat exchanger network. The method starts by setting the energy targets for the selected value of  $\Delta t_{\min}$ . The hot and cold utilities are added to the process stream system and the composite curves for the process, and the utility streams are constructed. No external utility requirement will be needed for these set of composite curves. Hence, these are called the balanced composite curves.<sup>13</sup> The method estimates the number of shells based on the balanced composite curves. The method involves two steps:

*Step 1:* Estimate the total number of shells required by the cold process streams and the cold utility streams. See [Figure 30.11a](#).

- Commencing with a cold stream target temperature, a horizontal line is drawn until it intercepts the hot composite curve. From that point a vertical line is dropped to the cold composite curve. This section, defined by the horizontal line, represents a single exchanger shell in which the cold stream under consideration gets heated without the possibility of a temperature cross. In this section, the cold stream will have at least one match with a hot stream. Thus, this section implies that the cold stream will require at least one match

**FIGURE 30.11**

(a) Shell targeting for cold streams on the balanced composite curves. Cold streams will require eight shells.  
 (b) Shell targeting for hot streams on the balanced composite curves. Hot streams will require nine shells.

with a hot stream. Further, it ensures that log mean temperature (LMTD) correction factor,  $F_t \geq 0.8$ .

- Repeat the procedure until a vertical line intercepts the cold composite curve at or below the starting temperature of that particular stream.
- The number of horizontal lines will be the number of shells the cold stream is likely to require to reach its target temperature.
- Repeat the procedure for all the cold streams including the cold utility streams.
- The sum of the number of shells for all the cold streams is the total number of shells required by the cold streams to reach their respective target temperatures.

**Step 2:** Estimate the total number of shells required by the hot process streams and the hot utility streams. See Figure 30.11b.

- Starting from the hot stream initial temperature, drop a vertical line on the balanced composite curve until it intercepts the cold composite curve. From this point construct the horizontal and vertical lines until a horizontal line intercepts the hot composite curve at or below the hot stream target temperature.
- The number of horizontal lines will be the number of shells required by the hot streams for heat exchange in the network.
- Repeat the procedure for all the hot streams including the hot utility streams.
- The sum of the number of shells required by the hot streams will be the total number of shells required by the hot streams to reach their respective target temperatures.

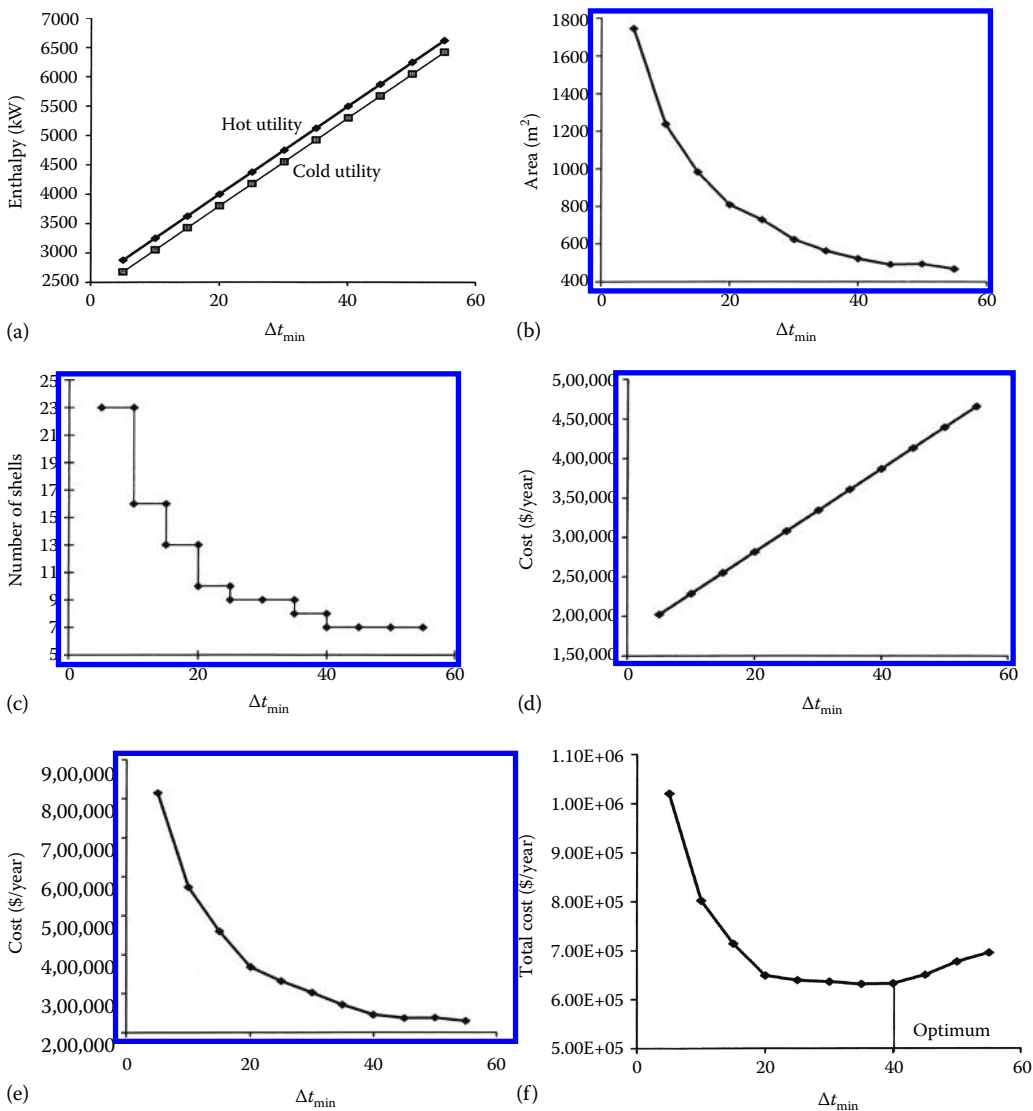

The quasi-minimum number of shells required in the network would be the larger of either the total number of shells required by the hot streams or the total number of shells required by the cold streams.

Ahmad and Smith<sup>14</sup> have pointed out that this procedure works for the problems whose composite curves are wide. They suggest that the procedure should be applied independently to the above and below pinch subnetworks. (Above and below pinch subnetworks are discussed in Section 30.1.7.2) They have also proposed another method for finding the number of shells in a network. Their method is more sophisticated and is not within the scope of this chapter.

### 30.1.5.3 Optimum $\Delta t_{\min}$ Value

The procedures presented so far establish, for a selected  $\Delta t_{\min}$  value, targets for minimum energy, minimum area, minimum number of units, and minimum number of shells. These targets along with the cost data can be translated into capital and energy cost for the network. The targets can be evaluated at different values of  $\Delta t_{\min}$  to obtain a bird's-eye view of the solution space and the optimal value of  $\Delta t_{\min}$  ahead of design. This philosophy was first proposed by Hohmann<sup>8</sup> and later developed by Linnhoff and Ahmad<sup>15</sup> as “supertargeting.”

For the process flowsheet illustrated in Figure 30.6, the different targeting curves are shown in Figure 30.12a through f. It is seen from the total annualized cost curve,

**FIGURE 30.12**

(a) Minimum energy targeting plot. (b) Minimum network area targeting plot. (c) Targeting plot for minimum number of shells. (d) Minimum energy cost targeting plot. (e) Minimum annualized capital cost targeting plot. (f) Targeting plot for total annualized cost.

**TABLE 30.6**

Comparison of Target and Design Values for Different Network Optimization Variables  
at  $\Delta t_{\min} = 40^\circ\text{C}$

	Target	Figure 30.24 MER Design		Figure 30.25 Design	
			% Deviation from Target		% Deviation from Target
Total network area (m <sup>2</sup> )	687	779	13	708	3
Total hot utility consumption (kW)	5,500	5,500		6,400	16
Total cold utility consumption (kW)	5,300	5,300		6,200	17
Number of units	7	7		6	
Number of shells	8	9		7	
Energy cost (\$/year)	387,250	387,250		450,700	16
Annualized capital cost (\$/year)	305,407	333,576	9	282,996	−7
Total annualized cost (\$/year)	692,657	720,826	4	733,696	6

Figure 30.12f, that the optimal region is very flat. While selecting a value of  $\Delta t_{\min}$  from the optimal region, a couple of points should be kept in mind. Different values of  $\Delta t_{\min}$  lead to different topologies. Hence, we should take into account different factors that can affect the final cost. They are the wideness of the composite curves and the problem constraints that have significance in the network synthesis and refinement. The optimal value of  $\Delta t_{\min}$  selected for this problem is  $40^\circ\text{C}$  and the target values for energy, area, units, shells, and annualized total cost are given in Table 30.6.

### 30.1.6 The Pinch Point

On the composite curves, are one or more enthalpy values for which the two composite curves are  $\Delta t_{\min}$  apart. For the example under consideration (see Figure 30.8), this occurs at a hot stream temperature interval in the problem table. In this interval, the heat cascade has zero heat flow (i.e., no heat is transferred across this interval when minimum hot utility is used). This interval, identified by a zero in the corrected heat cascade column, is referred to as the pinch point.<sup>11,16</sup> The significance of the pinch point is now clear—for the minimum external utility requirement do not transfer heat across the pinch point. Any extra amount of external heat that is put into the system above the minimum will be transferred across the pinch point and will be removed by the cold utility.<sup>17</sup>

#### 30.1.6.1 Cross Pinch Principle

For a given value of  $\Delta t_{\min}$ , if the network is using  $Q_h$  units of hot utility and if  $Q_{h\min}$  is the minimum energy target,<sup>17</sup> then

$$Q_h = Q_{h\min} + \alpha \quad (30.10)$$

If the network uses  $Q_c$  units of cold utility and if  $Q_{c\min}$  is the minimum energy target, then

$$Q_c = Q_{c\min} + \alpha \quad (30.11)$$

where  $\alpha$  is the amount of cross-pinch heat transfer.

### 30.1.6.2 The Pinch Point and Its Significance

The pinch point divides the stream system into two independent subsystems. The subsystem above the pinch point is a net heat sink, and the subsystem below the pinch point is a net heat source. Thus, for a system of hot and cold streams, to design a network that meets the minimum utility targets the following rules set by the pinch principle should be follows<sup>17</sup>:

- Do not transfer heat across the pinch point.
- Do not use hot utility below the pinch point.
- Do not use cold utility above the pinch point.

We shall use these principles to design the network for the optimal value of  $\Delta t_{\min}$ .

## 30.1.7 Network Design

### 30.1.7.1 Network Representation on the Grid Diagram

If we attempt to design the network using the conventional flowsheet format, any changes in the design may lead to redrawing the flowsheet. Hence, we shall use the grid diagram to represent and design the network. Figure 30.13 shows the grid diagram for the flowsheet shown in Figure 30.6. On this grid diagram we can place a heat exchanger match between two streams without redrawing the whole stream system. The grid representation reflects the countercurrent nature of heat transfer that makes it easier to check temperature feasibility of the match that is placed. Furthermore, we can easily represent the pinch point on the grid diagram as shown in Figure 30.13.

**FIGURE 30.13**

Grid diagram representation of the network in the flowsheet of Figure 30.9.

### 30.1.7.2 Pinch Point and Network Design

We now continue with the design of the example problem. Figure 30.8 shows the composite curves with  $\Delta t_{\min} = 30^\circ\text{C}$  for the process flowsheet. It also shows the pinch point. The pinch point is the most constrained region of the composite curves. From optimization principles, we know that for a constrained problem, the optimal solution is located at the point formed by the intersection of multiple constraints. Hence, if we can satisfy the constraints at that point then we are guaranteed an optimal design. Thus, we should start the design where the problem is most constrained, that is, the pinch point.<sup>17</sup> The pinch point divides the problem into two independent subnetworks—an above pinch subnetwork that requires only hot utility and a below pinch subnetwork that requires only cold utility.

#### 30.1.7.2.1 Pinch Design Rules and Maximum Energy Recovery

Let us make some observations at the pinch point. Immediately above the pinch point,<sup>17</sup>

$$\Sigma CP_h \leq \Sigma CP_c \quad (30.12)$$

and immediately below the pinch point,

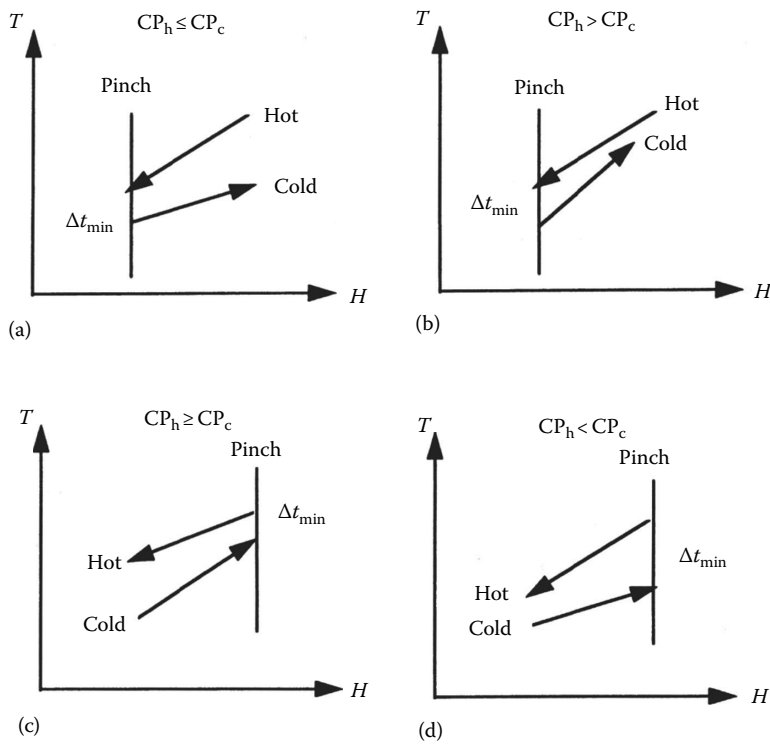

$$\Sigma CP_h \geq \Sigma CP_c \quad (30.13)$$

This condition defines the pinch point, that is, the constraint which the designer has to satisfy. Thus, each and every match in the sink subnetwork at the pinch point should be placed such that  $CP_h \leq CP_c$ . Similarly, each and every match in the source subnetwork at the pinch point should be placed such that  $CP_c \leq CP_h$ . Figure 30.14 shows these conditions on the  $T$ – $H$  diagram.

Two situations arise where the above condition may not be satisfied. The first condition is shown in Figure 30.15. The solution is to split the hot stream. Another situation is shown in Figure 30.16. Here we will have to split the cold stream.

Consider the situation shown in Figure 30.17, which shows the stream population at the pinch point in a sink subnetwork. Here, the number of hot streams is greater than the number of cold streams. Two matches can be easily placed, but for the third stream there is no cold stream to match unless we split a cold stream. Thus, immediately at the pinch for a sink subnetwork, the stream population constraint tells us that the number of hot streams should be less than or equal the number of cold stream. Applying the same logic to the source subnetwork immediately at the pinch point, the number of cold streams should be less than or equal to the number of hot streams. If this condition is not satisfied, then split a hot stream. Figure 30.18 shows the algorithms that are developed for placing matches immediately at the pinch point for both the above and below pinch subnetworks.

The matches and stream splitting can be easily identified with the CP table.<sup>17</sup> Consider the stream system shown in Figure 30.19. The CP table is shown in the same figure. The first row in this table contains the conditions that need to be satisfied for the subnetwork under consideration. The CP values of the hot and cold streams are arranged in a descending order in the columns. The stream numbers are shown in brackets adjacent to the CP values. For the sink subnetwork under consideration, the CP value for the hot streams is listed in the left column and the CP value for the cold stream is listed in the right column. There is no feasible match for hot stream 1. Hence, it will have to be split. Hot stream 2 can match with either stream 3 or 4. Once we split hot stream 1 we violate the stream population constraint. To satisfy this constraint we will have to split a cold stream. Either stream 3 or 4 can be split. The designer can use his or her judgment and decide which stream should be split

**FIGURE 30.14**

CP matching rules at the pinch point. (a) Match ok. (b) Match not feasible above pinch. (c) Match ok. (d) Match not feasible below pinch.

**FIGURE 30.15**

Stream splitting when CP rule is not satisfied.

depending on controllability and other physical constraints. For example, it is not advisable to split a stream that may have a two-phase flow.

Two different designs will be obtained depending on which stream is split. The hot stream is split into two streams having CP values of  $X$  and  $7 - X$ . In the first alternative, we split stream 4 into two streams having CP values of  $Y$  and  $6 - Y$ . In the second option we split stream 3 into two streams having CP values of  $Z$  and  $5 - Z$ . To find the initial values of  $X$ ,  $Y$ , and  $Z$  it is recommended that all matches except for one are set for CP equality. Thus, for

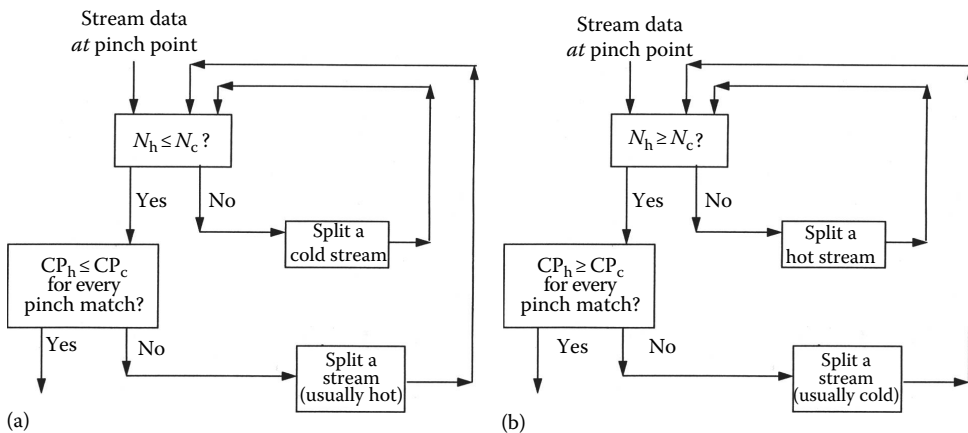

**FIGURE 30.16**

Stream splitting at the pinch point when CP rule is not satisfied for all hot streams above the pinch point.

**FIGURE 30.17**

Stream population at the pinch point may force a stream to split.

**FIGURE 30.18**

(a) Algorithm for sink subnetwork design at the pinch point. (b) Algorithm for source subnetwork design at the pinch point.

**FIGURE 30.19**

Identifying matches and stream splitting using the CP table.

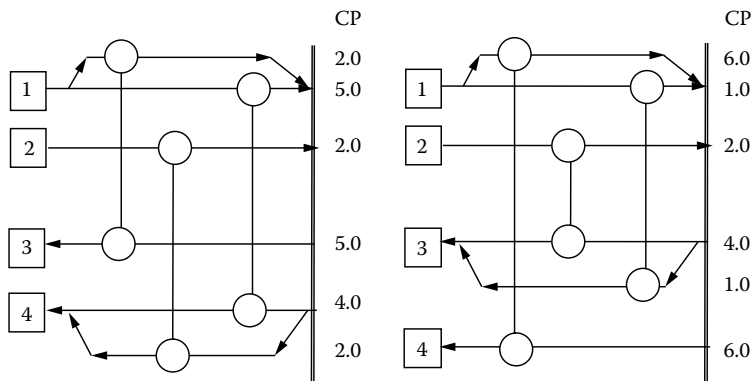

the first option set  $X = 5$  and  $Y = 2$ . For the second option set  $X = 6$  and  $Z = 1$ . This is an initial solution. The values of  $X$ ,  $Y$ , and  $Z$  can be adjusted to obtain an optimal design. The two different topologies obtained for this example are shown in Figure 30.20.

Once the matches are identified at the pinch, the heat loads for these matches are fixed to maximize the heat exchange to the limit of heat load of either the hot stream or the cold stream. This will eliminate that stream from the analysis. Fixing the heat loads for match with this heuristic will also help us to minimize the number of units and thus the installation cost.<sup>17</sup>

Matches away from the pinch point do not have to satisfy the condition just outlined, as the system is not constrained in this region. Matches are easily identified away from the pinch point. The network obtained will satisfy the energy targets set. Such a network is called maximum energy recovery (MER) network.<sup>17</sup>

### 30.1.7.3 $\Delta T - T_c$ Plot

To appropriately place matches in the network that utilize the correct driving forces, the driving force plot is very useful design aid.<sup>18</sup> A plot of the temperature difference  $\Delta T$  between the hot composite curve and the cold composite curve vs. the cold composite temperature is derived from the composite curves as shown in Figure 30.21. Different versions of this plot can also be used such as the  $\Delta T - T_h$  plot or  $T_h - T_c$  plot. To meet the area targets established

**FIGURE 30.20**

Two different topologies for the problem in Figure 30.23. (a) Targets for the original problem. (b) Targets for the remaining problem with the selected match; bad match as it incurs penalties. (c) Targets for the remaining problem with the selected match; good match as it incurs minimal penalty.

**FIGURE 30.21**

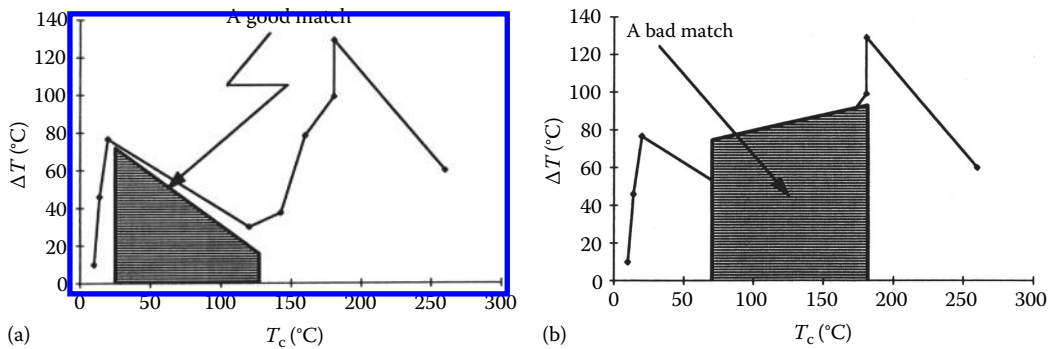

Construction of the  $\Delta T - T_c$  plot. (a) Composite curves. (b)  $\Delta T - T_c$  curve.

one must place the matches such that the  $\Delta T - T_c$  plot of the exchanger must fall in line with the  $\Delta T - T_c$  plot obtained from the composite curves. This is a good guiding principle when the heat transfer coefficients of all the streams are in the same order of magnitude.

Figure 30.22 shows two matches placed in the network. The match in Figure 30.22a is a good match, as it makes the correct utilization of the available driving forces. The match in Figure 30.22b is a bad match, as it uses more  $\Delta T$  than available. If a match uses more driving force than is available, it will force some other match in the network to use less driving force than available. This results in an overall increase in the total surface area of the network. Badly placed matches do not waste energy but waste surface area.<sup>3</sup>

#### 30.1.7.4 Remaining Problem Analysis

As we have noted, the rules that are established for design guidelines can identify multiple options. The option that satisfies the targets established ahead of design will be the optimal design. To help screen different options, Remaining Problem Analysis (RPA) technique<sup>18</sup> should be used. RPA evaluates the impact of the design decision made on the

**FIGURE 30.22**

Identifying good and bad matches using the  $\Delta T - T_c$  plot. (a) Good match. (b) Bad match.

remaining problem. Once a matching decision is made, the remaining stream data excluding the match is retargeted. The targets for the remaining problem should be in line with the original targets. In case they are not, look for other options such as decreasing the heat duty on the match or finding a new match.

Figure 30.23 shows how RPA is undertaken. For the original problem the targets are

$$Q_{\text{hmin}} = 30 \text{ MW}$$

$$Q_{\text{cmin}} = 20 \text{ MW}$$

$$\text{Minimum area} = 1000 \text{ m}^2$$

$$\text{Minimum number of shells} = 15$$

A match is placed that has a duty of 40 MW, has a 200 m<sup>2</sup> area, and needs three shells (see Figure 30.23b). The targets for the remaining stream data that excluded the match are

$$Q_{\text{hmin}} = 40 \text{ MW}$$

$$Q_{\text{cmin}} = 30 \text{ MW}$$

$$\text{Minimum area} = 900 \text{ m}^2$$

$$\text{Minimum number of shells} = 14$$

Thus, by placing the selected match, 10 MW of extra energy will be required, 100 m<sup>2</sup> more area will be required, and two extra shells will be needed. If we place a new match as shown in Figure 30.23c the remaining problem targets are in line with the original targets (i.e., only a small penalty is associated with this match). Hence this match should be selected.

The procedure is repeated after placing each and every match. This way the designer gets continuous feedback on the impact of the matching decisions and the heat load assigned to the match. The final design will meet all the targets set before we start the design.

### 30.1.7.5 Local Optimization—Energy Relaxation

The optimal region is generally very flat, and the optimal value of  $\Delta t_{\text{min}}$  is not a single point but a region. The targeting exercise helps identify this region. Once a value of  $\Delta t_{\text{min}}$  is selected, and the network is designed using the methodology outlined earlier, there is still some scope for further optimization. This is achieved by a process called energy relaxation.<sup>17</sup>

**FIGURE 30.23**

Remaining problem analysis.

The number of units in the design obtained using this procedure will generally be greater than the target value. This is due to the presence of loops. If we can eliminate the loops in a network, then the heat transfer area is concentrated on fewer matches and hence will decrease the piping and foundation requirements. This will tend to decrease the capital cost of the network. However, the same energy penalty may be incurred.

Identifying loops in a large network cannot be done visually as we had done in the example problem. Various algorithms exist to identify loops in a given network.<sup>19,20</sup> Trivedi et al.<sup>21</sup> have proposed LAPIT (Loop and Path Identification Tree) for identifying loops and paths present in the network. A path is the connection between a heater and a cooler via process-process matches.

Loops can be broken by removal of unit in a loop and redistributing the load of the unit among the remaining units of the loop. Some exchangers may result having a very small  $\Delta t_{\min}$  when a loop is broken. The  $\Delta t_{\min}$  across such exchangers can be increased by increasing the utility consumption along a path that consists of a heater, the unit having a small value of  $\Delta t_{\min}$ , and a cooler.

Loop breaking is a very complex optimization process. Trivedi et al.<sup>21,22</sup> have proposed a detail method that systematically breaks loop and identifies options available at each step of the process. The method is based on loop network interaction and load transfer analysis (LONITA)<sup>22</sup> and on a best-first-search procedure.<sup>21</sup>

### 30.1.7.6 Summary of the Design Procedure

The pinch design procedure can be summarized now. Establish the value of the optimum  $\Delta t_{\min}$  using the targeting techniques. This identifies the region in which the design should be initialized. Using the pinch design procedure, design the network. Reduce the number of units using the loop breaking and energy relaxation techniques outlined earlier.

### 30.1.7.7 Example

The principles and procedures just discussed are used for the design of the network for the flowsheet of Figure 30.6. The value of the optimum  $\Delta t_{\min}$  is 40°C. The final network MER design is shown in Figure 30.24. Note that the annualized capital cost of this network is only about 4% higher than the target value of \$692,700. This design is in the neighborhood of the predicted optimum.

The design after energy relaxation is shown in Figure 30.25. This design has one less unit than the MER design in Figure 30.24. Hence, this will decrease the piping, installation, and maintenance cost. The cost of the new design is about 2% higher than the MER design. Since we are using simplified models for costing, the cost of the design in Figure 30.25 is within the errors of cost estimating. However, this design will be cheaper when detail cost is evaluated, as it has less number of units.

Table 30.6 compares the target values of the various optimization parameters with actual design values for Figures 30.24 and 30.25.

FIGURE 30.24

Pinch design for the flowsheet in Figure 30.9. Total annualized cost is \$720,800.

**FIGURE 30.25**

Energy of the pinch design in Figure 30.30. Total annualized cost is \$773,700.  $\Delta t_{Nmin} = 52$  K and  $\Delta t_{Emin} = 40$  K.

### 30.1.8 The Dual Temperature Approach Design Method

#### 30.1.8.1 Concept

The pinch design procedure fixes the  $\Delta t_{min}$ , designs a network, and then undertakes local optimization. During the process of local optimization either the constraint of  $\Delta t_{min}$  across exchangers may be relaxed or the energy consumption may be increased. Thus, the final network will have a  $\Delta t_{min}$  less than the  $\Delta t_{min}$  on the composite curves corresponding to the final energy consumption.

The final network for the flowsheet in Figure 30.6 using pinch design is shown in Figure 30.25. In this network the energy consumption correspond to a  $\Delta t_{min}$  of 52°C on the composite curves. However, the minimum approach temperature is 40°C across exchanger 2. The dual temperature approach design method for the heat exchanger network synthesis is based on this observation.

The network is characterized by two approach temperatures. One approach temperature is called the network minimum approach temperature  $\Delta t_{Nmin}$ . This is the minimum approach temperature on the composite curves and thus fixes the energy consumption for the network. The other approach temperature is called the exchanger minimum approach temperature  $\Delta t_{Emin}$ . This is the minimum approach temperature that any exchanger will have in the network. In the network of Figure 30.25,  $\Delta t_{Nmin} = 52^\circ\text{C}$  and  $\Delta t_{Emin} = 40^\circ\text{C}$ . Generally,  $\Delta t_{Emin} \leq \Delta t_{Nmin}$ . When  $\Delta t_{Emin} = \Delta t_{Nmin}$  the network has a global minimum approach temperature just like the  $\Delta t_{min}$  parameter of the pinch design procedure. This is in contrast to the pinch design method, which utilizes a global value of  $\Delta t_{min}$  (i.e.,  $\Delta t_{Nmin} = \Delta t_{Emin}$ ) and then relaxes the energy consumption of the network (with the obvious implication of increase in  $\Delta t_{min}$ ).

The concept of using dual approach temperatures for the design of the network is very powerful as the designer retains complete control over the energy consumption of the network. This is in contrast with the pinch design method where energy consumption increases following loop breaking and is determined by the new topology and not the designer. Another advantage in using the dual temperature method is the reduction in the number of shells and units. As well, unnecessary stream splits may be avoided, making a more practical network with better operability characteristics. This may result in

substantial decrease (~20%) in the capital cost for a fixed operating cost, representing millions of dollars savings in industrial applications.<sup>23</sup>

The design procedure proposed by Trivedi et al.<sup>24</sup> incorporates the best features of both the pinch design method and the dual temperature approach design procedure. Their design procedure is based on the concept of a pseudo-pinch point.

### 30.1.8.2 Location of the Pseudo-Pinch Point

Initially two sets of composite curves are generated using  $\Delta t_{Nmin}$  and  $\Delta t_{Emin}$ , with  $\Delta t_{Nmin}$  selected such that  $\Delta t_{Nmin} \geq \Delta t_{Emin}$ . Both sets will have different energy consumption denoted as EC. As  $\Delta t_{Emin} \leq \Delta t_{Nmin}$ ,  $EC(\Delta t_{Nmin}) \geq EC(\Delta t_{Emin})$ .

Let us define the energy difference  $\alpha$  (see Figure 30.26a,b) as

$$\alpha = EC(\Delta t_{Nmin}) - EC(\Delta t_{Emin}) \quad (30.14)$$

As the network is designed employing two approach temperatures, a new interpretation of the problem could be this: As  $\Delta t_{Emin}$  is less than  $\Delta t_{Nmin}$ , an amount of energy  $\alpha$  traverses the  $\Delta t_{Emin}$  conventional pinch point. This can be compensated by energy carried upward across the pinch because heat exchange is allowed at temperature differences as low as  $\Delta t_{Emin}$  between streams. The maximum amount of this upward carriage that can be achieved is the value of  $\alpha$  defined earlier. This represents additional flexibility in stream matching by providing for upward and downward carriage, which is permitted by the reduced  $\Delta t_{Emin}$  between streams, while the total energy requirement remains fixed at  $EC(\Delta t_{Nmin})$ , which in turn is defined by the network approach temperature  $\Delta t_{Nmin}$ .

A pseudo-pinch point (actually a set of stream temperatures) is defined so that the stream temperatures at this point allow the problem to be partitioned as shown in Figure 30.27. Thus, the two parts of the network are in enthalpy balance with the utility consumption determined by  $\Delta t_{Nmin}$ .

The pseudo-pinch point is defined based on the observation that the changes in slope of the composite curve that occur at the conventional pinch point require (at least) one hot or cold stream entering at a real pinch point temperature.<sup>25</sup> This stream's starting temperature is chosen to determine the pseudo-pinch point. Let the subscripts pp denote the pseudo-pinch temperatures. To determine the pseudo-pinch point temperatures with  $\alpha$  units of

FIGURE 30.26

(a) Energy relaxation with heat transfer across the pinch point. (b) New pinch point with minimum energy consumption plus (a).

**FIGURE 30.27**

Pseudo-pinch division of the system.

heat transferred across the conventional pinch point at  $\Delta t_{Emin}$ , various strategies for allocating the  $\alpha$  units are proposed by Trivedi et al.<sup>24</sup> Generally the following heuristics are used:

1. Pseudo-pinch point temperatures having  $\Delta T = \Delta t_{Emin}$ : If a hot stream with a starting temperature  $T_{hs}$  determines the conventional pinch point for  $\Delta t_{Nmin}$  or  $\Delta t_{Emin}$ , then this stream is also assumed to be at the pseudo-pinch point with all the cold stream temperatures given by  $T_{hs} - \Delta t_{Emin}$ . Likewise, if a cold stream entrance determines the conventional pinch point, then the pseudo-pinch temperatures of all the hot streams are given by  $T_{cs} + \Delta t_{Emin}$ . It is possible that different streams may determine the conventional pinch point for both  $\Delta t_{Emin}$  and  $\Delta t_{Nmin}$ . In such a situation different topologies will result and all possible configurations should be investigated.
2. Pseudo-pinch point temperatures with  $\Delta T > \Delta t_{Emin}$ : The  $\alpha$  units of heat carried across the conventional pinch point will increase the pseudo-pinch point  $\Delta T$ 's for some stream combinations. Assuming that a hot stream determines the conventional pinch point, various strategies are used. Generally, if there are  $N$  other hot streams with  $T_{hsj} = T_{hspp}$ , then  $\alpha_j = \alpha/N$  is allocated to each of these streams so that their pseudo-pinch point temperatures are increased by  $\alpha/NCP_j$ .

### 30.1.8.3 Design of the Sink Subproblem

#### 30.1.8.3.1 Feasibility Criteria at the Pseudo-Pinch

As the problem constraints are relaxed at the conventional pinch point by passing heat across it, a wide variety of network topologies can be generated. The method commences the design at the pseudo-pinch point. As there are only a few essential matches to be made at the pseudo-pinch point, all the options available to the designer are readily identified. The designer, utilizing the process knowledge and experience, can now select the necessary matches. These could include imposed and constrained matches required for safe, controllable and practical network or any other preferences the designer may have. The feasibility criteria for stream matching and splitting follow.

*Number of process streams and branches:* In a conventional pinch situation, the stream population is compatible with a minimum utility design only if a pinch match is found for each hot stream above the conventional pinch point. The situation is illustrated in [Figure 30.17](#),

**FIGURE 30.28**

Stream splitting may not be necessary in pseudo-pinch problems.

where stream splitting is unavoidable. However, for the pseudo-pinch situation, splitting may not be necessary as demonstrated in Figure 30.28. This results from the relaxation of the conventional pinch temperatures resulting in an increase in the available driving forces for the pseudo-pinch matches.

It is exceedingly difficult to determine in advance if stream splitting is necessary. Hence, two approaches are suggested. The first approach is identical to the pinch design method. Stream splits may be removed once the initial design is generated. This will be discussed later. In the second approach, we place the pseudo-pinch matches and see if the unmatched streams at the pseudo-pinch can be satisfied. If the streams are matching violating  $\Delta t_{Emin}$ , then a stream is split and the pseudo-pinch matching is repeated.

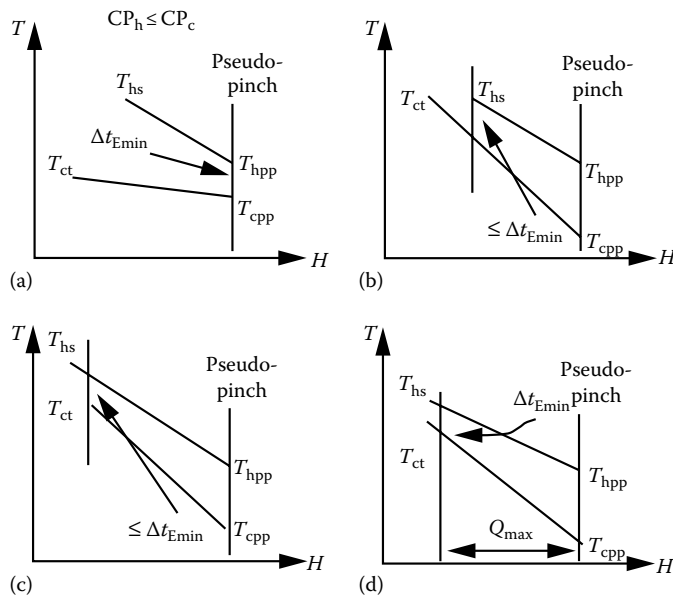

*Temperature feasibility criteria:* Four temperature profiles are possible for a match at the pseudo-pinch point as shown in Figure 30.29. These profiles are for the sink subproblem. The match illustrated in Figure 30.29a possesses the same characteristics as that of an above conventional pinch match. However, for a pseudo-pinch, other matches of the type illustrated in Figure 30.29b through d are also possible. Trivedi et al.<sup>24</sup> have outlined the various criteria to be used at the pseudo-pinch that determine the maximum heat load  $Q_{max}$  for a match between a hot and a cold stream.

#### 30.1.8.4 Design of the Source Subproblem

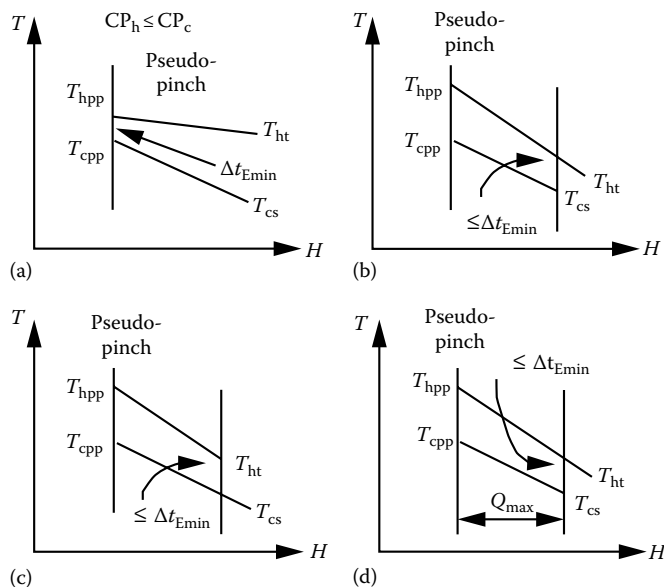

For the source subproblem analogous feasibility criteria can readily be developed. These depend both on the stream populations and temperature feasibility shown in Figure 30.30. The complete design procedure is summarized in Figure 30.31a and b.

#### 30.1.8.5 Design of the Remaining Network

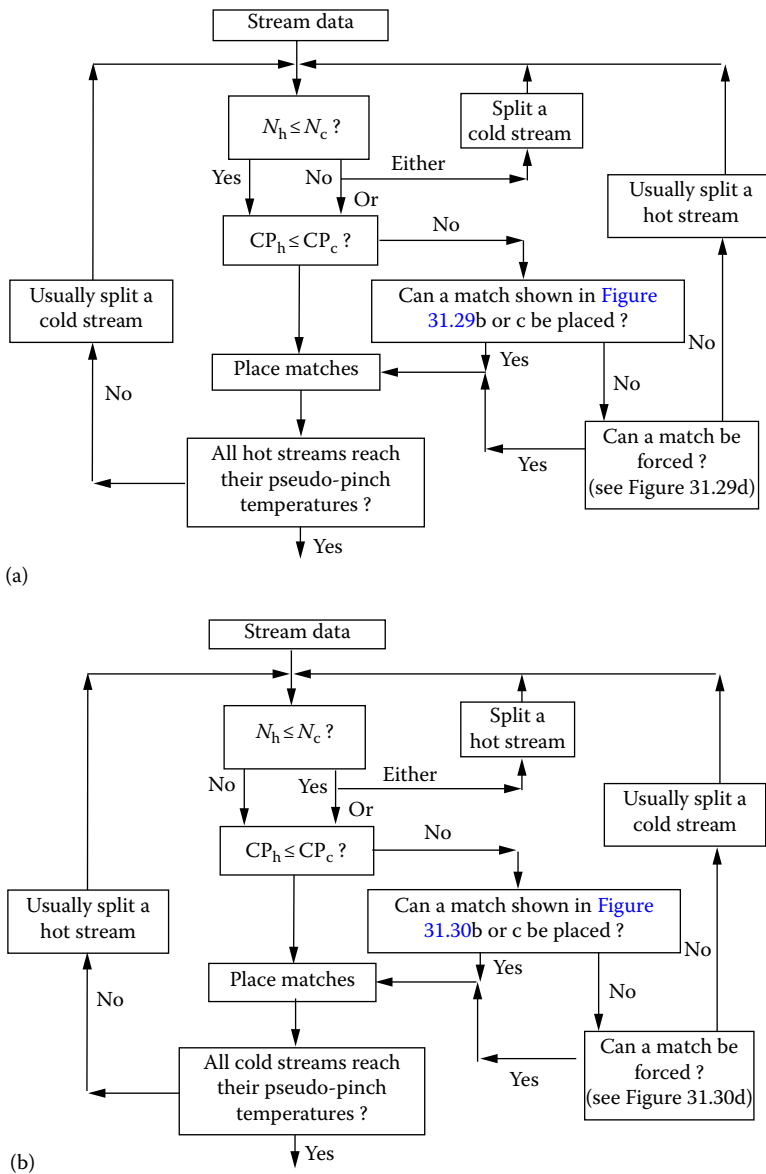

Once the pseudo-pinch matches are placed, the remaining problem can be designed employing the rules mentioned earlier depending on the subproblem. It should be noted

**FIGURE 30.29**

Temperature feasibility for stream splitting immediately adjacent to the pseudo-pinch point for the sink subproblem. (a) Temperature feasibility at pseudo-pinch point. (b) Temperature feasibility away from pseudo-pinch point; Hot stream starting temperature controls the duty of the match. (c) Temperature feasibility away from pseudo-pinch point; Cold stream target temperature controls the duty of the match. (d) Temperature feasibility away from pseudo-pinch point; Maximum feasible duty of the match.

**FIGURE 30.30**

Temperature feasibility for stream splitting immediately adjacent to the pseudo-pinch point for the source subproblem. (a) Temperature feasibility at pseudo-pinch point. (b) Temperature feasibility away from pseudo-pinch point; Cold stream starting temperature controls the duty of the match. (c) Temperature feasibility away from pseudo-pinch point; Hot stream target temperature controls the duty of the match. (d) Temperature feasibility away from pseudo-pinch point; Maximum feasible duty of the match.

**FIGURE 30.31**

(a) Above pseudo-pinch design algorithm. (b) Below pseudo-pinch design algorithm.

that the remaining problem is still in enthalpy balance and only requires either a hot or cold utility, depending on the subproblem. The utilities can be placed on either end or at an appropriate temperature level. (The rules outlined by Trivedi et al.<sup>24</sup> can also be employed in selecting the nonpinch matches when the pinch design method is employed.)

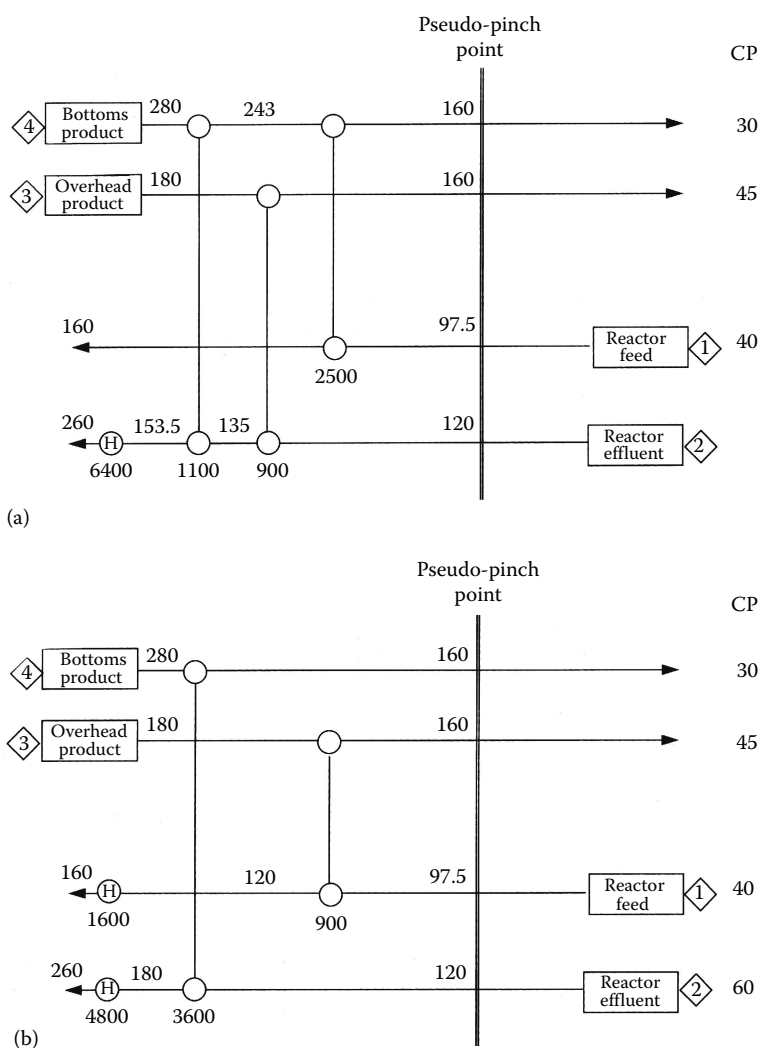

Once an initial topology is synthesized, its capital cost can be further reduced by decreasing the number of units and removing stream splits keeping the energy consumption constant. A linear program can be used to remove stream splits.<sup>24</sup> To reduce the number of units, LONITA can be used.

### 30.1.8.6 Example

We shall illustrate the dual temperature design method for the flowsheet shown in Figure 30.6. A final topology obtained by employing the pinch design method is illustrated in Figure 30.25. In this design  $\Delta t_{\text{Emin}} = 40^\circ\text{C}$  and  $\Delta t_{\text{Nmin}} = 52^\circ\text{C}$ . For  $\Delta t_{\text{Emin}} = 40^\circ\text{C}$ , the pinch point is determined by the entrance of cold stream 2. Hence, the pseudo-pinch temperature for all the hot streams is  $160^\circ\text{C}$  and for the cold stream 2 is  $120^\circ\text{C}$ . As the energy consumption of the network corresponds to  $\Delta t_{\text{Nmin}} = 52^\circ\text{C}$ ,  $\alpha = 900 \text{ kW}$ . This additional heat load is carried by stream 1, and hence the pseudo-pinch temperature of cold stream 1 is  $97.5^\circ\text{C}$ .

#### 30.1.8.6.1 Above Pseudo-Pinch Design

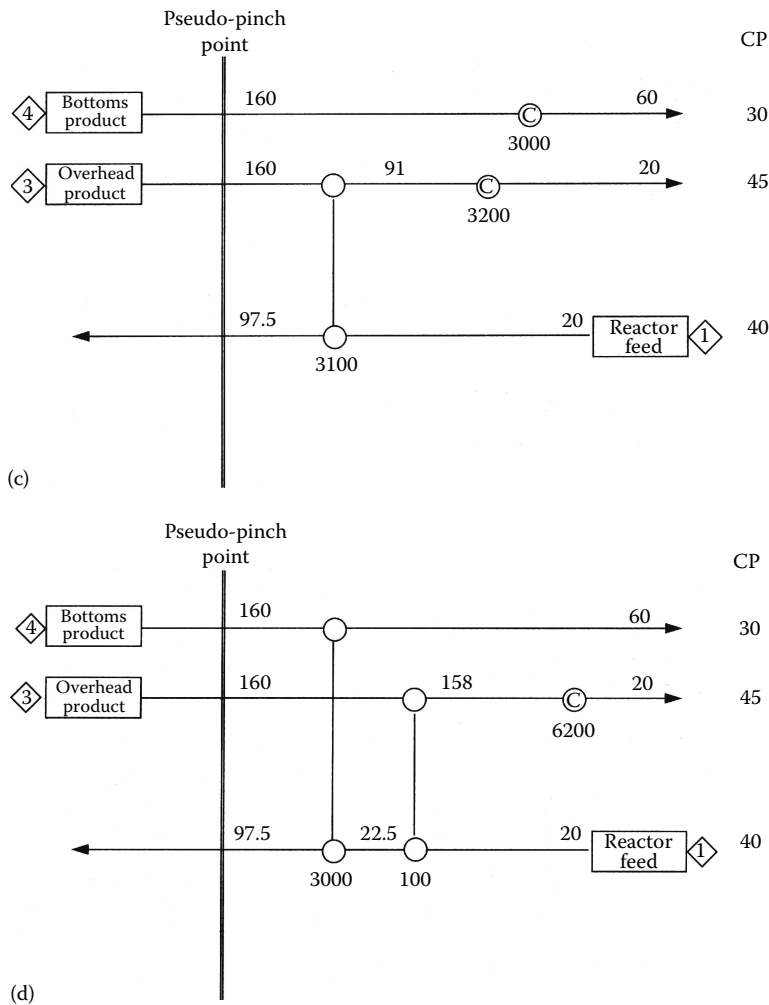

The two possible designs are illustrated in Figure 30.32a and b. It is interesting to note that the topology of Figure 30.32b will not be identified if the pinch design method is employed.

**FIGURE 30.32**

(a) Above pseudo-pinch design—1. (b) Above pseudo-pinch design—2.

(Continued)

**FIGURE 30.32 (Continued)**

(c) Below pseudo-pinch design—1. (d) Below pseudo-pinch design—2.

#### 30.1.8.6.2 Below Pseudo-Pinch Design

Again two designs are possible as illustrated in Figure 30.32c and d. The matches suggested in Figure 30.32c will not be identified by the use of pinch design rules.

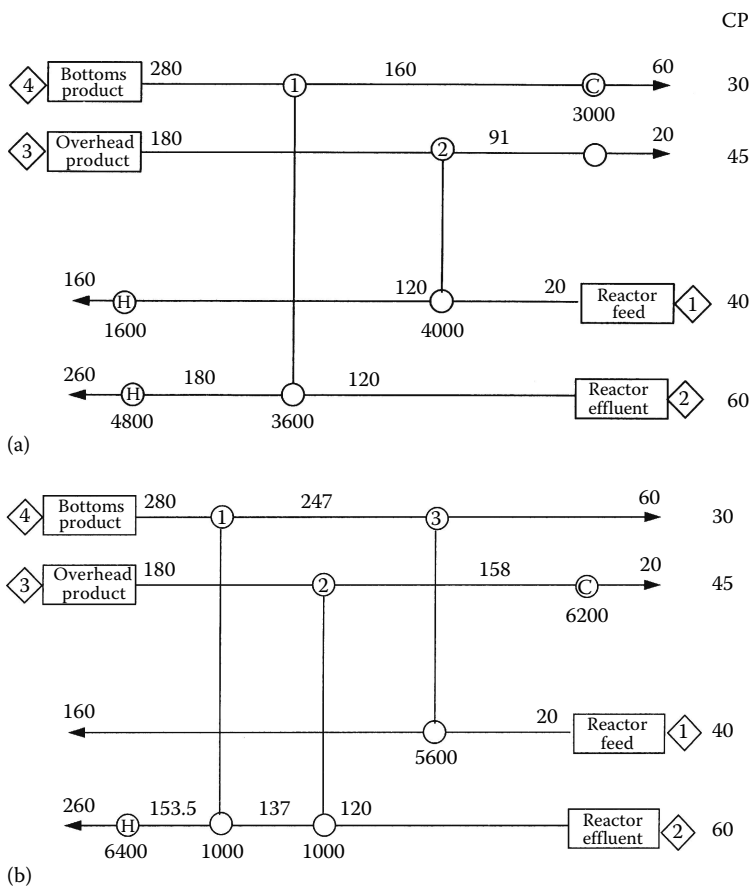

The above and below pseudo-pinch designs can be combined to create four different fixed-energy designs. Combining Figure 30.32a and c gives the same design as shown in Figure 30.25. The other designs are illustrated in Figure 30.33a through c. The capital cost of the designs obtained so far are within 3% of the one shown in Figure 30.24. As the cost of all these networks is very close, we will choose the final design based on other factors such as operability, controllability, and flexibility. A detailed analysis may have to be undertaken on all these designs.

The design shown in Figure 30.33a has utility matches for all the streams. This design will probably be the most controllable design. Hence it is selected. The final process flow diagram for the flowsheet in Figure 30.6 is shown in Figure 30.33d. Observe that there is a

heater on the reactor feed before it enters the reactor. This heater controls the reactor feed temperature. Similarly, the heater on the reactor effluent stream to the distillation column controls the distillation column feed enthalpy. The coolers on the products will control the final product temperatures.

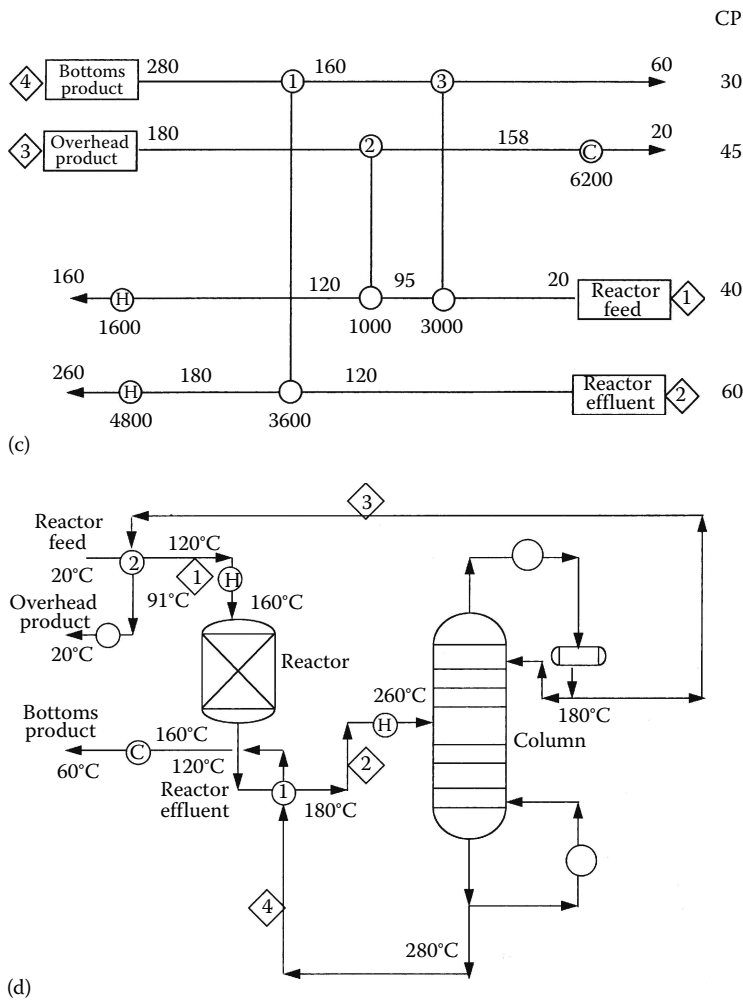

### 30.1.9 Criss-Cross Mode of Heat Transfer

The pinch design procedure, the  $\Delta T - T_c$  plot, and the remaining problem analysis try to achieve the targets set ahead of design. The area target is based on the assumption that vertical heat transfer takes place in the network. This target is good if the film heat transfer coefficients are the same for all the streams. In the majority of the processes phase changes will be occurring, and the streams will be in different phases. Thus, a process may consist of streams that have, at times, film heat transfer coefficients that differ by an order of magnitude. Such a situation is shown in Figure 30.34, where there are two gas streams and two liquid streams. A network that criss-crosses on the composite curves may have a smaller area than predicted by vertical heat transfer mode.<sup>26</sup>

**FIGURE 30.33**

(a) Pseudo-pinch design—2. Total annualized cost is \$743,400. (b) Pseudo-pinch design—3. Total annualized cost is \$727,600. (Continued)

**FIGURE 30.33 (Continued)**

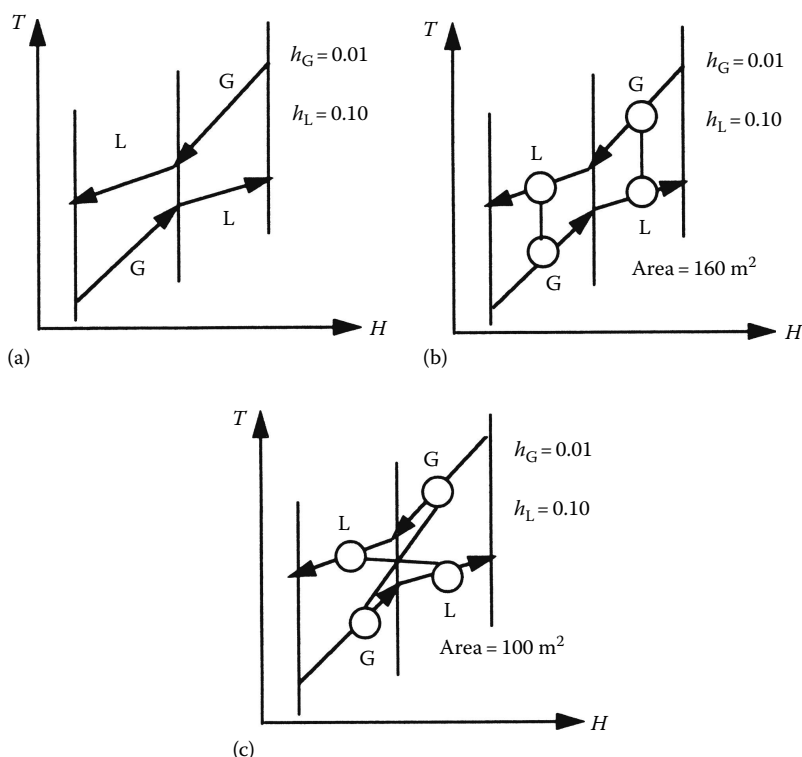

(c) Pseudo-pinch design—4. Total annualized cost is \$740,100. (d) Final flow diagram for the plant in [Figure 30.9](#).

A network will generally have different types of exchangers. Further, each exchanger will have different material of construction and design temperature and pressure. These factors contribute to the capital cost of the network. Thus each stream match will have different coefficients in the cost equation. To optimize the network one will have to undertake criss-crossing on the composite curves.

Stream matching constraints may also require criss-crossing on the composite curve. For example, a match between two streams may be prohibited to maintain process safety or to avoid incurring excessive piping costs associated with a particular match. When constraints are imposed, extra utilities may be required. As a result, one may have to use cold utilities above the pinch point, use hot utilities below the pinch point, or transfer heat across the pinch point. This is totally in contrast to the pinch design rules.

All these scenarios force the designer to criss-cross on the composite curves. Various design methods are proposed in the literature to obtain optimal designs using the criss-cross mode of heat transfer in the network and is not within the scope of this work.

**FIGURE 30.34**

Criss-cross heat transfer will reduce the network area when heat transfer coefficients are very different. (a) Composite curves with streams having different heat transfer coefficients. (b) Vertical heat transfer. (c) Criss-cross heat transfer.

### 30.1.10 Selection of Utility Loads and Levels

The annual operating cost depends on the amount and type of utilities used. In a complex process such as an ethylene plant, there would be about four or five steam levels and about seven or eight refrigeration levels. High-pressure steam generated within the process is let down to other steam levels via steam turbines that generate power. Steam from these levels is used for heating the process. The power generated from the turbines is used by the compressors and pumps and to generate various levels of refrigeration needed. The question faced is what pressure levels of steam to use and what the load is on each level. Also, what are the best temperature levels of refrigeration and what will be their respective loads?

Pinch technology helps us answer these questions in a very simple manner using the Grand Composite Curves (GCC).<sup>27</sup> The GCC is the curve that shows the heat demand and supply within each temperature interval. This curve is derived from the problem table (refer to Table 30.5). In the problem table, we had modified the stream starting and target temperatures depending on the value of  $\Delta t_{\min}$ . From now on we shall refer these modified temperatures as shifted temperature. The heat flows between two adjacent shifted temperature intervals can be plotted on the shifted temperature-enthalpy plot. Figure 30.35 shows the heat cascade and how the grand composite curve is developed for the flowsheet shown in Figure 30.6. The grand composite curve gives us a graphical representation of heat flows taking place in the system. At the pinch point the heat flow is zero.

This section demands external heat of 2000 kW. Hence we should place a hot utility such as high-pressure steam or hot oil to supply it.

Next, consider section BC of the GCC between the shifted temperature intervals of 280°C and 250°C. This section has a heat surplus, so we can use it else where in the system. We can drop a vertical line from B to meet the GCC at point D. Section CD of the GCC, which is a heat deficit region of the system, can now be satisfied by the heat surplus from the BC section. This section of the GCC is called a pocket, and the process is self-sufficient with respect to energy in this region. The section DE now needs external heat. This heat can be supplied at any temperature ranging from the highest available temperature to a minimum temperature corresponding to point D.

Following the same logic, EFG will be a pocket. In section GHI one hot utility level can be used at a shifted temperature level of point G with a total duty of 3000 kW, or two levels can be used—one at 160°C with a duty of 1500 kW, and other at the shifted temperature level of point H (i.e., 140°C with a duty of 1500 kW). The choice is dictated by the trade-off between the power requirement, capital investment, and complexity of the design. Using only one level will make the design of the utility system simpler and the capital cost of the heat exchanger smaller due to higher-temperature approaches. On the other hand, if there is demand for power, then using two levels will produce more power.

A similar economic trade-off will be required for supplying the external heating requirement in section KL of the composite curve. Point L is the pinch point. Below point L heat needs to be rejected into a cooling utility such as an air cooler or cooling water. Also, in the below pinch section of the process we can address the question, Is it possible to raise steam at some temperature? If so, how much?

For example, for the process grand composite curve shown in [Figure 30.36](#), we want to find out how much low-pressure superheated steam can be generated. The saturation temperature of the low-pressure steam is 70°C and boiler feed water is available at 30°C. The superheat is 10°C. Using a simple trial-and-error procedure we can find out how much steam will be generated. Assume the amount of steam that is generated. Develop a heat curve for the low-pressure steam generation on the shifted temperature scale. As generation of low-pressure steam will be a cold stream, the temperature of the stream will be increased by  $\Delta t_{\min}/2$ . Keep on increasing the amount of steam generated till the steam generation heat curve touches the process grand composite curve at any point. The selection of refrigeration levels uses the same technique.

Once the utility levels are decided, introduce them into the stream data and obtain the balanced composite curves. The number of pinch points will increase. In addition to the original process pinch point, each utility level will introduce at least one pinch point. A balanced grid diagram that includes all the utility streams and all the pinch points identified on the balanced composite curve can now be used along with the network design algorithms to develop a network that achieves the target set. Advances have made the task of selecting and optimizing multiple utilities easier.<sup>28,29</sup>

### 30.1.11 Process Integration

Until now we have discussed the design and optimization of heat exchanger networks. But heat exchanger networks are a part of a whole process. Processes consist of reactors, distillation columns, utilities, and so on. For the process to be optimally designed, all the unit operations should be properly integrated. Generally each unit operation is individually optimized. It is a misconception that if each individual unit is individually optimized then the resulting

**FIGURE 30.37**  
Onion diagram.

process is also optimized. Each unit operation interacts with the other in the process. Hence, for the process to be optimized, each unit operation should be properly integrated.

Figure 30.37 shows the onion diagram proposed by Linnhoff et al.<sup>30</sup> that represents the hierarchy of process design. Generally, the reactors are designed first that fix the heat and material balance for the whole process. The products, by-products, and reactants are then separated using the most common unit operation—distillation. A number of columns may be used if a large number of components need to be separated. To achieve the separation and to carry out the reaction in the reactor, the heat exchanger network, using heat exchangers, heats and cools the process streams. External heating and cooling is supplied by the utility system. The utility system may consist of a simple boiler system or a cogeneration unit that produces the necessary steam for the process and the power requirement. All these layers interact. An optimal process design must take into account these interactions and must be properly integrated.

Process integration uses principles that we have already established. Process integration starts by optimizing stand-alone distillation columns with respect to reflux ratio, feed conditioning, side-reboilers, and side-condensers.<sup>31</sup> To properly integrate the distillation column with the background process, it should be placed above or below but not across the background process pinch point.<sup>32</sup> The same principle applies for the appropriate integration of heat engines. Heat pumps should be placed across the pinch point.<sup>27</sup> Linnhoff and de Leur<sup>33</sup> have developed procedures for integrating furnaces with the rest of the process.

### 30.1.12 Process Modification

In the above pinch region, hot streams should be modified such that they can transfer more heat to the cold streams. The cold streams should be modified such that they require less heat. Both of these modifications will decrease the amount of external hot utility requirement. Similarly, in the below pinch region, the cold streams should be modified such that

**FIGURE 30.38**  
The plus/minus principle.

they require more heat and the hot streams should be modified such that they transfer less heat. These modifications will reduce the amount of cold utility requirement. This principle is called the plus/minus principle<sup>3</sup> and is illustrated in Figure 30.38.

### 30.1.13 Shaftwork Targets

Recently, Linnhoff and Dhole<sup>34</sup> have proposed shaftwork targets based on exergy analysis of the stream data for a plant. The shaftwork targeting procedure calculates the change in the total shaftwork requirement of the system due to any changes in the base case. They use exergy composite and grand composite curves that are obtained from the composite and grand composite curves by changing the temperature axis to the carnot factor. Shaftwork targets are very important in the design of low-temperature processes.

### 30.1.14 Sitewide Integration

Generally, individual process are located in a site. The site consist of multiple units. For example a refinery may consist of a crude unit, vacuum unit, naphtha hydrotreater, diesel hydrotreater, fluidized catalytic cracking (FCC) unit, visbreaker unit coker unit, and so on. A petrochemical complex may consist of an ethylene unit, polyethylene unit, and so on. All these units will have one utility system that provides hot and cold utilities as well as power to the whole site. Each unit will have steam demands at different temperatures. At the same time, each unit may be producing steam at different levels. It is possible to directly integrate different units, but that may cause political problems or piping problems. Hence, different units are generally integrated indirectly through the utility system. The problem that sitewide integration addresses is what is the correct level of steam for a site and what is the trade-off between heat and power. Should power be imported or cogenerated?<sup>35</sup>

The most important benefit of the sitewide analysis is that correct pricing for different levels of steam are no longer required. The impact of any modification in terms of fuel or power can be easily evaluated. There is no need for “cost of steam,” as energy pricing is only done with respect to either fuel or power at the battery limit.

Sitewide analysis has increased the understanding of global emissions associated with any processing industry. To minimize the emissions associated with a process, sharper

separations are required. Since distillation is the workhorse of the chemical industry, to obtain sharp separation, the reboiler and condenser duties will increase or additional processes may be added that require additional heating and cooling. External energy is obtained by burning fuel, and when fuel is burned emissions are generated. If extra power is used, then the emissions in the utility company will increase. Thus, to decrease the emissions in the process we might end up increasing the emissions associated with burning the fuel. The net effect might be that we increase the global emissions.<sup>1</sup> Recently, Smith and Delaby<sup>36</sup> have established techniques to target for CO<sub>2</sub> emissions associated with energy. Combining these CO<sub>2</sub> targeting techniques with sitewide analysis will help in trading off different emissions.<sup>37</sup>

### 30.1.15 Data Extraction

Process integration studies start from a base-case flowsheet. This flowsheet may be existing or may be developed from designer's experience. To conduct pinch analysis properly, it is important to extract the flow rate, temperature, and heat duty data correctly.

Stream target and starting temperatures should be chosen so that we do not generate the original flowsheet.<sup>30</sup> To illustrate this, consider the flowsheet shown in Figure 30.39. If we extract the data as two streams, then we might end up with the original flowsheet. If the drum temperature is not important then we can consider it to be one stream and we stand a chance for finding new matches. The drum and the pump can then be kept as a natural break point in the system.

While extracting data, extra care should be taken when streams are mixing nonisothermally.<sup>30</sup> Consider the system shown in Figure 30.40. Stream A is being cooled to the mixed temperature, and stream B is being heated to the mixed temperature. This happens due to mixing the streams. The mixed stream is then heated to a higher temperature. If we extract the data as shown in Figure 30.40a and if the pinch temperature is 70°C then we are inherently transferring heat across the pinch point by mixing the two streams. In the process of mixing we are cooling stream A and then subsequently heating it up again. The correct way to extract the data is shown in Figure 30.40b.

**FIGURE 30.39**  
Flowsheet for data extraction example.

**FIGURE 30.40**

Data extraction for streams that are mixing. (a) A hot stream mixed with a cold stream reaching a combined target temperature. (b) Hot stream and cold stream reaching the same target temperature.

**FIGURE 30.41**

(a) Original stream system. (b) Stream bypassing and mixing can save a unit.

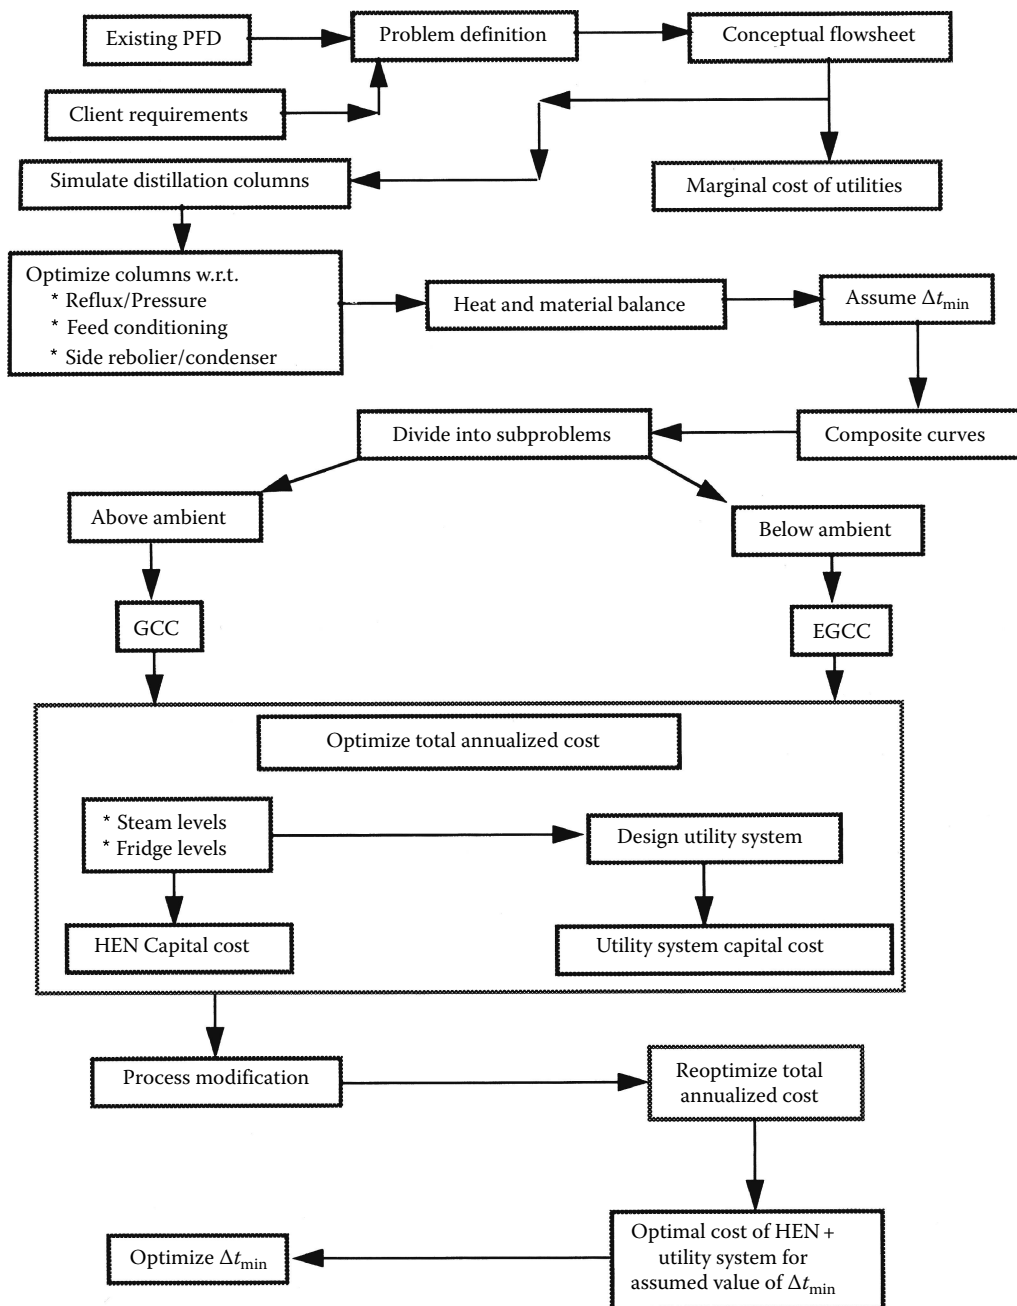

When a stream is split and the split streams have two different target temperatures then each stream is considered as two separate streams. However during the design phase we can use the stream splitting and mixing technique to eliminate one unit.<sup>30,38</sup> See Figure 30.41.

### 30.1.16 Procedure for Optimization of an Existing Design

Process design generally starts with an existing flowsheet. The flowsheet is modified to meet the new requirements defined by the project. Figure 30.42 shows the procedure proposed by Trivedi et al.<sup>39</sup> that utilizes all the concepts of pinch technology for optimizing an existing design. The following sections discuss various steps of this procedure.

#### 30.1.16.1 Problem Definition

From the existing process flow diagram and the project requirement develop a problem definition and scope of the project. At this early stage in the design process, identify all the key project constraints. These constraints may be utility temperature levels (if the construction of the plant is going to be in an existing site), environmental constraints, budget constraints, schedule constraints, and so on.

**FIGURE 30.42**  
Proposed new procedure.

### **30.1.16.2 Conceptual Flow Design**

On the basis of the problem definition and project constraints, develop a new conceptual flow diagram. This flow diagram need not be detailed. However, it should at least contain the reactors, the distillation columns, and the associated conceptual utility system. Furthermore, it should also contain key operating parameters such as feed conditions to distillation columns, operating temperature, and pressure of distillation columns. This flow diagram becomes the basis for optimization.

### **30.1.16.3 Marginal Cost of Utilities**

Develop a simulation model of the conceptual utility system to evaluate the marginal cost of various utility levels. With this model it is possible to evaluate the interactions between the various utility levels. Use a reference utility level as the basis for calculating the savings associated with the other levels. The reference utility level may be the fuel fired to generate steam or to export/import steam at a certain level.

### **30.1.16.4 Simulate and Optimize Distillation Columns**

In this step, simulate the distillation columns using the conditions set by the problem definition and the conceptual flow diagram. Optimize these columns on a stand-alone basis using the procedures outlined by Dhole and Linnhoff.<sup>31</sup>

### **30.1.16.5 Stream Data Extraction**

The conceptual flow diagram along with the simulation of the distillation columns establish the heat and material balance for the entire process. Simulation will also generate the heat curves for all the hot and cold streams. Extract stream data from the process flow diagram using the guidelines established earlier.

### **30.1.16.6 Targeting**

Assume a value of  $\Delta t_{\min}$ . Set overall energy targets using the composite curves. Divide the problem into above ambient temperature and below ambient temperature subproblems. The temperature of cooling water will generally decide this division point. Construct the grand composite curve (GCC) for the above ambient temperature subproblem. For the below ambient temperature subproblem, construct the process exergy grand composite curve. Fine-tune the column optimization undertaken previously.

### **30.1.16.7 Optimize Total Annualized Cost**

From the grand composite curve, optimize the steam levels and their corresponding loads. From these utility loads and levels, design the utility system and estimate its capital cost. Now construct the composite curves that include the utilities. These set of composite curves are the balanced composite curves. Estimate the capital cost of the heat exchanger network from these curves. Calculate the utility cost from the utility loads and levels. Hence, estimate the total annualized cost for the heat exchanger network and the utility system. Optimize this cost by changing the utility loads and levels.

### 30.1.16.8 Process Modification

Use the balanced composite curves to identify process modifications that can potentially reduce the total annualized cost. Changing the operating pressure of a distillation column or modifying the flow rate of a stream are some of the potential process modifications that can be made. The total annualized cost needs to be reoptimized if the utility system design changes significantly.

### 30.1.16.9 Optimize the Value of $\Delta t_{\min}$

At this stage we have the optimal total annualized cost targets for the heat exchanger network and the utility system for the assumed value of  $\Delta t_{\min}$ . Assuming another value of  $\Delta t_{\min}$  will give another optimized total annualized capital cost. Repeat the exercise over a range of  $\Delta t_{\min}$  values to find the optimal value. Design the heat exchanger network at the optimal value of  $\Delta t_{\min}$ .

Trivedi et al.<sup>39</sup> have reported a case study that discusses the application of the above outlined approach to optimize Brown and Root's state-of-the-art Ethylene process. They achieved 12% savings in energy consumption. The capital cost increased by 2% with a simple payback period of 2 years. (Typical specific energy consumption of an ethylene plant for cracking ethane through naphtha ranges from 3000 to 5000 kcal/kg. The total world production capacity of ethylene in 1989 was 61 million MTY<sup>40</sup>).

## 30.1.17 Recent Developments

Recent developments have been made to solve different process design problems using pinch technology principles and concepts. We shall discuss these developments in brief.

Normally plants have many variables that change during the course of time. For example, depending on market conditions the through put may change or the feed stock can change. Process conditions can change from summer to winter operations. Catalytic reactors lose their effectiveness and heat exchangers get fouled over time. The final process design should be able to handle such changes. Sensitivity analysis and multiple base-case design procedures are developed that address the issue of flexibility.<sup>8,41</sup>

The pressure drop in a heat exchanger network is also important. Polley et al.<sup>42</sup> have developed methods that account for stream pressure drops during the targeting and detail design phase. Stream pressure drop constraints are very important during revamp projects. Pinch technology concepts are also applied to retrofit projects, heat integrate batch processes, minimize waste water, integrate evaporator systems, and design power cycles.<sup>1</sup>

---

## 30.2 Pinch Technology in Practice

The approach typically taken in a pinch study begins with the formation of a team consisting of pinch experts, key plant personnel, and possibly utility representatives. The team then visits the site to gather data pertaining to the processes, as well as economic and

utility information. With data in hand, the pinch experts characterize the heating and cooling requirements of the plant's processing units using pinch technology. They next quantify the scope for potential improvement in each unit and the overall site. Then, the team identifies specific projects based on process change, process heat recovery, etc. that can be implemented to achieve target energy savings. The target energy savings is the summation of savings from practical, cost-effective projects identified to move the energy use at the site as close as possible to the minimum total process heating and cooling energy defined by the pinch analysis.

The Electric Power Research Institute (EPRI) and its utility members in the United States and overseas have sponsored a variety of energy-related projects in the process industries through EPRI's Industrial Technology Application Service. The Industrial Technology Application Service is now owned and operated by Global Energy Partners. Pinch studies have historically been a key element of EPRI's process industries programs, particularly in the Pulp, Paper, and Forest Products program (see Section 30.2.2) and the Chemicals, Pharmaceuticals, Petroleum Refining, and Natural Gas program (see Section 30.2.3). Electric Power Research Institute has also carried out numerous studies for the food and beverage industry and several studies for the textile and fiber industry. In all, EPRI has conducted more than 50 pinch studies in the last 15 years that, on average, have identified energy cost savings of more than 20% with 1–3 year payback periods.

### **30.2.1 Pinch Technology in Pulp and Paper Industries**

Pulping and papermaking are energy-intensive. Rising energy costs have triggered a new awareness of energy usage and have spawned a number of energy efficiency studies across the industry. The U.S. Department of Energy cofunds several programs for improving energy efficiency. Its short-term initiatives include the popular plant-wide energy assessments where energy audits identify cost-reduction opportunities. Longer term, its Agenda 2020 program focuses on developing major technology jumps meant to reduce the energy costs of papermaking and to provide environmental benefits. Energy and environmental issues are intertwined; lower energy use reduces emissions from both the mill and from the power plant that generates the energy.

EPRI and associates have conducted over 30 pinch studies for the pulp, paper, and forest products industry alone. Collectively, the studies have pinpointed potential energy savings of over \$80 million/year, with many projects having a simple payback period of about 1 year. [Table 30.7](#) summarizes results from some of these studies. The table shows the target, actual, and scope energy values, as well as practical energy and cost savings by mill type. Target values represent the minimum energy required to run a process; actual values represent the current, actual energy use; scope values represent the maximum possible heat recovery; and practical values represent what is realistically feasible considering constraints. As the table shows, practical energy savings per mill range from about 50 to 350 million Btu/h (~15–100 MW), and practical cost savings range from about \$1 to \$6 million/year.

[Table 30.8](#) lists the average cost savings per ton of product for several types of mills. Savings range from \$1.3 per bone dry short ton (BDST) (\$1.4/metric ton) for nonintegrated papermaking to \$5.5/BDST (\$6.1/metric ton) for bleached market pulp.

Two specific examples of pinch technology being applied to the pulp, paper, and forest products industry are described in the following case studies.

**TABLE 30.7**

Summary of Results from Pinch Studies in the Pulp, Paper, and Forest Products Industry

Mill Type	Target 10 <sup>6</sup> Btu/h (MW)	Actual 10 <sup>6</sup> Btu/h (MW)	Scope 10 <sup>6</sup> Btu/h (MW)	Practical Savings	
				10 <sup>6</sup> Btu/h (MW)	\$10 <sup>6</sup> /year
Semisulfite/OCC linerboard	297 (87)	417 (122)	120 (35)	45–80 (13–23)	1.4–2.8

**TABLE 30.8**

Practical Steam Cost Savings Identified by Pinch Technology in the Pulp, Paper, and Forest Products Industry

Mill Type	\$/BDST (\$/metric ton)
Bleached kraft/NSSC	2.9 (3.2)
Bleached kraft/TMP and other	5.0 (5.5)
Bleached market pulp	5.5 (6.1)
Nonintegrated papermaking	1.3 (1.4)
Kraft/NSSC/OCC	2.9 (3.2)
Sulfite or semisulfite	4.4 (4.9)

### 30.2.1.1 Case Study 1: Minimizing Process Energy Use in a Large Thermomechanical Pulp (TMP) Mill\*

EPRI and American Process, Inc. conducted an energy targeting scoping study using pinch analysis at a large TMP mill in Canada. A local utility company cofunded the project. The mill produces bleached, unbleached, and semibleached kraft market pulp and standard and offset newsprint. Fiber is prepared in kraft continuous and batch digesters, groundwood, and TMP departments. The kraft digesters separate wood chips into fiber by use of chemicals that act on the wood's binding agent (lignin). In the groundwood process, wood chips are mechanically pressed against a grindstone and, with the addition of water, are separated into fibers. The TMP process uses both heat and mechanical forces to convert wood chips into fibers.

Spent chemicals and lignin, which are referred to as *black liquor*, are recovered from the kraft process in a recovery cycle that includes three evaporators and three recovery boilers, a recausticizing line, and two kilns. First, the black liquor is removed from the pulp in washers; next, it is thickened in the evaporators; then, it is burned in the recovery boilers. During the burning process, the chemicals and lignin are recovered and the steam raised in the boilers is used to support operations. Two lime kilns provide calcium oxide for causticizing. Chlorine dioxide is produced onsite and used in a six-stage bleach plant.

The mill also has power boilers that use oil and hog fuels. The steam from the power boilers is used in steam turbines to generate a portion of the mill's power requirement, as well as to support various operations. The balance of the mill's power is purchased.

The intent of the energy targeting scoping study using pinch analysis was to identify ways for the mill to reduce energy costs as part of a long-term improvement in competitiveness. In particular, operators of the mill wanted to reduce process steam consumption so that they could decrease steam production from the power boilers.

Pinch analysis yielded the hot and cold composite curves shown in [Figure 30.43](#) and the grand composite curve shown in [Figure 30.44](#). The figures show that the pinch interval temperature is 246°F (119°C) and the thermal energy target (minimum thermal energy required to run the extracted process steam) is 1023 million Btu/h (300 MW). Because the existing process thermal consumption is 1,336 million Btu/h (392 MW), the maximum potential process steam savings (scope) is about 313 million Btu/h (~310,000 lb/h, 92 MW, 140,000 kg/h).

To accomplish the objective of reducing steam consumption, two options were developed for the recovery of TMP dirty steam. Option 1 uses TMP steam in the mill's pulp and paper companies, and option 2 restricts the use of TMP steam to the paper company. For option 1, implementation of TMP heat recovery in conjunction with several other recommended projects was found to potentially save 292,400 lb/h (132,600 kg/h) of process steam; for option 2, the potential savings were found to be 232,800 lb/h (105,600 kg/h). These steam savings equate to cost savings of about Can\$9.5 million/year (Canadian dollars per year) for option 1 and Can\$8.7 million/year for option 2 as a result of decreased steam production in the power boilers. The simple payback periods were estimated to be 2.5 years for option 1 and 2.1 years for option 2.

Additionally, a target cogeneration analysis showed that with the existing steam consumption, there was an opportunity to increase onsite power generation by about 21 MW (which equates to a savings of about Can\$6.3 million/year) by correcting

\* Data from EPRI, Minimizing process energy use for a large TMP mill with pinch technology, EPRI, Palo Alto, CA, 2000.

**FIGURE 30.43**

Hot and cold composite curves for thermomechanical pulping (TMP) mill.

**FIGURE 30.44**

Grand composite curve for thermomechanical pulping (TMP) mill.

turbine inefficiency, pressure-reducing valve operation, and incorrect use of steam levels. After implementation of the proposed projects and the resulting new steam consumption, this additional power generation opportunity decreases to about 9.1 MW and Can\$2.7 million/year.

Furthermore, a comparison of the steam cycle with a combined cogeneration cycle showed that a combined cycle would potentially generate 49 MW as opposed to only 8.6 MW in the steam cycle. This generation capacity equates to a monetary savings of Can\$5.3 million/year.

### 30.2.1.2 Case Study 2: Minimizing Process Energy Use in a Newsprint Mill\*

With support from a local utility company, EPRI and American Process, Inc. carried out an energy-targeting scoping study using pinch analysis at a newsprint mill in Mississippi. The mill generates 780 tons/day (707 metric tons/day) of newsprint from a combination of TMP and purchased kraft pulp. Steam is produced in a reboiler using TMP-generated steam and in a bark boiler using mill-generated and purchased hog fuel. To take advantage of off-peak power rates, the mill swings the refiner operation.

Prior to the pinch analysis, the mill had already completed a cost assessment study and established several possible energy savings projects. The objective of the pinch analysis was to augment previous efforts and identify additional possible projects, as well as to prioritize all projects and ensure that the savings were additive.

For the steam duties evaluated, the hot and cold composite curves and the grand composite curve yielded a pinch interval temperature of 244°F (118°C) for the minimum temperature driving force of the  $\Delta t_{\min} = 20^\circ\text{F}$  (11°C), and a thermal energy target (minimum thermal energy required to run the extracted process streams) of 42 million Btu/h (12 MW). Because the existing process thermal consumption of the streams is 96 million Btu/h (28 MW), the scope (or maximum potential to reduce process heat demand) is 54 million Btu/h (16 MW).

The significance of the pinch results is that, ideally:

- No utility steam should be used for heating cold streams below 224°F (107°C).
- No cold water should be used for cooling streams above 264°F (129°C) and no heat should be rejected to the environment above 264°F (129°C).
- No heat exchange should occur between above-the-pinch streams and below-the-pinch streams.

The instances where these rules are violated are referred to as *cross-pinch heat exchanges* or “XPs,” and are the reasons why the actual steam consumption by the mill is larger than the minimum or “target” quantity. These XP heat exchanges need to be corrected for the mill to get closer to its target energy consumption.

The existing configuration was placed on a heat recovery grid to identify where the 54 million Btu/h (16 MW) of XP heat transfer was being used inappropriately. [Table 30.9](#) lists the XP occurrences.

---

\* Data from EPRI, Energy targeting scoping study using pinch analysis: Bowater newsprint, Grenada, MS, EPRI, Palo Alto, CA, 2004.

**TABLE 30.9**

Existing Cross-Pinch Heat Transfer Occurrences in a Newsprint Mill

Stream	Process-Process XP 10 <sup>6</sup> Btu/h (MW)	Stream XP 10 <sup>6</sup> Btu/h (MW)	Waste XP 10 <sup>6</sup> Btu/h (MW)	Total XP 10 <sup>6</sup> Btu/h (MW)
Bark boiler air heating		3.78 (1.11)		
Demin water heating		7.88 (2.31)		
Condensate return heating		2.90 (0.85)		
White water heating		3.70 (1.08)		
Off machine silo heating		5.64 (1.65)		
Warm water heating		1.30 (0.38)		
Paper machine PV air heating		14.12 (4.14)		
Paper machine building air heating		0.86 (0.25)		
Primary and secondary refiners steam			12.20 (3.58)	
Primary and secondary refiners steam condensate	1.36 (0.40)		0.63 (0.18)	
Subtotals	1.36 (0.40)	40.18 (11.78)	12.83 (3.76)	54.37 (15.93)

The team developed a variety of projects for the mill to consider to achieve energy savings. For the energy savings to correspond to realistic monetary savings, the energy savings by steam reduction must lead to a decrease in purchased hog fuel. Some of the projects initially developed would have had good payback periods if the steam were produced with fossil fuel; however, they yielded poor returns based on the cost of marginal steam from hog fuel. Six additional low-cost projects were proposed that would result in steam savings of 9,000 lb/h (4,080 kg/h) in the summer and 29,000 lb/h (13,150 kg/h) in the winter with payback periods of only 5–20 months. An additional project was recommended to temper incoming mill water with effluent during the winter months to reduce the seasonal variation in steam demand, yielding a potential savings of 15,000 lb/h (6,800 kg/h) during the winter. Table 30.10 summarizes the energy costs savings, capital costs, and payback periods

**TABLE 30.10**

Summary of Costs and Benefits of Projects Developed for a Newsprint Mill

No.	Description	Savings (\$/year)	Capital Cost (\$)	Payback (years)
1	Scrubber—condensate storage tank vent	30,000	25,000	0.83
2	Sewer pressate purge after pressate coolers	25,000	10,300	0.41
3	Turpentine condenser—heated water generation	30,000	50,100	1.67
4	Optimize reject refinery vent heat recovery	39,900	55,500	1.39
5	Ejector for vent steam to chip bin	58,400	103,200	1.77
6	Series water flow through pressate coolers	15,000	10,700	0.71
7	Tempering mill water with process effluent	74,800	207,300	2.77
1–7	Totals	273,100	462,100	1.69

**TABLE 30.11**

Representative Results from Pinch Studies in the Chemical and Petroleum Industries

Type of Facility	Study Highlights
Petroleum refinery	\$840,000/year savings at 1.5-year payback, plus capital savings of \$390,000 for planned retrofit
Petroleum refinery	Scope for 32% reduction in net fuel consumption
Petroleum refinery	Revised heat exchanger network in crude distillation unit to reduce costs by \$1 million/year at less than 1.5-year payback
Petroleum refinery	Revised heat exchanger network in hydrocracker to save \$2.7 million/year in steam/fuel costs at 1.6-year payback
Petroleum refinery	Steam cost savings of \$5 million/year with 1–4-year payback
Pharmaceutical company	Increased heat recovery to reduce fuel costs by 13% at less than 1-year payback
Pharmaceutical company	Identified measures to reduce thermal energy requirements by 30%; annual savings of \$70,000/year at 1.3–2.5-year payback
Specialty chemical plant: kelp harvesting and extraction	Steam savings of \$2.8 million/year at 1–2-year payback
Wax extraction plant	Cost savings of \$930,000/year at 2.3-year payback

for all of the recommended projects. If implemented, the potential savings would be about \$273,100/year with a capital cost of \$462,100 and a simple payback period of 1.69 years.

### 30.2.2 Pinch Technology in Chemical and Petroleum Industries

The chemical and petroleum industries offer tremendous opportunities for energy savings from pinch analysis. EPRI and associates have carried out several dozen pinch studies in these industries since 1988. The calculated payback periods for most of the projects have been below 2 years and energy cost savings have typically been over \$1 million. Table 30.11 summarizes a few of the studies conducted. Two more detailed examples are provided in the following case studies.

#### 30.2.2.1 Case Study 1: Minimizing Process Energy Use in a Petroleum Refinery\*

With cofunding from local utility company, EPRI and Aspen Technology, Inc. conducted a sitewide pinch study at an oil refinery in Illinois. The objective of the study was to recommend ways to improve the refinery processes and utility system to achieve plant-wide energy savings. The project was conducted in two phases. The first phase consisted of a targeting and scoping study of the overall site. The second phase involved revising the basic design of selected process units. The following processing units were included in the study:

- Atmospheric crude and vacuum distillation unit (VDU)
- Two delayed coker units
- Reformer and naphtha hydrotreater
- CCR reformer and naphtha hydrotreater
- Isom and LSR hydrotreater

\* Data from EPRI, Pinch technology/process optimization: Volume 9: Case study, EPRI, Palo Alto, CA, 1997.

**TABLE 30.12**

Sitewide Energy Targets for a Petroleum Refinery

Unit	Rating	Total Hot Existing	Total Hot Target	Hot Delta	Total Cold Existing	Total Cold Target	Cold Delta	Sum Delta

- HF alkylation
- FCCU and light ends recovery
- Diesel hydrotreater
- MTBE
- Two saturated gas plants
- Two sulfur recovery trains and tail gas units
- Hydrocracker
- Utility system

During the first phase, the team performed an overall site analysis that included energy targeting, utility placement, and total site targeting. Table 30.12 summarizes the results of the study for each of the individual processes and for the total site. The table compares the total existing hot and cold utility usage for each of the processes to the total hot and cold utility targets. The final rows repeat this comparison for the total site.

The estimated existing process hot utility usage for the refinery is 1000 energy units and the energy target for the complete refinery is 856 energy units. Therefore, the scope for energy reduction is 144 energy units, or 14.4%.

The table indicates that of the 18 units included in the study, there are eight that are key to the overall refinery efficiency improvement, three others have an impact but are less important, and the remaining seven need not be considered further. The key units are the crude/vacuum unit, FCC, Isom, CCR reformer, two cokers, reformer, and hydrocracker. The eight key units account for 73% of the existing hot utility usages, or 730 energy units,

and 71% of the energy target, or 606 energy units. Therefore, concentrating on the eight key units reduces the scope for energy reduction to 124 energy units, or 12% of the site.

Phase 2 of the project involved using pinch analysis to study the key units in detail. Six of the eight key units were chosen:

1. Coker A
2. Coker B
3. Crude/vacuum unit
4. CCR reformer
5. Hydrocracker
6. Reformer

For reasons mainly associated with future investment plans and plant turnaround schedules, the FCC and Isom were not studied further.

Phase 2 analysis resulted in the identification of several projects with energy cost savings ranging from \$200,000/year to \$1,410,000/year and simple payback periods of as low as 0.5 years up through 16 years. The projects with the biggest energy savings were associated with the longest payback periods; however, these projects also offer significant, cost-effective debottlenecking potential for the units. Implementation of all mutually exclusive projects would result in energy savings of about \$4.6 million/year.

A plant-side steam balance was also conducted. The results from the steam balance showed an overall energy savings potential in the steam system of about \$5 million/year with a payback of 1–4 years. However, it is important to note that projects identified within the units and within the steam system sometimes compete. Therefore, energy cost savings for the projects and steam system are not directly additive.

#### **30.2.2.2 Case Study 2: Minimizing Process Energy Use in a Wax Extraction Plant\***

Together with support from a local utility company, EPRI and Linnhoff March, Inc. conducted a comprehensive energy study using pinch analysis at a wax extraction plant in Pennsylvania. The plant produces high-grade waxes for use in a variety of commercial and consumer markets. The objective of the study was to identify ways for the plant to reduce processing costs per barrel of throughput. The plant's first priority was to implement quick payback projects such as insulation of storage tanks. The plant was also interested in increasing manufacturing flexibility and achieving compliance with a nitrogen oxide ( $\text{NO}_x$ ) abatement order at a minimum cost.

The waxes produced at the plant are petroleum based. Waxy crudes and distillates are first fractionated in a VDU to separate the oil into several distinct cuts. The VDU bottoms stream is treated with propane in the propane deasphalting (PDA) unit to separate out the asphaltenes (or heavy resin fraction), and the main oil fraction is recovered for further processing. The side cuts from VDU and recovered oil from PDA are then subjected to solvent extraction using methyl ethyl ketone (MEK) to separate wax from oil. The waxes are purified by bauxite filtration. The residual oils are sold as by-products to lube oil processors and heating oil dealers, and asphalt is used onsite as fuel.

The project team was charged with improving operating economics, debottlenecking processing capacity, evaluating the feasibility of hydrotreating vs. bauxite filtration for the wax

---

\* Data from EPRI, Pinch technology/process optimization: Volume 7: Case study—A wax extraction plant, EPRI, Palo Alto, CA, 1995.

**TABLE 30.13**

Economics of Developed Projects for a Wax Extraction Plant

Project	Savings (\$/year)	Capital Cost (\$)	Payback (years)
VDU retrofit	300,000	300,000	1.0
MEK retrofit	350,000	1,500,000	4.2
Tank insulation	280,000	300,000	1.0
Total	930,000	2,100,000	2.3

finishing operation, and determining the optimum combined heat and power strategy for the site, paying particular heed to compliance with rather stringent NO<sub>x</sub> abatement requirements.

The results of the study yielded a comprehensive process improvement strategy that improved wax yield by 8%, debottlenecked refrigeration capacity by 10%, and reduced total steam demand by 22%. The steam savings would allow shut down of two of the plant's four boilers, automatically reducing NO<sub>x</sub> emissions, enabling compliance with the NO<sub>x</sub> abatement order without installing expensive end-of-pipe controls. Implementation of suggested retrofits in the VDU and MEK process areas along with tank insulation would potentially yield operating savings of \$930,000 million/year with a cost of \$2.1 million and a simple payback period of 2.3 years. Evaluations related to cogeneration and to replacing the existing bauxite process with a hydrotreater showed that the economics did not favor either measure. Table 30.13 summarizes the economics of the proposed retrofits. Note that although the stand-alone economics of the MEK revamp are not particularly attractive (i.e., the payback period is 4.2 years), this project is essential to enable shutdown of two of the boilers, thereby achieving a relatively low-cost NO<sub>x</sub> reduction.

### **31.1 Introduction**

Since the oil embargo of 1973, significant improvements have been made in the energy efficiency of new buildings. However, the vast majority of the existing building stock is more than 20 years old and does not meet current energy efficiency construction standards (EIA, 2008). Therefore, energy retrofits of existing buildings will be required for decades to come if the overall energy efficiency of the building stock is to meet the standards.

Investing to improve the energy efficiency of buildings provides an immediate and relatively predictable positive cash flow resulting from lower energy bills. In addition to the conventional financing options available to owners and building operators (such as loans and leases), other methods are available to finance energy retrofit projects for buildings. One of these methods is performance contracting in which payment for a retrofit project is contingent upon its successful outcome. Typically, an energy services company (ESCO) assumes all the risks for a retrofit project by performing the engineering analysis and obtaining the initial capital to purchase and install equipment needed for energy efficiency improvements. Energy auditing is an important step used by energy service companies to insure the success of their performance contracting projects.

Moreover, several large industrial and commercial buildings have established internal energy management programs based on energy audits to reduce waste in energy use or to comply with the specifications of some regulations and standards. Other building owners and operators take advantage of available financial incentives typically offered by utilities or state agencies to perform energy audits and implement energy conservation measures (ECMs).

In the 1970s, building energy retrofits consisted of simple measures such as shutting off lights, turning down heating temperatures, turning up air-conditioning temperatures, and reducing the hot water temperatures. Today, building energy management includes a comprehensive evaluation of almost all the energy systems within a facility. Therefore, the energy auditor should be aware of key energy issues such as the subtleties of electrical utility rate structures and of the latest building energy efficiency technologies and their applications.

This chapter describes a general but systematic procedure for energy auditing suitable for both commercial buildings and industrial facilities. Some of the commonly recommended ECMs are briefly discussed. A case study for an office building is presented to illustrate the various tasks involved in an energy audit. Finally, an overview is provided to outline the existing methods for measurement and verification of energy savings incurred by the implementation of ECMs.

---

## 31.2 Types of Energy Audits

The term *energy audit* is widely used and may have different meanings depending on the energy service companies. Energy auditing of buildings can range from a short walk-through of the facility to a detailed analysis with hourly computer simulation. Generally, four types of energy audits can be distinguished as briefly described in the following (Krarti, 2010).

### 31.2.1 Walk-Through Audit

This audit consists of a short on-site visit of the facility to identify areas where simple and inexpensive actions can provide immediate energy use and/or operating cost savings. Some engineers refer to these types of actions as operating and maintenance (O&M) measures. Examples of O&M measures include setting back heating set point temperatures, replacing broken windows, insulating exposed hot water or steam pipes, and adjusting boiler fuel–air ratio.

### **31.2.2 Utility Cost Analysis**

The main purpose of this type of audit is to carefully analyze the operating costs of the facility. Typically, the utility data over several years are evaluated to identify the patterns of energy use, peak demand, weather effects, and potential for energy savings. To perform this analysis, it is recommended that the energy auditor conducts a walk-through survey to get acquainted with the facility and its energy systems.

It is important that the energy auditor understands clearly the utility rate structure that applies to the facility for several reasons:

- To check the utility charges and insure that no mistakes were made in calculating the monthly bills. Indeed, the utility rate structures for commercial and industrial facilities can be quite complex with ratchet charges and power factor penalties.
- To determine the most dominant charges in the utility bills. For instance, peak demand charges can be significant portion of the utility bill especially when ratchet rates are applied. Peak shaving measures can be then recommended to reduce these demand charges.
- To identify whether or not the facility can benefit from using other utility rate structures to purchase cheaper fuel and reduce its operating costs. This analysis can provide a significant reduction in the utility bills especially with implementation of the electrical deregulation and the advent of real-time pricing rate structures.

Moreover, the energy auditor can determine whether or not the facility is prime for energy retrofit projects by analyzing the utility data. Indeed, the energy use of the facility can be normalized and compared to indices (for instance, the energy use per unit of floor area—for commercial buildings—or per unit of a product, for industrial facilities).

### **31.2.3 Standard Energy Audit**

The standard audit provides a comprehensive energy analysis for the energy systems of the facility. In addition to the activities described for the walk-through audit and for the utility cost analysis described earlier, the standard energy audit includes the development of a baseline for the energy use of the facility and the evaluation of the energy savings and the cost-effectiveness of appropriately selected ECMs. The step-by-step approach of the standard energy audit is similar to that of the detailed energy audit that is described later on in the following section.

Typically, simplified tools are used in the standard energy audit to develop baseline energy models and to predict the energy savings of ECMs. Among these tools are the degree-day methods and linear regression models (Fels, 1986). In addition, a simple pay-back analysis is generally performed to determine the cost-effectiveness of ECMs.

### **31.2.4 Detailed Energy Audit**

This audit is the most comprehensive but also time-consuming energy audit type. Specifically, the detailed energy audit includes the use of instruments to measure energy use for the whole building and/or for some energy systems within the building (for instance, by end uses, lighting systems, office equipment, fans, and chillers). In addition, sophisticated computer simulation programs are typically considered for detailed energy audits to evaluate and recommend energy retrofits for the facility.

The techniques available to perform measurements for an energy audit are diverse. During on-site visit, handheld and clamp-on instruments can be used to determine the variation of

some building parameters such as the indoor air temperature, the luminance level, and the electrical energy use. When long-term measurements are needed, sensors are typically used and connected to a data-acquisition system so measured data can be stored and be remotely accessible. Recently, nonintrusive load monitoring (NILM) techniques have been proposed (Shaw et al., 1998). The NILM technique can determine the real-time energy use of the significant electrical loads in a facility using only a single set of sensors at the facility service entrance. The minimal effort associated with using the NILM technique when compared to the traditional submetering approach (which requires separate set of sensors to monitor energy consumption for each end use) makes the NILM a very attractive and inexpensive load monitoring technique for energy service companies and facility owners.

The computer simulation programs used in the detailed energy audit can provide typically the energy use distribution by load type (i.e., energy use for lighting, fans, chillers, and boilers). They are often based on dynamic thermal performance of the building energy systems and require typically high level of engineering expertise and training. These simulation programs range from those based on the bin method (Knebel, 1983) to those that provide hourly building thermal and electrical loads such as DOE-2 (LBL, 1980). The reader is referred to Krarti (2010) for more detailed discussion of the energy analysis tools that can be used to estimate energy and cost savings attributed to ECMs.

In the detailed energy audit, more rigorous economical evaluation of the ECMs is generally performed. Specifically, the cost-effectiveness of energy retrofits may be determined based on the life-cycle cost (LCC) analysis rather than the simple payback period analysis. LCC analysis takes into account a number of economic parameters such as interest, inflation, and tax rates. Krarti (2010) describes some of the basic analysis tools that are often used to evaluate energy efficiency projects.

---

### 31.3 General Procedure for a Detailed Energy Audit

To perform an energy audit, several tasks are typically carried out depending on the type of the audit and the size and function of the audited building. Some of the tasks may have to be repeated, reduced in scope, or even eliminated based on the findings of other tasks. Therefore, the execution of an energy audit is often not a linear process and is rather iterative. However, a general procedure can be outlined for most buildings.

#### 31.3.1 Step 1: Building and Utility Data Analysis

The main purpose of this step is to evaluate the characteristics of the energy systems and the patterns of energy use for the building. The building characteristics can be collected from the architectural/mechanical/electrical drawings and/or from discussions with building operators. The energy use patterns can be obtained from a compilation of utility bills over several years. Analysis of the historical variation of the utility bills allows the energy auditor to determine if there are any seasonal and weather effects on the building energy use. Some of the tasks that can be performed in this step are presented here with the key results expected from each task and are noted:

- Collect at least 3 years of utility data (*to identify a historical energy use pattern*).
- Identify the fuel types used (electricity, natural gas, oil, etc.) (*to determine the fuel type that accounts for the largest energy use*).

- Determine the patterns of fuel use by fuel type (*to identify the peak demand for energy use by fuel type*).
- Understand utility rate structure (energy and demand rates) (*to evaluate if the building is penalized for peak demand and if cheaper fuel can be purchased*).
- Analyze the effect of weather on fuel consumption (*to pinpoint any variations of energy use related to extreme weather conditions*).
- Perform utility energy use analysis by building type and size (building signature can be determined including energy use per unit area) (*to compare against typical indices*).

### 31.3.2 Step 2: Walk-Through Survey

From this step, potential energy savings measures should be identified. The results of this step are important since they determine if the building warrants any further energy auditing work. The following are some of the tasks involved in this step:

- Identify the customer concerns and needs.
- Check the current O&M procedures.
- Determine the existing operating conditions of major energy use equipment (lighting, HVAC systems, motors, etc.).
- Estimate the occupancy, equipment, and lighting (energy use density and hours of operation).

### 31.3.3 Step 3: Baseline for Building Energy Use

The main purpose of this step is to develop a base-case model that represents the existing energy use and operating conditions for the building. This model is to be used as a reference to estimate the energy savings incurred from appropriately selected ECMs. There are major tasks to be performed during this step:

- Obtain and review architectural, mechanical, electrical, and control drawings.
- Inspect, test, and evaluate building equipment for efficiency, performance, and reliability.
- Obtain all occupancy and operating schedules for equipment (including lighting and HVAC systems).
- Develop a baseline model for building energy use.
- Calibrate the baseline model using the utility data and/or metered data.

### 31.3.4 Step 4: Evaluation of Energy Savings Measures

In this step, a list of cost-effective ECMs is determined using both energy savings and economical analysis. To achieve this goal, the following tasks are recommended:

- Prepare a comprehensive list of ECMs (using the information collected in the walk-through survey).

- Determine the energy savings due to the various ECMs pertinent to the building using the baseline energy use simulation model developed in phase 3.
- Estimate the initial costs required to implement the ECMs.
- Evaluate the cost-effectiveness of each ECM using an economical analysis method (simple payback or LCC analysis).

Tables 31.1 and 31.2 provide summaries of the energy audit procedure recommended, respectively, for commercial buildings and for industrial facilities. Energy audits for thermal and electrical systems are separated since they are typically subject to different utility rates.

### 31.4 Common Energy Conservation Measures

In this section, some ECMs commonly recommended for commercial and industrial facilities are briefly discussed. It should be noted that the list of ECMs presented in this section does not pretend to be exhaustive nor comprehensive. It is provided merely to indicate some of the options that the energy auditor can consider when performing an energy analysis of a commercial or an industrial facility. More discussion of energy efficiency measures for various building energy systems is provided in later chapters of this book. However, it is strongly advised that the energy auditor keeps abreast of any new technologies that can improve the building energy efficiency. Moreover, the energy auditor should recommend the ECMs only based on a sound economical analysis for each ECM.

### 31.4.1 Building Envelope

For some buildings, the envelope (i.e., walls, roofs, floors, windows, and doors) can have an important impact on the energy used to condition the facility. The energy auditor should determine the actual characteristics of the building envelope. During the survey, a descriptive sheet for the building envelope should be established to include information such as materials of construction (for instance, the level of insulation in walls, floors, and roofs) and the area and the number of building envelope assemblies (for instance, the type and the number of panes for the windows). In addition, comments on the repair needs and recent replacement should be noted during the survey.

The following are some of the commonly recommended ECMs to improve the thermal performance of building envelope:

- (a) *Addition of thermal insulation:* For building surfaces without any thermal insulation, this measure can be cost-effective.
- (b) *Replacement of windows:* When windows represent a significant portion of the exposed building surfaces, using more energy-efficient windows (high *R*-value, low-emissivity glazing, air tight, etc.) can be beneficial in both reducing the energy use and improving the indoor comfort level.
- (c) *Reduction of air leakage:* When infiltration load is significant, leakage area of the building envelope can be reduced by simple and inexpensive weather-stripping techniques.

The energy audit of the envelope is especially important for residential buildings. Indeed, the energy use from residential buildings is dominated by weather since heat gain and/or loss from direct conduction of heat or from air infiltration/exfiltration through building surfaces accounts for a major portion (50%–80%) of the energy consumption. For commercial buildings, improvements to building envelope are often not cost-effective due to the fact that modifications to the building envelope (replacing windows, adding thermal insulation in walls) are typically considerably expensive. However, it is recommended to systematically audit the envelope components not only to determine the potential for energy savings but also to insure the integrity of its overall condition. For instance, thermal bridges—if present—can lead to heat transfer increase and to moisture condensation. The moisture condensation is often more damaging and costly than the increase in heat transfer since it can affect the structural integrity of the building envelope.

### 31.4.2 Electrical Systems

For most commercial buildings and a large number of industrial facilities, the electrical energy cost constitutes the dominant part of the utility bill. Lighting, office equipment, and motors are the electrical systems that consume the major part of energy in commercial and industrial buildings.

- (a) *Lighting:* Lighting for a typical office building represents on average 40% of the total electrical energy use. There are a variety of simple and inexpensive measures to improve the efficiency of lighting systems. These measures include the use of energy-efficient lighting lamps and ballasts, the addition of reflective devices, delamping (when the luminance levels are above the recommended levels by

40	88.5	93.6
50	89.5	94.1

the standards), and the use of daylighting controls. Most lighting measures are especially cost-effective for office buildings for which payback periods are less than 1 year.

- (b) *Office equipment*: Office equipment constitutes the fastest-growing part of the electrical loads especially in commercial buildings. Office equipment includes computers, fax machines, printers, and copiers. Today, there are several manufacturers that provide energy-efficient office equipment (such those that comply with the U.S. EPA Energy Star specifications). For instance, energy-efficient computers automatically switch to a low-power *sleep* mode or off mode when not in use.
- (c) *Motors*: The energy cost to operate electric motors can be a significant part of the operating budget of any commercial and industrial building. Measures to reduce the energy cost of using motors include reducing operating time (turning off unnecessary equipment), optimizing motor systems, using controls to match motor output with demand, using variable speed drives for air and water distribution, and installing energy-efficient motors. Table 31.3 provides typical efficiencies for several motor sizes.

In addition to the reduction in the total facility electrical energy use, retrofits of the electrical systems decrease space cooling loads and therefore further reduce the electrical energy use in the building. These cooling energy reductions as well as possible increases in thermal energy use (for space heating) should be accounted for when evaluating the cost-effectiveness of improvements in lighting and office equipment.

### 31.4.3 Daylighting Controls

Several studies indicated that daylighting can offer a cost-effective alternative to electrical lighting for commercial and institutional buildings. Through sensors and controllers, daylighting can reduce and even eliminate the use of electrical lighting required to provide sufficient illuminance levels inside office spaces. Recently, a simplified calculation method has been developed by Krarti et al. (2005) to estimate the reduction in the total lighting energy use due to daylighting with dimming controls for office buildings. The method

has been shown to apply for office buildings in the United States as well as in Egypt (El Mohimem et al., 2005). The simplified calculation method is easy to use and can be used as a predesign tool to assess the potential of daylighting in saving electricity use associated with artificial lighting for office buildings.

To determine the percent savings,  $f_d$ , in annual use of artificial lighting due to implementing daylighting using daylighting controls in office buildings, Krarti et al. (2005) found that the following equation can be used:

$$f_d = b[1 - \exp(-a\tau_w A_w / A_p)] \frac{A_p}{A_f} \quad (31.1)$$

where

$A_w/A_p$  is the window to perimeter floor area. This parameter provides a good indicator of the window size relative to the daylit floor area

$A_p/A_f$  is the perimeter to total floor area. This parameter indicates the extent of the daylit area relative to the total building floor area. Thus, when  $A_p/A_f = 1$ , the whole building can benefit from daylighting

$a$  and  $b$  are the coefficients that depend only on the building location and are given by Table 31.4 for various sites throughout the world

$\tau_w$  is the visible transmittance of the glazing

**TABLE 31.4**

#### 31.4.4 HVAC Systems

The energy use due to HVAC systems can represent 40% of the total energy consumed by a typical commercial building. The energy auditor should obtain the characteristics of major HVAC equipment to determine the condition of the equipment, their operating schedule, their quality of maintenance, and their control procedures. A large number of measures can be considered to improve the energy performance of both primary and secondary HVAC systems. Some of these measures are listed:

- (a) *Setting up/back thermostat temperatures:* When appropriate, setting back heating temperatures can be recommended during unoccupied periods. Similarly, setting up cooling temperatures can be considered.
- (b) *Retrofit of constant air volume systems:* For commercial buildings, variable air volume (VAV) systems should be considered when the existing HVAC systems rely on constant volume fans to condition part or the entire building.
- (c) *Installation of heat recovery systems:* Heat can be recovered from some HVAC equipment. For instance, heat exchangers can be installed to recover heat from air handling unit (AHU) exhaust air streams and from boiler stacks.
- (d) *Retrofit of central heating plants:* The efficiency of a boiler can be drastically improved by adjusting the fuel–air ratio for proper combustion. In addition, installation of new energy-efficient boilers can be economically justified when old boilers are to be replaced.
- (e) *Retrofit of central cooling plants:* Currently, there are several chillers that are energy efficient and easy to control and operate and are suitable for retrofit projects.

It should be noted that there is a strong interaction between various components of heating and cooling system. Therefore, a whole-system analysis approach should be followed when retrofitting a building HVAC system. Optimizing the energy use of a central cooling plant (which may include chillers, pumps, and cooling towers) is one example of using a whole-system approach to reduce the energy use for heating and cooling buildings.

#### 31.4.5 Compressed Air Systems

Compressed air has become an indispensable tool for most manufacturing facilities. Its uses range from air-powered hand tools and actuators to sophisticated pneumatic robotics. Unfortunately, staggering amounts of compressed air are currently wasted in a large number of facilities. It is estimated that only a fraction of 20%–25% of input electrical energy is delivered as useful compressed air energy. Leaks are reported to account for 10%–50% of the waste, while misapplication accounts for 5%–40% of loss in compressed air (Howe and Scales, 1998).

To improve the efficiency of compressed air systems, the auditor can consider several issues including whether or not compressed air is the right tool for the job (for instance, electric motors are more energy efficient than air-driven rotary devices), how compressed air is applied (for instance, lower pressures can be used to supply pneumatic tools), how it is delivered and controlled (for instance, the compressed air needs to be turned off when the process is not running), and how compressed air system is managed (for each machine or process, the cost of compressed air needs to be known to identify energy and cost savings opportunities).

### 31.4.6 Energy Management Controls

With the constant decrease in the cost of computer technology, automated control of a wide range of energy systems within commercial and industrial buildings is becoming increasingly popular and cost-effective. An energy management and control system (EMCS) can be designed to control and reduce the building energy consumption within a facility by continuously monitoring the energy use of various equipment and making appropriate adjustments. For instance, an EMCS can automatically monitor and adjust indoor ambient temperatures, set fan speeds, open and close AHU dampers, and control lighting systems.

If an EMCS is already installed in the building, it is important to recommend a system tune-up to insure that the controls are properly operating. For instance, the sensors should be calibrated regularly in accordance with manufacturers' specifications. Poorly calibrated sensors may cause increase in heating and cooling loads and may reduce occupant comfort.

### 31.4.7 Indoor Water Management

Water and energy savings can be achieved in buildings by using water-savings fixtures instead of the conventional fixtures for toilets, faucets, showerheads, dishwashers, and clothes washers. Savings can also be achieved by eliminating leaks in pipes and fixtures.

Table 31.5 provides typical water use of conventional and water-efficient fixtures for various end uses. In addition, Table 31.5 indicates the hot water use by each fixture as a fraction of the total water. With water-efficient fixtures, savings of 50% of water use can be achieved for toilets, showers, and faucets.

### 31.4.8 Advanced Technologies

The energy auditor may consider the potential of implementing and integrating new technologies within the facility. It is therefore important that the energy auditor understands these new technologies and knows how to apply them. The following are among the new technologies that can be considered for commercial and industrial buildings:

- (a) *Building envelope technologies:* Recently, several materials and systems have been proposed to improve the energy efficiency of building envelope and especially windows including
  - Spectrally selective glasses that can optimize solar gains and shading effects

**TABLE 31.5**

Usage Characteristics of Water-Using Fixtures

End Use	Conventional Fixtures	Water-Efficient Fixtures	Usage Pattern	Hot Water (%)
Toilets	3.5 gal/flush	1.6 gal/flush	4 flushes/day	0
Showers	5.0 gal/min	2.5 gal/min	5 min/shower	60
Faucets	4.0 gal/min	2.0 gal/min	2.5 min/day	50
Dishwashers	14.0 gal/load	8.5 gal/load	0.17 loads/day	100
Clothes washers	55.0 gal/load	42.0 gal/load	0.3 loads/day	25
Leaks	10% of total use	2% of total use	N/A	50

- Chromogenic glazings that change its properties automatically depending on temperature and/or light level conditions (similar to sunglasses that become dark in sunlight)
  - Building integrated photovoltaic (PV) panels that can generate electricity while absorbing solar radiation and reducing heat gain through building envelope (typically roofs)
- (b) *Light pipe technologies*: While the use of daylighting is straightforward for perimeter zones that are near windows, it is not usually feasible for interior spaces, particularly those without any skylights. Recent but still emerging technologies allow to *pipe* light from roof or wall-mounted collectors to interior spaces that are not close to windows or skylights.
- (c) *HVAC systems and controls*: Several strategies can be considered for energy retrofits:
- Heat recovery technologies such as rotary heat wheels and heat pipes can recover 50%–80% of the energy used to heat or cool ventilation air supplied to the building.
  - Desiccant-based cooling systems are now available and can be used in buildings with large dehumidification loads during long periods (such as hospitals, swimming pools, and supermarket fresh produce areas).
  - Geothermal heat pumps can provide an opportunity to take advantage of the heat stored underground to condition building spaces.
  - Thermal energy storage (TES) systems offer a mean of using less expensive off-peak power to produce cooling or heating to condition the building during on-peak periods. Several optimal control strategies have been developed in recent years to maximize the cost savings of using TES systems.
- (d) *Cogeneration*: This is not really a new technology. However, recent improvements in its combined thermal and electrical efficiency made cogeneration cost-effective in several applications including institutional buildings such as hospitals and universities.

---

### 31.5 Net-Zero Energy Retrofits

While the concept of the zero net energy (ZNE) buildings has been mostly applied to new construction, it can be considered for retrofit projects including residential buildings. Typically, ZNE is defined in terms of either site energy or resource energy. Site energy consists of energy produced and consumed at the building site. Source or primary energy includes site energy as well as the energy used to generate, transmit, and distribute this site energy. Therefore, source energy provides a better indicator of the energy use of buildings and their impact on the environment and the society and thus is better suited for ZNE building analysis. An analysis based on source energy effectively allows different fuel types, such as electricity and natural gas commonly used in buildings, to be encompassed together.

It is generally understood that ZNE buildings produce as much energy as they consume on-site annually. These buildings typically include aggressive energy efficiency measures and active solar water heating systems. Moreover, ZNE buildings employ grid-tied,

net-metered renewable energy generation technologies, generally PV systems, to produce electricity. Effectively, ZNE buildings use the grid as *battery storage* to reduce required generation system capacity.

Unlike the case for new construction, analysis methods and case studies of net zero energy (NZE) retrofits of existing buildings are limited. A more detailed description of NZE retrofitting approaches, analysis techniques, and some case studies is provided by Krarti (2012). In this section, a case study for NZE retrofitting of existing homes in Mexico is provided. Specifically and in a study by Griego et al. (2012), NZE retrofits of Mexican residential building have been carried out. In the study, various combinations of energy efficiency are applied to arrive at an optimum set of recommendations for existing residential and new construction residential buildings. The optimum point is the minimum annualized energy-related costs and the corresponding annual source energy savings. Two separate optimizations are performed for an existing-unconditioned home and an existing-conditioned home.

The baseline annualized energy-related costs for the conditioned and unconditioned homes are US\$797 and US\$557, respectively. These costs are obtained before any of the energy efficiency and thermal comfort measures are applied. Therefore, it is determined that the cost of improved thermal comfort for a typical home in Salamanca is roughly US\$240/year. The optimum point for the unconditioned case occurs at 17.3% annual energy savings and a corresponding minimum cost of US\$433 as shown in Figure 31.1. The conditioned case on the other hand has a greater opportunity for energy savings and achieves a minimum cost of US\$542 at 35.0% energy savings as indicated in Figure 31.2. The optimum point for the conditioned case includes implementing methods to reduce miscellaneous plug loads,  $R-1.4 \text{ m}^2 \cdot \text{K/W}$  roof assembly, low-flow showerheads and sinks, an electric stove, 100% compact fluorescent lamps, and  $R-0.35 \text{ m}^2 \cdot \text{K/W}$  trunk-branch domestic hot water (DHW) pipe distribution. The optimum point for the unconditioned case includes all of the same measures as the conditioned model with the exception of the added roof insulation.

The comparison between the unconditioned and the conditioned optimization results outlined in Figure 31.3 reveals that the optimum point for the conditioned case (US\$542) is roughly the cost neutral point for the unconditioned case (US\$557). It is also useful to compare energy end uses to gauge measures with highest potential of the energy savings. Figures 31.4 and 31.5 include a summary of the total annual source energy consumption by

**FIGURE 31.1**

Retrofit optimization path for an unconditioned home in Salamanca, Mexico.

**FIGURE 31.2**  
Retrofit optimization path for an air-conditioned home in Salamanca, Mexico.

**FIGURE 31.3**  
Comparison of retrofit optimization paths for unconditioned and conditioned homes.

**FIGURE 31.4**  
Annual end-use source energy for NZE retrofitting of an unconditioned home in Salamanca, Mexico.

**FIGURE 31.5**

Annual end-use source energy for NZE retrofitting of an air-conditioned home in Salamanca, Mexico.

end use for the unconditioned and conditioned home models, respectively. The minimum cost option and the PV start options are compared with the baseline model. In the unconditioned case, the largest energy savings are obtained for the hot water, miscellaneous equipment, and lighting. The conditioned case has similar energy savings as the unconditioned case for miscellaneous equipment and domestic hot water; however, the greatest area for energy savings is for cooling, which is primarily attributed to the use of roof insulation.

The two renewable energy technologies evaluated in this study are solar domestic hot water systems and PV systems. Although solar DHW has a large potential for energy savings, the high implementation cost makes it unfeasible. Figures 31.1 and 31.2 show points hovering significantly above the optimization curve; those points are associated to combinations of measures that include solar domestic hot water systems. Note that the cost for labor and materials is assumed to be comparable to those in the United States.

The results for the PV system are shown by the sloped line leading to 100% energy savings. The size of PV to arrive at a ZNE solution for the unconditioned home model is a 3 kW system, and the conditioned home model is a 4 kW system. Both systems are south facing and installed in inclined panels to match the latitude in Salamanca. The slope of the line toward ZNE is relatively shallow where the annualized energy cost for 100% annual energy savings is US\$920 for the unconditioned and US\$1185 for the conditioned cases. Similar to the solar DHW system, U.S. costs are assumed for PV material and labor cost. PV technology may only be desirable with the appropriate subsidies for implementation costs.

The Predicted Mean Vote (PMV) thermal comfort analysis is used as verification for the optimization results by evaluating the improved indoor thermal comfort after implementing the recommended energy efficiency measures. First, the PMV ratings above and below the acceptable comfort range (i.e., PMV values between  $-1$  and  $1$ ) are determined, the baseline and optimal cases for both conditioned and unconditioned building models. The unconditioned building model shows roughly 1550 h above 1 PMV and 150 h below 1 PMV annually. This is in contrast to the conditioned building models, where thermal comfort is maintained throughout the year, as expected.

**FIGURE 31.6**

Comparison of various existing home configurations with and without NZE retrofits including thermal comfort analysis.

The thermal comfort analysis is also applied at the optimum building models. The annual energy consumption in the conditioned new construction and existing building models decreases relative to the baseline when thermal insulation is added to the building and, as predicted, the annual PMV ratings remain relatively constant. However, when the optimum set of ECMs from the conditioned case are applied to the unconditioned baseline home model, the number of hours outside of the thermal comfort zone decreases significantly as indicated in Figure 31.6.

In the conditioned baseline retrofit case, the cost of installing an electric heat pump is estimated at US\$4394 for a 3.5 tons unit. However, when roof insulation is added to the unconditioned retrofit building, the number of hours outside of the thermal comfort zone decreases by almost 60% for a much lower initial cost of roughly US\$426.

### 31.6 Verification Methods of Energy Savings

Energy conservation retrofits are deemed cost-effective based on predictions of energy and cost savings. However, several studies have found that large discrepancies exist between actual and predicted energy savings. Due to the significant increase in the activities of ESCOs, the need became evident for standardized methods for measurement and verification of energy savings. This interest has led to the development of the *North American Energy Measurement and Verification Protocol* published in 1996 and later expanded and revised under the *International Performance Measurement and Verification Protocol* (IPMVP, 1997, 2002, 2007).

**FIGURE 31.7**

Daily variation of a building energy consumption showing preretrofit, construction, and postretrofit periods.

In order to estimate the energy savings incurred by an energy project, it is important to first identify the implementation period of the project, that is, the construction phase where the facility is subject to operational or physical changes due to the retrofit (Guiterman and Krarti, 2011). Figure 31.7 illustrates an example of the variation of the electrical energy use in a facility that has been retrofitted from constant volume to a VAV HVAC system. The time-series plot of the facility energy use clearly indicated the duration of the construction period, the end of the preretrofit period, and the start of the postretrofit period. The duration of the construction period depends on the nature of the retrofit project and can range from few hours to several months.

In principle, the measurement of the retrofit energy savings can be obtained by simply comparing the energy use during pre- and postretrofit periods. Unfortunately, the change in energy use between the pre- and postretrofit periods is not only due to the retrofit itself but also to other factors such as changes in weather conditions, levels of occupancy, and HVAC operating procedures. It is important to account for all these changes to determine accurately the retrofit energy savings.

Several methods have been proposed to measure and verify energy savings of implemented ECMs in commercial and industrial buildings. Some of these techniques are briefly described:

*Regression models:* The early regression models used to measure savings adapted the variable-base degree-day method. Among these early regression models, the Princeton Scorekeeping Method is the method that uses measured monthly energy consumption data and daily average temperatures to calibrate a linear regression model and determine the best values for non-weather-dependent consumption, the temperature at which the energy consumption began to increase due to heating or cooling (the change-point or base temperature), and the rate at which the energy consumption increased. Several studies have indicated that the simple linear regression model is suitable for estimating energy savings for residential buildings. However, subsequent work has shown that the PRISM model does not provide accurate estimates for energy savings for most commercial buildings (Ruch and Claridge, 1992). Single-variable (temperature) regression models require the use of at least four-parameter segmented-linear or change-point regressions to be suitable for commercial buildings. [Figure 31.8](#) illustrates the basic functional forms commonly used for ambient-temperature linear

**FIGURE 31.8**

Basic forms of single-variable regression models using (a) 2 parameters (2P), (b) 3 parameters (3P), (c) 4 parameters (4P), and (d) 5 parameters (5P).

regression models. There are regression models that are also called change-point or segmented-linear models. [Table 31.6](#) summarizes the mathematical expressions of four change-point models and their applications. In general, the change-point regression models are more suitable for predicting heating rather than cooling energy use. Indeed, these regression models assume steady-state conditions and are insensitive to the building dynamic effects, solar effects, and nonlinear HVAC system controls such as on-off schedules.

Katipamula et al. (1994) proposed multiple linear regression models to include as independent variables internal gain, solar radiation, wind, and humidity ratio, in addition to

**TABLE 31.6**

Mathematical Expressions and Applications of Change-Point Regression Models

Model Type	Mathematical Expression	Applications
Two-parameter (2-P) model	$E = \beta_0 + \beta_1 \cdot T$	Buildings with constant air volume systems and simple controls
Three-parameter (3-P) model	Heating $E = \beta_0 + \beta_1 \cdot (\beta_2 - T)^+$ Cooling $E = \beta_0 + \beta_1 \cdot (T - \beta_2)^+$	Buildings with envelope-driven heating or cooling loads (most residential buildings follow this model)
Four-parameter (4-P) model	Heating $E = \beta_0 + \beta_1 \cdot (\beta_3 - T)^+ - \beta_2 \cdot (T - \beta_3)^+$ Cooling $E = \beta_0 - \beta_1 \cdot (\beta_3 - T)^+ + \beta_2 \cdot (T - \beta_3)^+$	Buildings with VAV systems and/or with high latent loads; also, buildings with nonlinear control features (such as economizer cycles and hot deck reset schedules)
Five-parameter (5-P) model	$E = \beta_0 + \beta_1 \cdot (\beta_3 - T)^+ + \beta_2 \cdot (T - \beta_4)^+$	Buildings with systems that use the same energy source for both heating and cooling (i.e., heat pumps, electric heating and cooling systems)

the outdoor temperature. For the buildings considered in their analysis, Katipamula et al. found that wind and solar radiation have small effects on the energy consumption. They also found that internal gains have generally modest impact on energy consumption. Katipamula et al. (1998) discussed in more details the advantages and the limitations of multivariate regression modeling.

*Time-variant models:* There are several techniques that are proposed to include the effect of time variation of several independent variables on estimating the energy savings due to retrofits of building energy systems. Among these techniques are the artificial neural networks (Krarti et al., 1998), Fourier series (Dhar et al., 1998), and NILM (Shaw et al., 1998). These techniques are typically involved and require high level of expertise and training.

## 31.7 Summary

Retrofitting of buildings encompasses a wide variety of tasks and requires expertise in a number of areas to determine the best ECMs suitable for an existing facility. This chapter provided a description of a general but a systematic approach to perform energy audits. If followed carefully, the approach helps facilitate the process of analyzing a seemingly endless array of alternatives and complex interrelationships between building and energy system components. In particular, the chapter discussed net-zero energy retrofitting of buildings using detailed simulation analysis and optimization techniques to ensure that over a period of 1 year, the retrofitted building would effectively consume as much source energy as it produces.

## **32.1 Introduction**

### **32.1.1 Background**

The term “cogeneration” as used in this chapter is defined as the combined production of electrical power\* and useful thermal energy by the sequential use of a fuel or fuels. Each term in this definition is important. Combined means that the production processes of the electric power and thermal energy are linked, and often are accomplished in a series or parallel fashion. Electrical power is the electricity produced by an electrical generator, which is most often powered by a prime mover such as a steam turbine, gas turbine, or reciprocating engine. Thermal energy is that product of the process which provides heating or cooling. Forms of this thermal energy include hot exhaust gases, hot water, steam, and chilled water. Useful means that the energy is directed at fulfilling an existing need for heating or cooling. Simply exhausting hot exhaust gases does not meet the definition of useful thermal energy. In other words, cogeneration is the production of electrical power and the capture of coexisting thermal energy for useful purposes.

The importance of cogeneration is monetary and energy savings. Any facility that uses electrical power and needs thermal energy is a candidate for cogeneration. Although many considerations are involved in determining if cogeneration is feasible for a particular

---

\* Although the power output of a cogeneration system could be mechanical power as well as electrical power, the majority of systems produce electrical power. This chapter will consider only cogeneration systems that produce electrical power.

facility, the basic consideration is if the saving on thermal energy costs is sufficient to justify the capital expenditures for a cogeneration system. Facilities that may be considered for cogeneration include those in the industrial, commercial, and institutional sectors.

The technology for cogeneration is for the most part available and exists over a range of sizes: from less than 100 kW to over 100 MW. The major equipment requirements include a prime mover, electrical generator, electrical controls, heat recovery systems, and other typical power plant equipment. These components are well developed, and the procedures to integrate these components into cogeneration systems are well established.

In addition to the economic and technical considerations, the application of cogeneration systems involves an understanding of the governmental regulations and legislation on electrical power production and on environmental impacts. With respect to electrical power production, certain governmental regulations were passed during the late 1970s that remove barriers and provide incentives to encourage cogeneration development. Finally, no cogeneration assessment would be complete without an understanding of the financial arrangements that are possible.

### 32.1.2 Overall Scope of the Chapter

The objective of this chapter is to provide a complete overview of the important aspects necessary to understand cogeneration. Specifically, this chapter includes information on the technical equipment and components, technical design issues, regulatory considerations, economic evaluations, financial aspects, computer models and simulations, and future technologies. As briefly described earlier, a thorough discussion of cogeneration includes many aspects of engineering, economics, law, finance, and other topics. The emphasis of this chapter is on the technical and engineering considerations. The descriptions of the economic, legal, and governmental aspects are provided for completeness, but should not be considered a substitute for consulting with appropriate specialists such as attorneys, accountants, and bankers.

This chapter is divided into sections on basic cogeneration systems and terminology, technical components, design issues, regulatory considerations, economic evaluations, and financial aspects. Also, two case studies are presented that illustrate the application of cogeneration to an industrial and an institutional facility. Finally, the chapter concludes with some comments on the future technologies of cogeneration. This introductory section ends with a brief review of the history of cogeneration.

### 32.1.3 History of Cogeneration

At the beginning of the twentieth century, electrical power generation was in its infancy. Most industrial facilities generated all their own electrical power and often supplied power to nearby communities. They used the thermal energy that was available during the electrical power production to provide or supplement process or building heat. These industrial facilities, therefore, were the first “cogenerators.” The dominant prime mover at this time was the reciprocating steam engine, and the low-pressure exhaust steam was used for heating applications.

Between the early 1920s and through the 1970s, the public electric utility industry grew rapidly because of increasing electrical power demands. Coincident with this rapid growth was a general reduction in the costs to produce electrical power, mainly due to the economies of scale, more efficient technologies, and decreasing fuel costs. During this period, industry often abandoned their own electrical power generation because of

(1) the decreasing electrical rates charged by public utilities, (2) income tax regulations that favored expenses instead of capital investments, (3) increasing costs of labor, and (4) the desire of industry to focus on their product rather than the side issue of electrical power generation. Estimates are available that suggest that industrial cogenerated electrical power decreased from about 25% to 9% of the total electrical power generated in the country between the years of 1954 and 1976. Since about the mid-1980s, this percentage has been fairly constant at about 5%. For example, at the end of 1992, 5.1% of the total U.S. electrical capacity was due to cogeneration systems.

During the 1960s and 1970s, the natural gas industry promoted a “total energy” concept of cogeneration. This effort was not very successful due to the relatively poor economics (e.g., relatively inexpensive electricity and expensive fuels), and the lack of governmental regulations to ease the interface with public utilities.

In late 1973 and again in 1979, America experienced major “energy crises” that were largely a result of reduced petroleum imports. Between 1973 and 1983, the prices of fuels and electrical power increased by a factor of approximately 5. Any facility purchasing electrical power began to consider (or reconsider) the economic savings associated with cogeneration. These considerations were facilitated by Federal regulations that were enacted to ease or remove barriers to cogeneration.

In 1978, the government passed the National Energy Act (NEA) that included several important pieces of legislation. The NEA included the Fuel Use Act, the Natural Gas Policy Act, and the Public Utility Regulatory Policies Act (PURPA). Each of these acts had a direct impact on cogeneration, but PURPA was the most significant. In particular, PURPA defined cogeneration systems to include those power plants that supplied a specified fraction of their input energy as useful thermal output in addition to a mechanical or electrical output. This legislation is discussed in more detail in later sections of this chapter.

In addition, other regulatory legislation passed beginning in the late 1950s and continuing through the early 1990s impacts the installation of cogeneration systems. In particular, Federal legislation directed at managing air and water quality significantly affects the installations of cogeneration systems. For managing air pollution, the original legislation is the Air Quality Act of 1967 that was amended with the Clean Air Act Amendments in 1970, 1977, and 1990. The main legislative basis for managing water pollution is the Federal Water Pollution Control Act of 1956, as amended by the Water Quality Act of 1965, the Federal Water Pollution Control Act amendments of 1972, and Clean Water Act of 1977. These acts and other legislation, including the Energy Policy Act of 2005, and their impacts on the development of cogeneration projects, are discussed in a subsequent section of this chapter.

The term *cogeneration* lost favor in the U.S. in the 1980s and 1990s, particularly with the electric utilities. Instead, a new term, “combined heat and power,” or CHP, became popular. A CHP Association was formed, and the U.S. Department of Energy began funding demonstration projects. A typical system might include a small combustion turbine producing electrical power used in conjunction with an absorption chiller that is direct-fired with the gas turbine exhaust gases. These smaller CHP systems are also being touted for use in buildings, called *building CHP* or *BCHP*. There has been an increased interest in distributed generation since parts of the U.S. and Canada suffered a massive electrical blackout in August 2003 that left eight states in the northeast and parts of Canada without power for several days.

The number of smaller CHP systems increased during the early part of the twenty-first century; however, relatively cheap electricity prices and moderate natural gas prices still hindered the widespread applications of CHP. Two natural disasters in the summer of 2005,

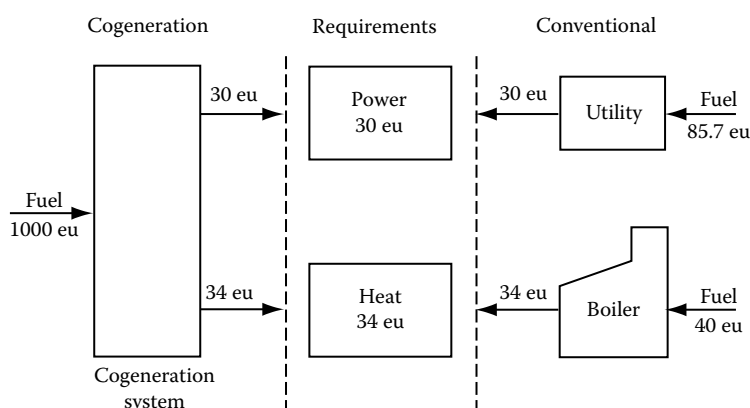

Hurricanes Katrina and Rita, caused widespread damage to offshore natural gas wells in the Gulf of Mexico. The price of natural gas virtually doubled over a 2-month period. This could have a profound impact on new cogeneration systems because, despite the increased system efficiency, the economics of most CHP systems depend on moderate gas prices (relative to electricity). The increased demand for natural gas, both in the U.S. and worldwide, and the price volatility make the near-term future of CHP highly uncertain. However, new technologies, transmission-grid problems forcing a greater reliance on distributed generation, and favorable electricity prices will make CHP systems more prominent in the twenty-first century. The overall CHP system efficiency will eventually drive the market to more widespread acceptance.

## 32.2 Basic Cogeneration Systems

### 32.2.1 Advantages of Cogeneration

To illustrate the fuel and monetary savings of a cogeneration system, the following simple comparison is presented. Figure 32.1 shows the details of this comparison. The power and thermal needs to be satisfied are 30 energy units\* of electrical power and 34 energy units of heat. These power and thermal needs may be satisfied by either a cogeneration system or by conventional systems. Conventional systems for this example would be an electric utility and a standard boiler.

At the left of Figure 32.1 is the cogeneration system, and at the right of Figure 32.1 is the conventional system. All the components of the cogeneration system are represented by the box. Assuming an electrical generation efficiency of 30% for the cogeneration system, then 30 energy units are produced with 100 energy units of fuel energy. This cogeneration system then supplies 34 energy units of heat. These are conservative numbers for the electrical and

**FIGURE 32.1**

A schematic illustration of the advantages of cogeneration relative to conventional systems.

\* For this example, an energy unit is defined as any consistent unit of energy such as kW, MW, Btu, MBtu, or Btu/h. The use of arbitrary units avoids confusion and the need for unit conversions.

thermal outputs of the cogeneration system, and many systems may have higher efficiencies. The overall thermodynamic efficiency\* of the cogeneration system is defined as

$$\eta_0 = \frac{(P + T)}{F} \quad (32.1)$$

where

$P$  represents the power

$T$  represents the thermal or heat energy rate

$F$  represents the fuel input rate (all in consistent units)

This overall efficiency also may be found as the sum of the individual efficiencies of the electrical and thermal production. For this example, the cogeneration system has an overall efficiency of

$$\eta_0 = \frac{(30 + 34)}{100} = 64\% \quad (32.2)$$

The conventional systems, diagrammed at the right of [Figure 32.1](#), satisfy the power and thermal needs by the use of an electric utility and a boiler. In this case, the utility is assumed to be able to deliver the 30 energy units of electrical power with a plant efficiency of 35% (which is on the high side for most utilities). This results in a fuel input of 85.7 energy units. The boiler supplies the 34 energy units of heat with an 85% efficiency, which requires a fuel input of 40 energy units. The overall efficiency is, therefore,

$$\eta_0 = \frac{(P + T)}{F} = \frac{(30 + 34)}{(85.7 + 40)} = 51\% \quad (32.3)$$

This simple example demonstrates the thermodynamic advantage of a cogeneration system relative to conventional systems for accomplishing the same objectives. In this example, the cogeneration system had an overall efficiency of 64% compared to 51% for the conventional systems. Compared to the conventional systems, this is an absolute increase of 13% and a relative improvement of 25% (based on the 51% efficiency).

To determine the fuel and monetary savings of the cogeneration system relative to the conventional systems, the output power will be assumed to be 50 MW. This is a typical power level for a large university or hospital. The associated thermal output rate for this example would be

$$T = \left( \frac{34}{30} \right) 50 \text{ MW} = 56.7 \text{ MW}. \quad (32.4)$$

This may be converted to units of MBtu/h (i.e., million Btu/h)

$$T = 56.7 \text{ MW} (3.41 \text{ MBtu/h/Mw}) = 193.4 \text{ MBtu/h}. \quad (32.5)$$

To determine the fuel inputs, the power must be converted to consistent units

$$P = 50 \text{ MW} (3.41 \text{ MBtu/h/MW}) = 170.7 \text{ MBtu/h}. \quad (32.6)$$

---

\* This overall thermodynamic efficiency should not be confused with the "PURPA" efficiency, which is a legislated definition and is described in a later subsection.

Now, the fuel inputs are

$$(\text{Fuel})_{\text{cogen}} = \frac{(P + T)}{(\eta_0)_{\text{cogen}}} = \frac{(170.7 + 173.4)}{0.64} = 569 \text{ MBtu/h.} \quad (32.7)$$

$$(\text{Fuel})_{\text{conv}} = \frac{(P + T)}{(\eta_0)_{\text{conv}}} = \frac{(170.7 + 193.4)}{0.51} = 714 \text{ MBtu/h.} \quad (32.8)$$

The fuel savings is the difference between these two numbers:

$$(\text{Fuel savings}) = (\text{Fuel})_{\text{conv}} - (\text{Fuel})_{\text{cogen}} = 714 - 569 = 145 \text{ MBtu/h.} \quad (32.9)$$

If the plant operates 6,000 h/year (this is about 68% of the time on average—a conservative estimate), then the fuel energy savings per year is 870,000 MBtu. If the fuel price is \$8.00/MBtu, then the monetary saving is  $\$6.96 \times 10^6$  per year. Although this is a simple economic analysis, the general trends are relevant. A later section of this chapter will describe more comprehensive economic analyses used in actual assessments of cogeneration applications.

In summary, the use of cogeneration is an effective way to more efficiently use fuels. The energy released from the fuels is used to both produce electrical power as well as provide useful thermal energy. The savings in energy and money can be substantial, and such systems have been shown to be technically and economically feasible in a wide range of applications.

### 32.2.2 Topping and Bottoming Cycles

A cogeneration system may be classified as either a topping-cycle system or a bottoming-cycle system. Figure 32.2 is a schematic illustration of a topping-cycle system. As shown, a prime mover uses fuel to power an electrical generator to produce electricity. This electricity may be used completely on-site or may be tied into an electrical distribution network for sale to the local utility or other customers. The hot exhaust gases are directed to a heat

**FIGURE 32.2**

A schematic illustration of a cogeneration topping-cycle system.

**FIGURE 32.3**

The gas temperature as a function of entropy for a topping-cycle system.

recovery boiler (HRB)\* to produce steam or hot water. This steam or hot water is used on-site for process or building heat.

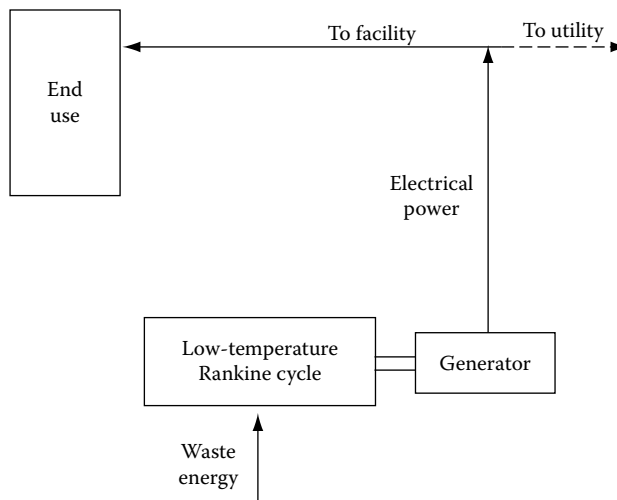

This cogeneration system is classified as a topping cycle because the electrical power is first generated at the higher (top) temperatures associated with the fuel combustion process and then the rejected or exhausted energy is used to produce useful thermal energy (such as the steam or hot water in this example). Figure 32.3 shows the thermodynamic states of the exhaust gases for this process on a temperature-entropy diagram. For this process, as energy is removed from the combustion gases, the temperature and entropy decrease (since the process involves energy removal). As shown, the top or high-temperature gases are used first to produce the electrical power and then the lower-temperature gases (exhaust) are used to produce useful thermal energy. The majority of cogeneration systems are based on topping cycles.

The other classification of cogeneration systems is bottoming cycle systems. Figure 32.4 is a schematic illustration of a bottoming cycle system. As shown, the high-temperature combustion gases are used first in a high-temperature thermal process (such as high-temperature metal treatment) and then the lower-temperature gases are used in a special low-temperature cycle to produce electrical power. Figure 32.5 shows the thermodynamic states of the exhaust gases for this process on a temperature-entropy diagram. After the energy is removed at the high temperatures, the energy available at the bottom or lower temperatures is then used to produce electrical power.<sup>†</sup>

Bottoming-cycle cogeneration systems have fewer applications than topping-cycle systems and must compete with waste heat recovery systems such as feedwater heaters, recuperators, and process heat exchangers. One of the difficulties with bottoming cycle systems is the low-temperature electrical power producing cycle. One example, depicted in Figure 32.4, is a low-temperature Rankine cycle. The low-temperature Rankine cycle is

\* Many other terms for this boiler are common: for example, waste heat boiler (WHB) and heat recovery steam generator (HRSG).

<sup>†</sup> Other definitions of bottoming cycles are common. These other definitions often include any second use of the energy. For example, some authors refer to the steam turbine in a combined cycle as using a bottoming cycle. The more precise thermodynamic definition employed here is preferred, although fewer applications meet this definition.

**FIGURE 32.4**  
A schematic illustration of a cogeneration bottoming-cycle system.

**FIGURE 32.5**  
The gas temperature as a function of entropy for a bottoming-cycle system.

a power cycle similar to the conventional steam Rankine cycle, but a special fluid such as an organic substance (like a refrigerant) is used in place of water. This fluid vaporizes at a lower temperature than water, so this cycle is able to utilize the low-temperature energy. These cycles are generally much less efficient than conventional power cycles, often involve special equipment, and use more expensive working fluids. The majority of this chapter on cogeneration is based on topping cycle systems.

### 32.2.3 Combined Cycles

One power plant configuration that is based on a form of a topping cycle and is widely used in industry and by electrical utilities is known as a combined cycle. Typically in this configuration, a gas turbine is used to generate electricity and the exhaust gas is

ducted to a heat recovery steam generator. The steam then is ducted to a steam turbine, which produces additional electricity. Such a combined cycle gas turbine power plant is often denoted as CCGT. In a cogeneration application, some steam would then need to be used to satisfy a thermal requirement. As might be expected, combined cycles have high power-to-heat ratios and high electrical efficiencies. Current designs have electrical efficiencies of up to 55% depending on the equipment, location, and details of the specific application. These current designs for combined cycle plants result in gas turbine power of between 1.5 and 3.5 times the power obtained from the steam turbine. These plants are most often base load systems operating more than 6000 h/year. More details on gas turbines and steam turbines are provided in the following sections on the prime movers.

### **32.2.4 Applications of Cogeneration Systems**

#### **32.2.4.1 General**

Cogeneration systems may involve different types of equipment and may be designed to satisfy specific needs at individual sites. On the other hand, many sites have similar needs and packaged (pre-engineered) cogeneration systems may satisfy these needs and are more economical than custom-engineered systems. The following are examples of cogeneration systems in three different economic sectors.

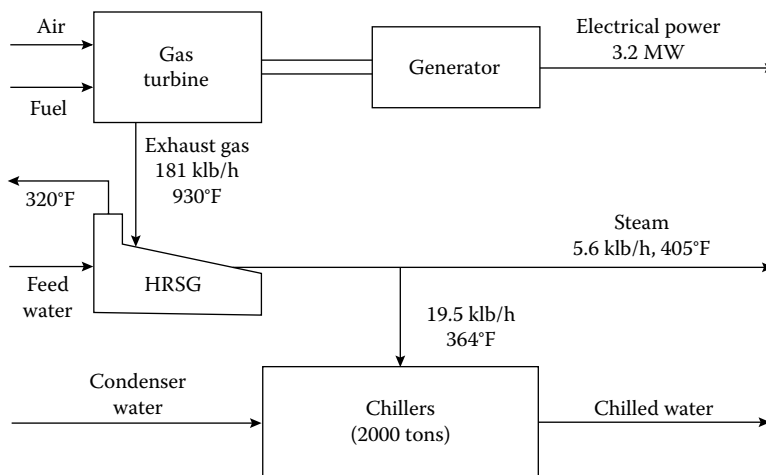

Cogeneration systems are found in all economic sectors of the world. For convenience, cogeneration systems are often grouped into one of three sectors: (1) industrial, (2) institutional, and (3) commercial. The types and sizes of the cogeneration systems in these sectors overlap to varying degrees, but these sectors are nonetheless convenient for describing various applications of cogeneration. This section will provide examples of the variety of applications that exist. Obviously, these examples are not inclusive, but are intended to illustrate the breadth of possibilities.

#### **32.2.4.2 Industrial Sector**

Compared to the other economic sectors, the industrial sector includes the oldest, largest, and greatest number of cogeneration systems. As mentioned in the preceding history, cogeneration was first used by industry in the early 1900s to supply both electrical and thermal needs in an efficient manner. Many industries have a rich and continuous history of cogeneration applications. The industrial sector is dominant in cogeneration for several reasons. Industrial facilities often operate continuously, have simultaneous electrical and thermal requirements, and already have a power plant and operating staff. Those industries that are particularly energy intensive, such as the petrochemical and paper and pulp industries, are significant cogenerators. Many of these industries are cogenerating hundreds of megawatts of electrical power at one site. In addition, of course, mid-sized and smaller industries also use cogeneration.

#### **32.2.4.3 Institutional Sector**

The institutional sector includes a wide range of largely not-for-profit enterprises including universities, colleges, other schools, government building complexes, hospitals, military bases, and not-for-profit institutes. Many of these enterprises operate for a majority of the day, if not continuously. Some, such as hospitals, may already have provisions for

**FIGURE 32.6**

A schematic diagram of the topping-cycle cogeneration system installed in 1986 at Rice University in Houston, Texas.

emergency backup power and have the staff to operate a cogeneration system. Although not as large as the largest industrial cogenerators, a large hospital complex or university may require 50 or more megawatts of cogenerated electrical power.

Figure 32.6 is a schematic of a cogeneration system installed in 1986 at Rice University in Houston, Texas. As shown, this is a topping-cycle cogeneration system that uses a 3.2 MW gas turbine, a heat recovery steam generator, and two 1000 ton absorption chillers. Because this system was so successful, a second cogeneration system using a combined cycle was installed in 1989. It included a 3.7 MW gas turbine, a 400 kW steam turbine, and a 1500 ton absorption chiller. These two cogeneration systems supply the university with 90% of its electrical power, heating, and cooling requirements.

#### 32.2.4.4 Commercial Sector

The commercial sector includes a wide range of for-profit enterprises including businesses, hotels, motels, apartment and housing complexes, restaurants, shopping centers, laundries, and laboratories. Generally, this sector includes the smallest cogenerators, and unless the electrical rates are unusually high, the economics are often less favorable than for the other sectors. There has been a greater interest in building cogeneration systems with the push for distributed generation and increased efficiency of electrical generation. Fuel cells are also being used for cogeneration applications in buildings.

### 32.3 Equipment and Components

Cogeneration systems consist of several major pieces of equipment and many smaller components. This section will describe and provide guidance on the selection of this equipment and components. The following discussion is grouped into four subsections: (1) prime movers, (2) electrical equipment, (3) heat recovery devices, and (4) absorption chillers.

### **32.3.1 Prime Movers**

Prime movers include those devices that convert fuel energy into rotating-shaft power to drive electrical generators. The prime movers that are used most often in cogeneration systems are steam turbines, gas turbines, and reciprocating engines. Each of these prime movers is described here. Important distinctions between the prime movers are the fuels that they may use, their combustion processes, their overall thermal efficiency, and the type, amount, and temperature of their rejected thermal energy. In cogeneration applications, a significant parameter for each type of prime mover is the ratio of the rate of supplied thermal energy and the output power. This ratio is called the heat-to-power ratio, and is unitless (i.e., kW/kW or Btu h/Btu h). Knowing the value of the heat-to-power ratio assists in matching a particular prime mover to a particular application. This matching is discussed in a later section.

#### **32.3.1.1 Steam Turbines**

Steam turbines are widely used in power plants throughout industry and electric utilities. Steam turbines use high-pressure, high-temperature steam from a boiler. The steam flows through the turbine, forcing the turbine to rotate. The steam exits the turbine at a lower pressure and temperature. A major difference of the steam turbine relative to the reciprocating engines and gas turbines is that the combustion occurs externally in a separate device (boiler). This allows a wide range of fuels to be used including solid fuels such as coal or solid waste materials. The exit steam, of course, can be used for thermal heating or to supply the energy to an absorption chiller.

Steam turbines are available in a multitude of configurations and sizes. This description will highlight only the major possibilities, but more complete information is available elsewhere (Wood 1982). A major distinction is whether the machine is a condensing or noncondensing (back-pressure) steam turbine. Condensing steam turbines are steam turbines designed so that the steam exits at a low pressure (less than atmospheric) such that the steam may be condensed in a condenser at near ambient temperatures. Condensing steam turbines provide the maximum electrical output, and hence, are most often used by central plants and electric utilities. Since the exiting steam possesses little available energy, the application of condensing steam turbines for cogeneration is negligible.

Noncondensing steam turbines are steam turbines designed such that the exiting steam is at a pressure above atmospheric. These steam turbines are also referred to as back-pressure steam turbines. The exiting steam possesses sufficient energy to provide process or building heat. Either type of steam turbine may be equipped with one or more extraction ports so that a portion of the steam may be extracted from the steam turbine at pressures between the inlet and exit pressures. This extracted steam may be used for higher temperature heating or process requirements.

Noncondensing steam turbines are available in a wide range of outputs beginning at about 50 kW and increasing to over 100 MW. Inlet steam pressures range from 150 to 2000 psig, and inlet temperatures range from 500°F to 1050°F. Depending on the specific design and application, the heat-to-power ratio for steam turbines could range from 4 to over 10. The thermal efficiency increases with size (or power level) from typically 8% to 20%. Although the major source of thermal energy is the exit or extracted steam, the boiler exhaust may be a possible secondary source of thermal energy in some cases.

### 32.3.1.2 Gas Turbines

As with steam turbines, stationary gas turbines are major components in many power plants. Stationary gas turbines share many of the same components with the familiar aircraft gas turbines. In fact, both stationary (or industrial) and aircraft gas turbines are used in cogeneration systems. This brief description will highlight the important characteristics of gas turbines as applied to cogeneration.

Many configurations, designs, and sizes of gas turbines are available. The simple-cycle gas turbine uses no external techniques such as regeneration to improve its efficiency. The thermal efficiency of simple-cycle gas turbines may therefore be increased by the use of several external techniques, but the designs and configurations become more complex. Many of these modifications to the simple-cycle gas turbine are directed at using the energy in the exhaust gases to increase the electrical output and efficiency. Of course, such modifications will decrease the available energy in the exhaust. For cogeneration applications, therefore, the most efficient gas turbine may not always be the appropriate choice.

Gas turbines are available in a wide range of outputs beginning at about 100 kW and increasing to over 100 MW. Depending on the specific design, the heat-to-power ratio for gas turbines could range from about 1 to 3. The design point thermal efficiency increases with size (or power level) and complexity from typically 20% to 45%. The higher thermal efficiencies, compared to steam turbines, is the reason the heat-to-power ratio is lower than for steam turbines. These high efficiencies are for full-load (design point) operation. At part load, a gas turbine's efficiency decreases rapidly. As mentioned earlier, the use of regeneration, intercooling, reheating, and other modifications are used to improve the overall performance of the simple-cycle gas turbine.

Due to the large amount of excess air (the total air mass may be on the order of 100 times the fuel mass) used in the combustion process of gas turbines, the exiting exhaust gas contains a relatively high concentration of nitrogen and oxygen. Hence, the gas turbine exhaust may be characterized as mostly heated air and is nearly ideal for process or heating purposes. Gas turbines may use liquid fuels such as jet fuel or kerosene, or they may use gaseous fuels such as natural gas or propane. The highest performance is possible with liquid fuels, but the lowest emissions have been reported for natural gas operation.

Power ratings for gas turbines are provided for continuous and intermittent duty cycles. The continuous ratings are slightly lower than the intermittent ratings to provide long life and good durability. In both cases, the power ratings are provided for a set of standard operating conditions known as ISO conditions. ISO conditions include 1 atm, 59°F (15°C), sea level, and no inlet or exhaust pressure losses. For a specific application, the local conditions must be used to adjust the rated power to reflect the actual operating conditions. Most manufacturers will provide potential users with their recommended adjustments, which depend on the difference between the local and standard conditions. In particular, the local ambient inlet air temperature affects the gas turbine output in a significant manner. As the ambient air temperature increases, the performance of a gas turbine decreases due to the lower air density.

Gas turbines require more frequent and specialized maintenance than steam turbines. Major overhauls are required at 20,000–75,000 h of operation, depending on the service duty and the manufacturer. Aircraft gas turbines are designed to have their "hot section" returned to the manufacturer and replaced with a conditioned unit to minimize downtime, although the overhaul is more expensive. Industrial gas turbines are designed to be overhauled in the field, and this is generally a less expensive procedure.

### 32.3.1.3 Reciprocating Engines

A third category of prime movers for cogeneration systems is internal combustion (IC), reciprocating engines. Although rotary engines could be used in cogeneration systems, no significant applications are known. The remaining discussion will focus on reciprocating engines. These engines are available in several forms. Probably the most common form of the reciprocating engine is the typical spark-ignited, gasoline engine used in automobiles. For cogeneration applications, the spark-ignited gasoline engine has been converted to operate in a stationary, continuous mode with fuels such as natural gas. The majority of reciprocating engines for mid- to large-sized cogeneration systems are stationary diesel engines operating either with diesel fuel or in a dual-fuel mode with natural gas. These engines share some common characteristics for cogeneration applications and have some distinctive features as well.

Power ratings for reciprocating engines are similar to those for gas turbines in that both continuous and intermittent duty cycle ratings are provided. As with the gas turbines, these power ratings are provided for a set of standard conditions for ambient temperature, pressure, and elevation. The standard power ratings need to be adjusted for the local conditions at the site of the installation. For cogeneration applications, reciprocating engines are available in many power levels and designs. These power levels range from less than 50 kW to over 200 MW. Some manufacturers even offer “mini” cogeneration systems with outputs as low as 6 kW.

For those reciprocating, internal combustion engines that are liquid cooled (the majority of the engines considered here), the cooling liquid is a secondary source of thermal energy. Although not at the high temperatures of exhaust gas, this energy can be used to produce hot water or low-pressure steam. Several designs are available for recovering the energy in the cooling liquid. These designs use one or more direct or indirect heat exchangers to generate the hot water or low-pressure steam. Liquid-to-liquid heat exchangers can have high efficiencies, and most of this energy is recoverable (but at relatively low temperatures). Other energy sources from reciprocating engines include oil-coolers and turbocharger after-coolers. This energy is usually at temperatures below 160°F, and would only be practical to recover for low-temperature requirements. Another benefit of the reciprocating engine is that the maintenance and repair is less specialized than for gas turbines. On the other hand, the maintenance may be more frequent and more costly.

### 32.3.1.4 Heat-to-Power Characteristics

As mentioned earlier, an important feature in the selection of a prime mover for a cogeneration system is the heat-to-power ratio. This ratio may be a fairly constant characteristic of a family of a particular type of prime mover. Figures 32.7 and 32.8 show the electrical power output as a function of the potential available thermal energy rate output for a specific family of gas turbines and a specific family of reciprocating engines, respectively. The symbols represent the power and thermal output for individual gas turbines and engines in the two “families.” The solid lines are the linear best fits to this data and represent the average heat-to-power (H/P) ratio for each family. As shown, the data does scatter some about the linear line, but the characteristic for each prime mover family is a good average. Also as shown, the average heat-to-power ratio is 2.0 for the gas turbine and 0.5 for the reciprocating engine. These are representative values for these two types of prime movers. These characteristic heat-to-power ratios will be used here in matching the prime mover to a specific application.

**FIGURE 32.7**

The electrical power as a function of the useful thermal energy (in arbitrary units) for a number of simple-cycle gas turbines. The average heat-to-power ratio for this family of gas turbines is 2.0, and is shown as the solid line.

**FIGURE 32.8**

The electrical power as a function of the useful thermal energy (in arbitrary units) for similar diesel engines. The average heat-to-power ratio for this family of reciprocating engines is 0.5, and is shown as the solid line.

### 32.3.2 Electrical Equipment

The electrical equipment for cogeneration systems includes electrical generators, transformers, switching components, circuit breakers, relays, electric meters, controls, transmission lines, and related equipment. In addition to the equipment that supports electrical production, cogeneration systems may need equipment to interconnect with an electric utility to operate in parallel for the use of backup (emergency) power or for electrical sales to the utility. This section will briefly highlight some of the aspects regarding electrical generators and interconnections, but will not be able to review the other important electrical considerations.

The electric generator is a device for converting the rotating mechanical energy of a prime mover to electrical energy (i.e., electricity). The basic principle for this process,

known as the Faraday effect, is that when an electrically conductive material such as a wire moves across a magnetic field, an electric current is produced in the wire. This can be accomplished in a variety of ways, so there are several types of electric generators. The frequency of the generator's output depends on the rotational speed of the assembly.

An important feature of generators is that they require a magnetic field to operate. The source of the energy for this magnetic field serves to distinguish the two major types of generators. If the generator is connected to an electric source and uses that source for the magnetic field, it is called an induction generator. In this case, the generator operates above the synchronous speed, and cannot operate if the external current (usually from the electric utility) is not available. On the other hand, if the magnetic field is generated internally using a small alternator, the generator is called a synchronous generator and operates at the synchronous speed. Synchronous generators can operate independent of the external electric grid.

Most often the manufacturer of the prime mover will provide the prime mover and generator as an integrated, packaged assembly (called a genset). Performance characteristics of generators include power rating, efficiency, voltage, power factor, and current ratings. Each of these performance characteristics must be considered when selecting the proper generator for a given application. Electric generators may have conversion efficiencies of between about 50% to over 98%. The efficiency increases in this range as the generator increases in size and power rating. Only the largest electric generators (say, on the order of 100 MW) can attain efficiencies of 98%.

In many cases, the cogeneration system will need to be interconnected to the utility. Although a cogeneration system could be isolated from the electric grid, there are several reasons why the system may need to be interconnected. An interconnection is necessary for receiving supplementary or backup (emergency) electric power. Also, if the cogenerator elects to sell excess power, such an interconnection would be needed. The interconnection equipment includes relays, circuit breakers, fuses, switches, transformers, synchronizers, and meters. The specific equipment and design for the interconnection largely is dictated by the utility for safety and compatibility reasons. The utility has specific responsibilities for the integrity of the electric grid and for maintaining the electrical power quality.

### **32.3.3 Heat Recovery Equipment**

The primary heat recovery equipment used in cogeneration systems includes several types of steam and hot-water production facilities. In addition, absorption chillers could be considered in this section, but for organizational reasons, chillers will be discussed in the following section. Several configurations of heat recovery devices are available. As mentioned earlier, these devices may be referred to as "heat recovery steam generators" or HRSGs. HRSGs are often divided into the following categories: (1) unfired, (2) partially fired, and (3) fully fired. An unfired HRSG is essentially a convective heat exchanger. A partially fired HRSG may include a "duct burner," which often uses a natural gas burner upstream of the HRSG to increase the exhaust gas temperature. A fully fired HRSG is basically a boiler that simply uses the exhaust gas as preheated air.

For most of these heat recovery devices, exhaust gas flows up through the device and exits at the top. Energy from the exhaust gas is used to heat and vaporize the water, and to superheat the steam. [Figure 32.9](#) shows this process on a temperature diagram. The top line shows the exhaust gas temperature decreasing from left to right as energy is removed from the gas to heat the water. The lower line represents the water heating up from right to left in the diagram. The lower-temperature exhaust is used to preheat the water to

**FIGURE 32.9**

The temperatures of the exhaust gas and water/steam as a function of the heat transfer coordinate for the steam generation process of an HRSG.

saturation conditions in the economizer. The intermediate-temperature exhaust is used to vaporize (or boil) the water to form saturated steam. Finally, the highest-temperature exhaust is used to superheat the steam.

The temperature difference between the exhaust gas and the water where the water first starts to vaporize is referred to as the pinch point temperature difference. This is the smallest temperature difference in the HRSG and may limit the overall performance of the heat recovery device. Since the rate of heat transfer is proportional to the temperature difference, the greater this difference the greater the heat transfer rate. On the other hand, as this temperature difference increases the steam flow rate must decrease and less of the exhaust gas energy will be utilized. To use smaller temperature differences and maintain higher heat transfer rates, larger heat exchanger surfaces are required. Larger heat transfer surface areas result in higher capital costs. These, then, are the types of trade-offs that must be decided when incorporating a heat recovery device into a cogeneration system design.

The proper selection of HRSG equipment depends on the prime mover, the required steam conditions, and other interdependent factors. Some of these considerations are described next. Most of these considerations involve a trade-off between increased performance and higher initial capital cost.

The “back-pressure” of the HRSG unit affects the overall system performance. As the back-pressure decreases, the HRSG efficiency increases, but the cost of the HRSG unit increases. Successful units often have 10–15 in. water pressure of back-pressure. As mentioned earlier, the selection of the “pinch point” temperature difference affects the performance and cost. Typical pinch point temperature differences are between 30°F and 80°F. High-efficiency, high-cost units may use a temperature difference as low as 25°F.

The final outlet stack gas temperature must be selected so as to avoid significant acid formation. This requires the outlet stack temperature to be above the water condensation temperature. This is typically above 300°F. The amount of sulfur in the fuel affects this decision, since the sulfur forms sulfuric acid. As the amount of sulfur in the fuel increases, the recommended stack gas outlet temperature increases.

The final consideration is the steam temperature and pressure. This is a complex decision that depends on many factors such as the application for the steam, the source of the exhaust gas, the exhaust gas temperature and flow rate, and inlet water condition and temperature.

### **32.3.4 Absorption Chillers**

Absorption chillers may use the thermal energy from cogeneration systems to provide cooling for a facility. This section will briefly review the operation of absorption chillers and their application to cogeneration systems. Absorption chillers use special fluids and a unique thermodynamic cycle that produces low temperatures without the requirement of a vapor compressor, which is used in mechanical chillers. Instead of the vapor compressor, an absorption chiller uses liquid pumps and energy from low-temperature sources such as hot water, steam, or exhaust gas.

Absorption chillers utilize fluids that are solutions of two components. The basic principle of the operation of absorption chillers is that once the solution is pumped to a high pressure, low-temperature energy is used to vaporize one component from the solution. This component serves as the “refrigerant” for this cycle. Examples of these solutions are (1) water and ammonia, (2) lithium bromide and water, and (3) lithium chloride and water. In the first case the ammonia serves as the refrigerant, and in the latter two cases the water serves as the refrigerant.

For cogeneration applications, the important feature of absorption chillers is that they use relatively low-temperature energy available directly or indirectly from the prime mover and produce chilled water for cooling. The use of absorption chillers is particularly advantageous for locations where space and water heating loads are minimal during a good part of the year. For these situations, the thermal output of a cogeneration system can be used for heating during the colder part of the year and, using an absorption chiller, for cooling during the warmer part of the year. Furthermore, by not using electric chillers, the electric loads are more constant throughout the year. In warm climates, absorption chillers are often an important, if not an essential, aspect of technically and economically successful cogeneration systems.

Some machines are designed as indirect-fired units using hot water or steam. As examples of typical numbers, a single-stage unit could use steam at 250°F to produce a ton of cooling for every 18 lb of steam flow per hour. A dual-stage unit would need 365°F steam to produce a ton of cooling for every 10 lb of steam flow per hour. If hot water is available, a ton of cooling could be produced for every 220 lb of 190°F hot water per hour.

Other machines use the exhaust gas directly and are called direct-fired units. In these cases, the exhaust gas temperature needs to be 550°F–1000°F. The higher the exhaust temperature, the less energy (or exhaust gas flow) is needed per ton of cooling. For example, for 1000°F exhaust gas, a ton of cooling requires 77 lb/h of flow whereas for 550°F exhaust gas a ton of cooling requires 313 lb/h of flow.

---

## **32.4 Technical Design Issues**

### **32.4.1 Selecting and Sizing the Prime Mover**

The selection of a prime mover for a cogeneration system involves the consideration of a variety of technical and nontechnical issues. Technical issues, which often dominate the selection process, include the operating mode or modes of the facility, the required heat-to-power ratio of the facility, the overall power level, and any special site considerations (e.g., low noise). Other issues, which may play a role in the selection process, include matching existing equipment and utilizing the skills of existing plant personnel. Of course, the final decision is often dominated by the economics.

Steam turbines and boilers usually are selected for a cogeneration system if the fuel of choice is coal or another solid fuel. Occasionally, for very large (>50 MW) systems operating at base load, a steam turbine system may be selected even for a liquid or gaseous fuel. Also, steam turbines and boilers would be selected if a high heat-to-power ratio is needed. Steam turbines also may be selected for a cogeneration system in certain specialized cases. For example, a large pressure reduction valve in an existing steam system could be replaced with a steam turbine and thereby provide electrical power and thermal energy. In many applications, however, steam turbines are selected to be used in conjunction with a gas turbine in a combined cycle power plant to increase the power output. Combined cycle gas turbine power plants were described in an earlier section.

Gas turbines are selected for many cogeneration systems where the required heat-to-power ratio and the electrical power need are high. Also, gas turbines are the prime mover of choice where minimal vibration or a low weight-to-power ratio (such as for a roof installation) is required. Reciprocating engines are selected where the heat-to-power ratio is modest, the temperature level of the thermal energy is low, and the highest electrical efficiency is necessary for the economics. Additionally, reciprocating engines may be selected if the plant personnel are more suited to the operation and maintenance of these engines.

Selecting the appropriate size prime mover involves identifying the most economic cogeneration operating mode. This is accomplished by first obtaining the electrical and thermal energy requirements of the facility. Next, various operating modes are considered to satisfy these loads. By conducting a comprehensive economic analysis, the most economic operating mode and prime mover size can be identified. The process of matching the prime mover and the loads is described next.

### 32.4.2 Matching Electrical and Thermal Loads

To properly select the size and operating mode of the prime mover, the electric and thermal loads of the facility need to be obtained. For the most thorough “matching,” these loads are needed on an hourly, daily, monthly, and yearly basis. Figure 32.10 is an example of the hourly electrical and thermal loads of a hypothetical facility for a typical work day in the winter. As shown, the heating and power demands begin to increase at 6:00 a.m.

**FIGURE 32.10**

The power and thermal loads (in arbitrary units) as a function of the hour of the day for a hypothetical facility for one work day in the winter.

**FIGURE 32.11**

The total power and thermal loads (in arbitrary units) as a function of the month of the year for a hypothetical facility.

as the day's activities begin. The heating load is shown to peak shortly after 8:00 a.m. and then decrease for the remainder of the day. The electrical load remains nearly constant during the working part of the day, and is somewhat lower during the evening and nighttime hours.

Figure 32.11 shows the month totals for the electrical and thermal loads for the same hypothetical facility. For the summer months, the heating and electrical loads are minimum. In addition, this figure shows dotted and dashed lines, which represent the "base loads" for the electrical and heating loads, respectively. The base loads are the minimum loads during the year and form a floor or base for the total loads. Often a cogeneration system may be sized so as to provide only the base loads. In this case, auxiliary boilers would provide the additional heating needed during the days where the heating needs exceeded the base amount. Similarly, electrical power would need to be purchased to supplement the base power provided by the cogeneration system.

Several options exist in matching the facility's electrical power and thermal needs to a prime mover for a cogeneration system. To illustrate this matching procedure, consider Figure 32.12, which shows electrical power as a function of thermal energy. The three dashed lines are the heat-to-power characteristics of three families of prime movers. In this example, the heat-to-power ratio increases from A to B to C. The facility's needed electrical power and thermal energy are shown as the horizontal and vertical dotted lines, respectively. This needed power and thermal energy is often the base load of the facility as explained earlier.

Five operating points are identified:

1. Point 1 represents an exact match between the facility's needed power and thermal energy, and the power and thermal energy available from a prime mover with the heat-to-power ratio characteristic B. Such an exact match is not likely or desired, so the other operating points must be considered.
2. Point 2 represents a case where a prime mover is selected with a characteristic C such that the thermal needs are matched but the electrical power supplied is too low. In this case, the facility would need to purchase supplementary electrical

**FIGURE 32.12**

The electrical power as a function of the useful thermal energy (in arbitrary units).

power usually from the local electrical utility. This is a common case that is often the best economic and operational choice.

3. Point 3 represents a case where a prime mover is selected with a characteristic C such that the electrical power needs are matched, but excess thermal energy is available. Generally, this is not an economical choice because the overall system efficiency is low. For certain situations, however, this case might be selected—for example, if future thermal loads are expected to increase or if a customer can be identified to purchase the excess thermal energy.
4. Point 4 represents a case where a prime mover is selected with a characteristic A such that the electrical power needs are matched but the available thermal energy does not satisfy the needs of the facility. In this case, supplementary boilers are often used to supply the additional thermal energy. This may be the best economic choice, particularly if existing boilers are available and the desire is to size the cogeneration system such that all the thermal energy is used.
5. Point 5 represents a case where a prime mover is selected with a characteristic A such that the thermal needs are matched but the electrical power supplied is too high. This would only be economical if an external customer was available to purchase the excess electrical power. This is often the situation with third-party cogenerators, who own and operate a cogeneration system and sell the thermal energy and electrical power to one or more customers.

These cases represent distinct operating mode selections. In practice, other technical and nontechnical aspects must be considered in the final selection. These cases are presented to illustrate the global decision process.

The possible overall operating modes for a cogeneration power plant are often categorized into one of three classes. (1) The plant may operate as a base load system with little or no variation in power output. Base load plants operate in excess of 6000 h/year. Power needs above the base load are typically provided by interconnections to a local utility or by an auxiliary power plant. (2) The plant may operate as an intermediate system for 3000–4000 h/year. These systems are less likely than base load systems, but if the economics are positive, may have application for facilities that are not continuously operated such as

some commercial enterprises. (3) Finally, a third class of plant is a peaking system, which operates only for 1000 h or less per year. Utility plants often use peaking systems to provide peaking power during periods of high electrical use. For cogeneration applications, peaking units may be economical where the cost of the electricity above a certain level is unusually high. These units are sometimes referred to as peak shaving systems.

### **32.4.3 Packaged Systems**

In general, facilities with low electrical power needs cannot utilize customized cogeneration systems because of the relatively high initial costs that are associated with any size system. These initial costs include at least a portion of the costs related to the initial design, engineering, and related development and installation matters. Also, smaller facilities often do not have the specialized staff available to develop and operate complex power plants.

To solve some of these above problems, pre-engineered, factory-assembled, “packaged” cogeneration systems have been developed. Packaged cogeneration systems range from less than 50 kW to over 1 MW. Some larger units (say, 20 MW or larger) using gas turbines or reciprocating engines are sometimes described as packaged cogeneration systems, and are, at least to some degree, “packaged.” For example, a gas turbine and generator may be factory assembled, tested, and skid mounted for shipping. These units, although packaged, do not completely eliminate the problems of project development, installation, and operation. The remainder of this section will consider only the smaller packaged cogeneration systems.

The major advantage of packaged cogeneration systems is that the initial engineering, design, and development costs can be spread over many units, which reduces the capital cost (per kW) for these systems. Other advantages of packaged cogeneration systems include factory assembly and testing of the complete system. If there are any problems, they can be fixed while the system is still at the manufacturer’s plant. The standard design and reduced installation time result in short overall implementation times. In some cases, a packaged cogeneration system could be operational within a few months after the order is received. This short implementation time reduces the project’s uncertainty, which eases making decisions and securing financing.

Another advantage of packaged cogeneration systems is that the customer only interacts with one manufacturer. In some cases, the packaged cogeneration system manufacturer will serve as project engineer and take the project from initial design to installation to operation. The customer often may decide to purchase a Turnkey system. This provides the customer with little uncertainty and places the burden of successful project completion on the manufacturer. Also, the manufacturer of a packaged cogeneration system will have experience interacting with regulating boards, financing concerns, and utilities, and may assist the customer in these interactions.

The major disadvantage of packaged cogeneration systems is that the system is not customized for a specific facility. This may mean some compromise and lack of complete optimization. Specialized configurations may not be available. Also, beyond a certain size, packaged cogeneration systems are simply not offered and a customized unit is the only alternative.

Although the initial capital costs of packaged cogeneration systems are low (on a per kW basis), the other site-specific costs could be relatively high and result in unsatisfactory economics. These other costs depend on the selected fuel, the available space at the site, and the compatibility of existing electrical and mechanical facilities. In particular, the interconnection costs associated with the electric utility and the mechanical systems

can be prohibitively high. The electric interconnection costs depend on the electric utility's requirements. The fuel system costs depend on whether the selected fuel is already available on site at the appropriate conditions (such as gas pressure for gaseous fuels). Other miscellaneous costs include those for services and assistance with engineering, permitting, zoning, financing, legal review, and construction oversight.

In summary, packaged cogeneration systems offer a cost-effective solution for facilities with low power and thermal requirements such as small to medium hospitals, schools, hotels, and restaurants. The majority of current packaged cogeneration systems use reciprocating engines and standard components. They are factory assembled and tested, and are often sold as Turnkey installations. Although the packaged cogeneration systems' costs can be attractive, each facility must be assessed for total costs to determine the economic feasibility. Future developments of packaged cogeneration systems will include even more efficient and cost-effective engines, more advanced microprocessor control systems, and more effective integration of the various components.

---

## 32.5 Regulatory Considerations

This section includes brief overviews of the relevant Federal regulations on electric power generation and the related environmental constraints. It should be pointed out that some sections of PURPA were repealed by the Energy Policy Act of 2005; however, its importance to cogeneration is so significant that it deserves the recognition and discussion as noted here.

### 32.5.1 Federal Regulations Related to Cogeneration—Early History

As mentioned earlier, the passage of PURPA, the Public Utility Regulatory Policies Act, in 1978, helped make cogeneration a much more attractive option for electric power generation for a variety of facilities. PURPA is one of the most controversial bills relating to power generation that has been passed by Congress. PURPA was one of five separate acts comprising the National Energy Act passed by Congress in 1978:

1. National Energy Conservation Policy Act (NECPA)
2. Natural Gas Policy Act (NGPA)
3. Powerplant and Industrial Fuel Use Act (FUA)
4. Energy Tax Act (ETA)
5. Public Utility Regulatory Policies Act (PURPA)

The Federal government, and for that matter the entire nation, was concerned about the oil crisis in 1973, the rapidly increasing price of energy, the increased dependence on foreign oil, and our lack of concern for energy efficiency and the use of renewable energy. The National Energy Act addressed most of those concerns, and PURPA, in particular, dealt with independent power generation, energy efficiency, and the use of renewables for power generation. Although all five acts had an impact on our nation's energy consumption and energy use patterns, PURPA had the greatest overall impact and led to a resurgence of interest in cogeneration. Prior to the passage of PURPA, the three most common

barriers to cogeneration were (Laderoute 1980) (1) no general requirement by electric utilities to purchase electric power from cogenerators, (2) discriminatory backup power for cogenerators, and (3) fear on the part of the cogenerator that they might become subject to the same state and Federal regulations as electric utilities. The passage of PURPA helped to remove these obstacles to development of cogeneration facilities (Spiewak 1980, 1987).

Although PURPA was passed in 1978, it was not until 1980 that the Federal Energy Regulatory Commission (FERC) issued its final rulemakings and orders on PURPA. In the National Energy Act, FERC was designated as the regulatory agency for implementation of PURPA. The regulations dealing with PURPA are contained in Part 292 of the FERC regulations, and Sections 201 and 210 are the two primary sections relevant to small power production and cogeneration (FERC 1978).

Section 201 contains definitions of cogeneration and sets annual efficiency standards for new topping cycle\* cogeneration facilities that use oil or natural gas.<sup>†</sup> For a cogenerating facility to qualify for the privileges and exclusions specified in PURPA, the facility must meet these legislated standards. These standards define a legislated or artificial “efficiency,” which facilities must equal or exceed to be considered a “qualified facility” (QF). A qualified facility is eligible to use the provisions outlined in PURPA regarding nonutility electric power generation. This legislated “efficiency” is defined as

$$\eta_{\text{PURPA}} = \frac{\left(P + \frac{1}{2}T\right)}{F} \quad (32.10)$$

where

$P$  is the electrical energy output

$T$  is the useful thermal energy

$F$  is the fuel energy used

Table 32.1 lists the standards for the PURPA efficiencies. These standards state that a facility must produce at least 5% of the site energy in the form of useful thermal energy, and must meet the efficiency standards in Table 32.1. Values for the thermal fraction and the PURPA efficiency are based upon projected or estimated annual operations.

The purpose of introducing the “artificial” standards was to insure that useful thermal energy was produced on-site in sufficient quantities to make the cogenerator more

**TABLE 32.1**

Required Efficiency Standards for Qualified Facilities (QFs)

Useful Thermal Energy Fraction	Required $\eta_{\text{PURPA}}$
$\geq 5.0\%$	$\geq 45.0\%$
$\geq 15.0\%$	$\geq 42.5\%$

\* Since bottoming cycle cogeneration facilities do not use fuel for the primary production of electrical power, these facilities are only regulated when they use oil or natural gas for supplemental firing. The standards states that during any calendar year the useful power output of the bottoming cycle cogeneration facility must equal or exceed 45% of the energy input if natural gas or oil is used in the supplementary firing. The fuels are used first in the thermal process prior to the bottoming cycle cogeneration facility are not taken into account for satisfying PURPA requirements.

<sup>†</sup> For topping cycle cogeneration facilities using energy sources other than oil or natural gas (or facilities installed before March 13, 1980), no minimum has been set for efficiency.

efficient than the electric utility. Any facility that meets or exceeds the required efficiencies will be more efficient than any combination of techniques producing electrical power and thermal energy separately. Section 201 also put limitations on cogenerator ownership; that is, electric utilities could not own a majority share of a cogeneration facility, nor could any utility holding company, nor a combination thereof. This section also defined the procedures for obtaining QF status.

Section 210 of the PURPA regulations specifically addressed major obstacles to developing cogeneration facilities. In fact, the regulations in Section 210 not only leveled the playing field, they tilted it in favor of the cogenerator. The principal issues in Section 210 include the following legal obligations of the electric utility toward the cogenerator:

- Obligation to purchase cogenerated energy and capacity from QFs.
- Obligation to sell energy and capacity to QFs.
- Obligation to interconnect.
- Obligation to provide access to transmission grid to “wheel” to another electric utility.
- Obligation to operate in parallel with QFs.
- Obligation to provide supplementary power, Backup power, maintenance power, and interruptible power.

Section 210 also exempted QFs from utility status and established a cost basis for purchase of the power from QFs. FERC specified that the price paid to the QF must be determined both on the basis of the utility’s avoided cost for producing that energy and, if applicable, on the capacity deferred as a result of the QF power (e.g., cost savings from not having to build a new power plant). Other factors, such as QF power dispatchability, reliability, and cooperation in scheduling planned outages, could also be figured into the price paid to the QFs by the electric utilities. The state public utility commissions were responsible for determining the value of these avoided cost rates.

PURPA also gave special consideration to power produced from small (less than 80 MW) power production facilities (SPPFs). These must be fueled by biomass, geothermal, wastes, renewable resources, or any combination thereof. H.R. 4808, passed by the 101st Congress, lifted the 80 MW size restriction on wind, solar, geothermal cogeneration, and some waste facilities.\* These SPPFs could become QFs and have the same status as a large gas-fired industrial cogeneration facility. Facilities between 1 kW and 30 MW may receive exemptions from the Federal Power Act (FPA) and the Public Utility Holding Company Act (PUHCA), and SPPFs using biomass are exempt from PUHCA and certain state restrictions, but not from the FPA.

---

## 32.6 Regulatory Developments of the 1990s and Early Twenty-First Century

New and restored terms in the power generation area were introduced in the early 1990s: nonutility generators (NUGs), independent power producers (IPPs), and exempt wholesale generators (EWGs). An EWG is an entity that wishes to build a

---

\* Serial 101–160, Hearing of the Committee on Energy and Commerce, U.S. House of Representatives, June 14, 1990.

new nonrate-based power plant under PUHCA and is only in the business of selling wholesale power. A revised PUHCA and a 1992 FERC ruling gave more open access to transmission lines and limited what a utility could charge third-party transmission users for that access.

The Energy Policy Act of 1992 enacted into law many of FERC's rules on EWGs and defined their legal status. In addition to opening up transmission-line access, the Energy Act also opened the possibility of retail wheeling, an area strongly favored by industry and heavily opposed by the electric utilities. An example of retail wheeling might be an industrial cogenerator in the Texas Gulf Coast area selling power to an industry in the Dallas area. Two or more electric utilities would be affected on their transmission lines, and the Dallas-area utility would lose the revenue from the customer in their service territory. From industry's viewpoint, they would like the ability to buy power wherever they could purchase it cheaper. The Energy Policy Act of 1992 was, in part, responsible for the deregulation of the electric utility industry.

The California Public Utility Commission held hearings in August 1994 on a proposal to have individual consumers choose their own electric company. California led the way "for the now-inevitable downfall of regulated electric utility monopolies...."\* The California experience with deregulation was not pleasant. Electric rates remained high for consumers, brownouts occurred, and price fixing was prevalent among some of the state's power generators. The California experiences in 2000 and 2001 discouraged many states from deregulating their electric utilities. However, in 2005 approximately half of the states in the lower 48 have some form of deregulation already in place or a time schedule for deregulation. States in the northeastern United States, anchored by Pennsylvania, and the state of Texas accomplished deregulation without experiencing many of the problems that occurred in California.

The Energy Policy Act of 2005 modified a number of provisions in PURPA. Because so many states have already deregulated their electrical utilities, some of the PURPA provisions discussed above were no longer needed. Section 1251 of the EPACT of 2005 amended PURPA by adding a "Net Metering" requirement for cogenerating facilities; Section 1252 added a requirement for "Smart Meters"; Section 1253 terminated the mandatory purchase of cogenerated power and power produced by small power cogenerators. Section 1254 of the 2005 act requires electric utilities to interconnect with customers who are also cogenerators. Section 1263 of the EPACT 2005 repeals PUHCA in its entirety and shifts all PUHCA responsibilities to FERC.

The Energy Policy Act of 2005 is a very broad energy act, placing more emphasis on energy efficiency, distributed generation, improved transmission systems, and fuel cells. Overall, it is favorable to cogeneration.

---

## **32.7 Environmental Considerations, Permitting, Water Quality**

As described in the introduction, air and water regulations have been legislated since the 1950s. The Clean Air Act Amendments of 1977 established a new source of performance standards and placed environmental enforcement in the hands of the Environmental

---

\* *USA Today*, Electricity consumers may get power of choice, August 5, 1994, p. 10A.

Protection Agency (EPA). The National Energy Policy Act of 1992 and the revised Clean Air Act Amendments (1990) placed even more stringent regulations on environmental pollutants. Concerns over acid rain, global warming, and the depletion of the ozone layer have prompted these tougher regulations.

The Clean Air Act Amendment of 1990 also produced new challenges and opportunities for power generation—trading and selling of emissions. Certain areas in the U.S. were designated as nonattainment zones where no new emissions sources could be located. Industries could, however, trade or even sell emissions (i.e., so much per ton of CO<sub>2</sub> or SO<sub>2</sub>). This could become very important if a cogenerator wanted to locate a plant in a nonattainment zone and could buy emissions from a company that reduced production or somehow cut emissions from their plant.

A number of certifications are required to get a cogeneration plant approved. These include not only a FERC certificate but also various state permits. Since each state will set its own permitting requirements, it is not possible to generalize what is required on each application, but the following information will likely be required:

1. Nature of pollutant source.
2. Type of pollutant.
3. Level of emissions.
4. Description of process technology.
5. Process flow diagram.
6. Certification that the “Best Available Control Technology” (BACT) is being used.

Different requirements must be met if the proposed site is in an attainment or non-attainment zone. An attainment area will require sufficient modeling of ambient air conditions to insure that no significant deterioration of existing air quality occurs. This is PSD modeling or “prevention of significant deterioration.” For a nonattainment area, no new emissions can be added unless they are offset by the removal of existing emissions. This has led to the selling or trading of emissions by industrial facilities and utilities.

### 32.7.1 Water Quality and Solid Waste Disposal

Water quality is usually not a problem with natural gas-fired cogeneration plants but will probably be monitored and will require both state and Federal permits if the wastewater is discharged into a public waterway. In extreme conditions it may be necessary to control both wastewater temperature and pH.

Solid waste disposal is not a problem with either natural gas or oil-fired cogeneration plants but could be a major problem for a coal-fired, coal gasification, or waste-to-energy cogeneration system. In some states the bottom ash from waste-to-energy plants was considered hazardous waste and the ash disposal cost per ton was more expensive than the refuse disposal cost. In 1994, bottom ash was declared by the EPA to be nonhazardous and therefore was allowed for land filling in standard landfills. Again, all states have different standards for both the quality of the water discharged and the requirements for solid waste disposal, and all project planners should check with the appropriate regulatory agencies in the state where the project is planned to be sure what air, water, and solid waste (if applicable) permits are required.

---

## **32.8 Economic Evaluations**

This section will present a brief summary of the important aspects of economic evaluations of cogeneration systems. This section is not intended to be a complete presentation of engineering economics, which would be beyond the scope of this chapter. Rather, those aspects of economic evaluations that are specific or especially important to cogeneration systems will be described. These aspects include the baseline (or “business as usual”) financial considerations, cogeneration economics including capital and operating costs, and the available economic and engineering computer programs. The two case studies presented at the end of this chapter will further illustrate some of the economic principles discussed in this section.

### **32.8.1 Baseline Considerations**

Because a cogeneration project is capital intensive, it is extremely important to have accurate data to determine current and estimated (projected) future energy consumption and costs. In a large industrial plant with known process steam needs and 15 min electric data available, it is usually fairly straightforward to establish the baseline case (i.e., the no-cogeneration case). For universities, hospitals, small manufacturing plants, and so on, the data are not always available. Typically whole campus/facility electrical data are available on a monthly basis only (from utility bills), and hourly electrical profiles may have to be “constructed” from monthly energy and demand data. Hourly thermal data also may not exist. Boiler operators may have daily logs, but these are typically not in electronic form. Constructing accurate hourly thermal energy profiles can involve hours of tedious work pouring over graphs and boiler operator logs. In the worst-case scenario, only monthly gas bills may be available, and it may be necessary to construct hourly thermal profiles from monthly bills, boiler efficiencies, and Btu content of the fuel. Since the monthly dollars have to be matched, there is often a great deal of trial and error involved before there is a match between assumed hourly energy profiles and monthly energy consumption and costs from the utility bills.

While a first-cut energy and cost analysis may be done on a monthly basis for an industrial facility that operates 7 days a week, 24 h a day, that is not the case for a university, a commercial building complex, or a one- or two-shift manufacturing facility. Energy loads are highly variable, and hourly analyses are required. The possible exception may be hospitals, where 7-day-a-week operation is normally the case. However, there will often be a significant difference between weekday and weekend loads, which would require some sort of “day typing” in the analysis.

Assuming a good energy profile (hourly preferred) can be constructed, the “business as usual” scenario costs are determined. This is the annual cost of doing business without the cogeneration system, including annual purchased electrical energy sales, electrical demand charges, boiler fuel costs, and boiler maintenance. That total number is the baseline to which the cogeneration economics are compared.

### **32.8.2 Cogeneration Economics**

If a simple payback approach is used, the cogeneration system costs divided by the savings over the baseline costs, would be the simple payback:

Annual savings = Baseline costs – Cost with cogeneration system

$$\text{Simple payback} = \frac{\text{Cogeneration system capital costs}}{\text{Annual savings}} \quad (32.11)$$

For many analyses, a simple payback approach is often enough. Once an acceptable payback period is defined, the cogeneration decision can be made. If the simple payback period is fairly short (2–3 years), then small variations in energy prices will have little effect on the decision. As the payback period lengthens (e.g., 4–8 years), then other factors should be examined. The time value of money has to be considered, as well as projected energy rates, and projected changes in energy needs for the facility. See Chapter 12 for more information.

A typical scenario for a project financed over 15–20 years might require an economic analysis that would include the following steps:

1. Determine current energy costs and current thermal and electrical energy requirements.
2. Project energy costs into the 15- to 20-year future using forecasts from the local utility or from the state public utility commission.
3. Project thermal and electrical needs into the future, considering possible growth (or declines) in energy requirements.

*Note:* Any projections of future thermal and electrical loads should carefully consider the impact of energy conservation on the total energy needs. Energy conservation is extremely important in the cost analysis because it represents dollars that do not have to be spent. The term “negawatt” has been applied to demand-side management programs as a means of expressing a decrease in electrical demand at a facility.

4. Project increasing maintenance costs associated with an expected increase in thermal loads (if appropriate).

Summing these costs will provide a more realistic “business as usual” case over the expected financing period of the cogeneration system.

Once the base case is determined, various sizing and operating scenarios for the cogeneration system should then be evaluated. These scenarios include (1) sizing a base-load cogeneration system and, if necessary, purchasing additional required electrical energy and producing supplemental required thermal energy, (2) following the thermal load profile and purchasing electrical energy needs, (3) following the electrical load profile and producing supplemental thermal energy, and (4) following the thermal profile with excess electricity produced. Note that with any potential scenario considered, all the thermal energy produced by the cogeneration system is used. It is the use of all the thermal energy that generally makes a cogeneration system feasible. If electricity production were the primary output, the cogenerator could not compete with the local electric utility. It is the simultaneous production of and need for the thermal energy that makes cogeneration attractive.

The next step is to determine the costs associated with a cogeneration system. This will depend on the type and size of system selected—diesel engine/generator, dual fuel diesel engine/generator, natural gas-fired engine/generator, or gas turbine/generator. As described in a previous section, a variety of possibilities exist in sizing the cogeneration system for a particular application (see Section 32.4.2). Ideally, the cogeneration system

**TABLE 32.2**

Possible Scenarios to Consider for Cogeneration System Sizing

Scenario	Result	Application
Baseline cogeneration system that meets a portion of the facility's electrical and thermal requirements	Requires production of supplemental thermal energy and purchase of additional electrical energy	Universities/commercial buildings/thermal energy plants that have variable loads and do not want to get into the power sales business
Cogeneration system where the thermal load exceeds the equivalent electrical output of the generator-thermal load sizing	Electrical energy will have to be purchased from the local utility	Industrial facility or manufacturing plant with relatively constant thermal load
Cogeneration system designed to match electrical loads	Thermal energy to be produced by a boiler	Industrial facility with fairly high and constant electrical loads and lower, but variable, thermal loads
Cogeneration system sized to meet high thermal loads, but with lower equivalent electrical requirements	Excess electrical power sales to the local utility	Industrial or university facility that has lower or variable electrical needs, which require electricity sales to make the project economical

could be sized to match the electrical and thermal loads exactly; however, seldom is there an exact match. Table 32.2 summarizes four possible outcomes.

### 32.8.3 Operating and Capital Costs

In any scenario, the savings and income from the cogeneration system must be determined as well as the additional costs such as the additional fuel, and the maintenance. Steps for determining the savings and income of the cogeneration system include

1. Savings in electricity generated (avoided purchase) = kWh × 4/kWh.
2. Savings in demand charges (decreased demand) = kW × \$/kW.
3. Savings in HRSG-produced steam.
4. Income from excess electrical power sales (if applicable).
5. Income from excess thermal energy sales (if applicable).

There will be additional costs for the cogeneration system. These include:

- Turbine/generator annual maintenance—use manufacturer's recommended fees, typically expressed in terms of ¢4/kWh of electricity produced. The range may be from 1.0 ¢/kWh for gas turbines to as much as 3.0 ¢/kWh for small engines.
- Fuel cost for the prime mover (fuel oil and/or natural gas) at cost per MBtu
- Maintenance cost for HRSG—use manufacturer's recommended fee schedule, typically around \$1/klb of steam.
- Any electrical utility charges for standby power, maintenance energy or power, etc., expressed in \$/kW or ¢/kWh

As an example of the savings and costs of a cogeneration system, see [Table 32.4](#) in the following case study of the Austin State Hospital. This table provides detailed cost and savings data for that application.

Finally, the system or capital costs must be determined. A general “rule of thumb” for estimating these system costs is as follows:

Major equipment packages (combustion turbine and HRSG)	40%
Balance of plant equipment	25%
Engineering and construction	15%
Other (interest during construction, permitting, contingency, etc.)	20%
	100%

Any cogeneration analysis is very complicated, and the results will vary greatly depending upon interest rates, cost of fuel, permitting requirements, cost of electricity sales, and other factors.

### 32.8.4 Final Comments on Economic Evaluations

Economic evaluations for assessing the feasibility of cogeneration projects is an important aspect of any development. Although many of the considerations are similar to other engineering economic evaluations, several aspects are unique to cogeneration projects. Obtaining detailed electric and thermal energy data is a prerequisite to completing accurate economic assessments. After the data are available, the savings and income of a cogeneration project must be compared to the additional costs of operating the system. If the net savings will “pay back” the capital expense of the cogeneration system in a reasonable time, then the project may make economic sense. A variety of sizes and operating modes of the cogeneration system should be examined to determine the most economical scenario. Computer programs are available to help in this process. Other detailed considerations that are often necessary in a thorough economic evaluation include tax and financing arrangements, but these considerations are beyond the scope of this chapter.

---

## 32.9 Financial Aspects

### 32.9.1 Overall Considerations

Cogeneration facilities can be financed by a variety of options. The traditional approach to financing is owner financing; however, cogeneration facilities are expensive to construct, and a company may choose not to use its own capital. When deciding on the most favorable financial arrangement, companies often consider the following factors:

- Shortage of capital.
- Effect on credit rating (if borrowing the money to finance the plant).
- Impact on balance sheet.
- Desire to fix savings (minimize risk).
- Inability to utilize available tax benefits.
- Lack of interest in operating or owning the plant (not main line of business).

Financing is critical to the success of a cogeneration facility, and it is best to determine, early on, the financing method to be used. Various financial structures are described below.

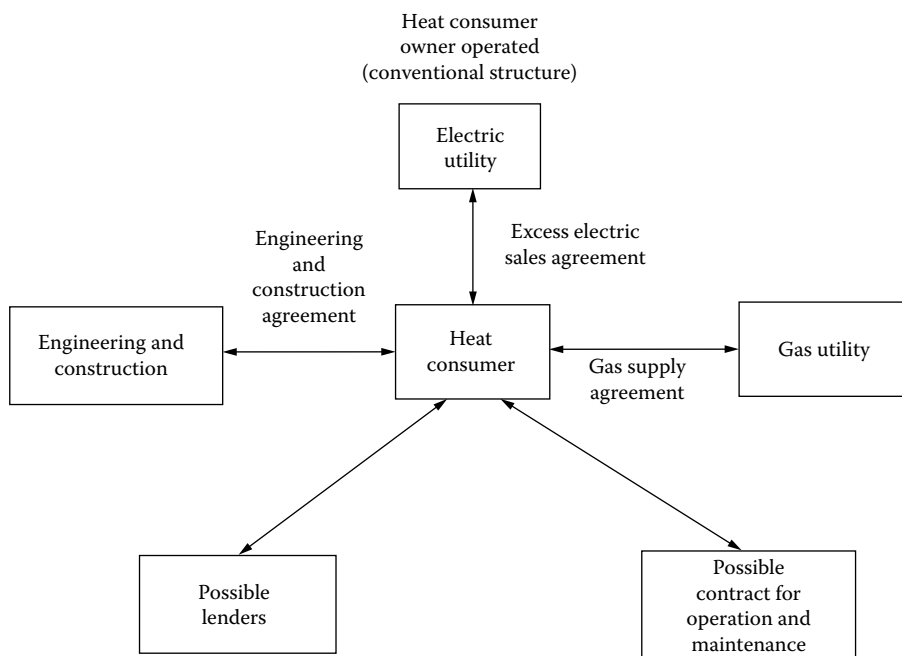

There may be other, more creative ways, to finance projects, including combinations of these, but most financing will fall under one of the following:

1. Conventional ownership and operation.
2. Joint venture partnership.
3. Lease.
4. Third-party ownership.
5. Guaranteed savings.

### 32.9.2 Conventional Ownership and Operation (100% Ownership)

The heat load owner has two basic financing options in a conventional owner/operate structure: (1) to fund the project internally from profits in other areas of the business, or (2) to fund part of the project from internal sources and borrow the remainder from a conventional lending institution. Figure 32.13 shows one such financial structure.

Most businesses have a minimum internal rate of return on equity that they require for any investment. They may not be willing to fund any project that does not meet the internal hurdle rate using 100% equity (internal) financing. With 100% internal financing the company avoids the problems of arranging external financing (perhaps having to add partners). If there is a marginal return on equity, however, the company will not finance the project, especially if the money could be used to expand a product line or create a new product that could provide a greater return on equity.

**FIGURE 32.13**

A schematic illustration of one financial structure for conventional ownership and operation of a cogeneration facility.

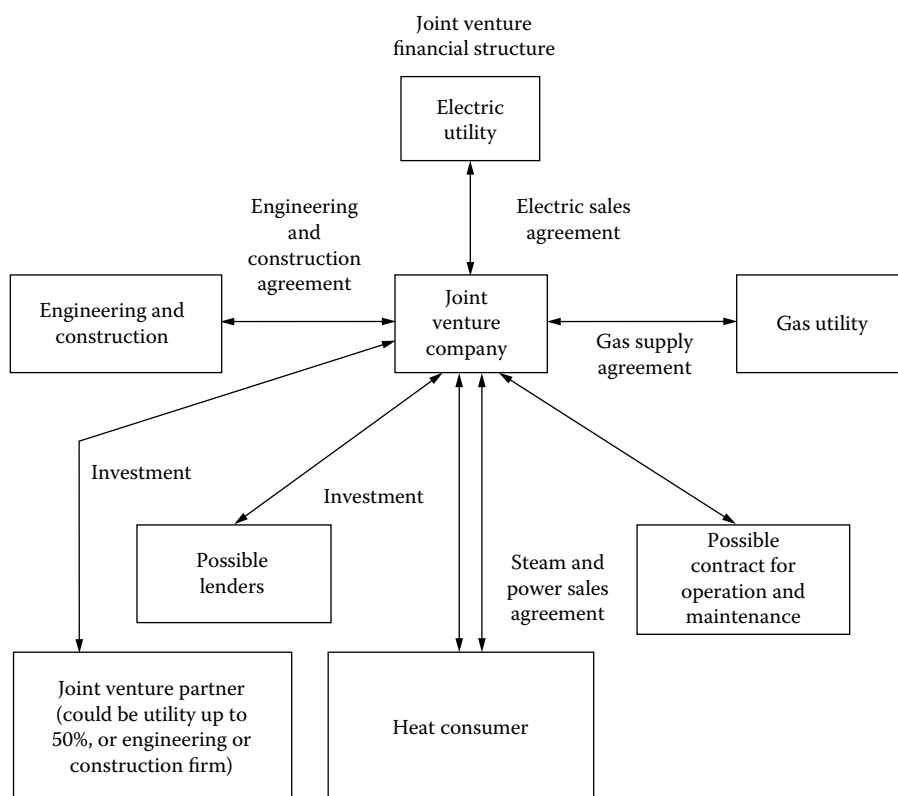

Because the cost of borrowed money is typically lower than a business's own return on equity requirements, the combination of partial funding internally and conventional borrowing is often used. By borrowing most of the funds, the internal funds can be leveraged for other projects, thus magnifying the overall return on equity.

External contract issues are simpler in conventional ownership. Contracts will be required for the gas supply, for excess power sales to the local utility, possible O&M agreements, plus any agreements with possible lenders, but no contracts may be needed for the steam and electricity if all is used internally.

### 32.9.3 Joint Venture

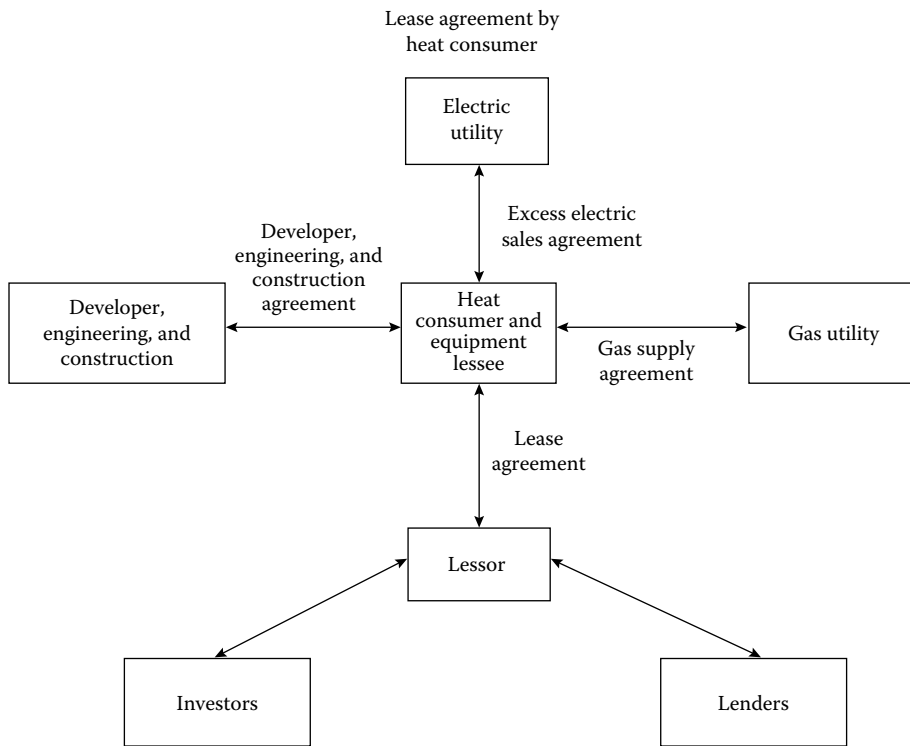

One alternative to 100% ownership is to share ownership. Figure 32.14 shows the outline of one possible arrangement of a joint venture project. PURPA regulations allow electric utilities to own up to a 50% share in a cogeneration facility. Profits shared with a utility in a partial ownership role are unregulated. Other partners might include a gas utility or a major equipment vendor, such as a major gas turbine producer.

The major advantages of a joint venture are the sharing of risks and credit. The disadvantages are that profits are also shared and that contract complexity increases.

**FIGURE 32.14**

A schematic illustration of one financial structure for a joint venture ownership of a cogeneration facility.

**FIGURE 32.15**

A schematic illustration of one financial structure for a lease arrangement for a cogeneration facility.

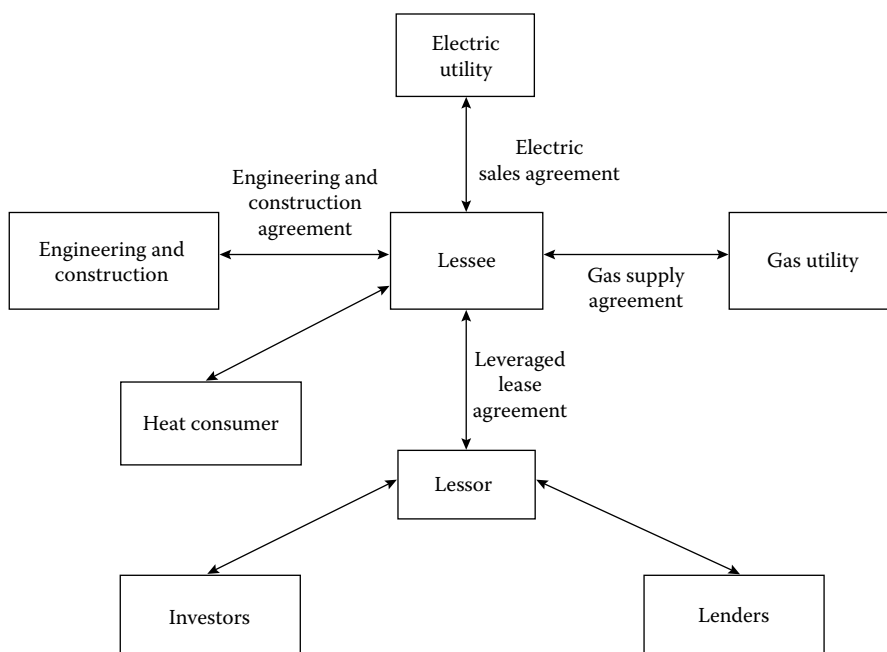

Since the joint venture company is the owner, steam and power sales agreements, in addition to the other contracts required under conventional ownership, have to be signed with the heat consumer.

### 32.9.4 Leasing

In this financing arrangement, a company will build the cogeneration plant with the agreement that the steam host or heat consumer will lease the plant from the builder. In this model, the heat consumer is still heavily involved with the project construction but keeps at arm's length from the financing, since the lessor will have put that package together. These deals are often more difficult to put together and could take longer to develop than either joint venture or conventional ownership financing. Figure 32.15 is a schematic of one such lease agreement approach.

### 32.9.5 Third-Party Ownership

In third-party ownership, the heat consumer is distanced from both the financing and construction of the cogeneration facility. A third party arranges the finances, develops the project, and arranges for gas supply, power sales for the excess power produced, steam sales to the heat consumer, and O&M agreements. Under the 1992 National Energy Policy Act, the third party may also be able to enter into a power sales contract with the heat consumer as well. Figure 32.16 is a schematic of one type of third-party arrangement. The lessee, shown in Figure 32.16, can be a minimally capitalized entity that is primarily

**FIGURE 32.16**

A schematic illustration of one financial structure for third-party ownership and operation of a cogeneration facility.

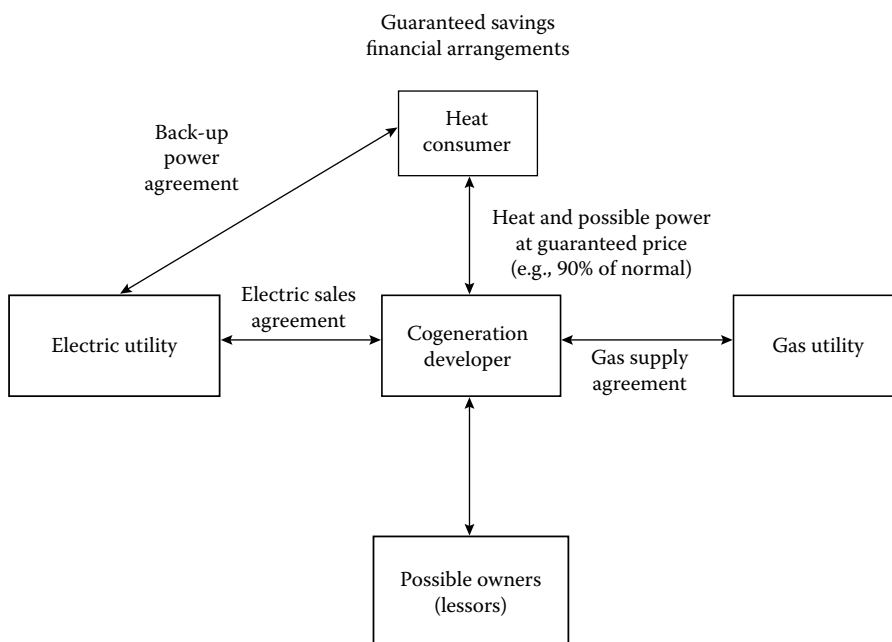

in the business of plant operation and handling energy sales once the plant is built. The contracts for firm energy sales are key to this type of financing operation. This type of financing option can be complex, requiring more development time, so development costs could be much higher.

### 32.9.6 Guaranteed Savings Contracts

These types of contracts are more common in smaller sized cogeneration systems, and typically may use packaged facilities. Figure 32.17 is a schematic of one possible guaranteed savings arrangement. A developer may pay all costs for construction of a cogeneration facility and then operate and maintain the system. Further, a guarantee of savings would be made to the owner over a specified length of time. Typically, a guaranteed savings contract will run from 5 to 10 years, with an average of 8 years, and will guarantee a fixed savings per year. The “split” between the guaranteed savings contractor usually ranges from a 75/25 division to a 95/5 division, with a “typical” split of 85/15; that is, 85% of the savings to the guaranteed savings contractor and 15% to the owner. Any additional savings above the guarantee are often split between the guaranteed savings contractor and the owner.

Guaranteed savings contracts have a distinct advantage to the owner in that all the capital and most of the risks are taken by the guaranteed savings contractor. The owner is guaranteed a percentage savings each year. These types of contracts should be considered when (1) the owner does not have capital to invest in a cogeneration system, or (2) when the owner does not have the necessary experience in-house to operate/manage such a project. If the capital is available, and if the in-house expertise exists, the company would be ahead financially to do the project itself, as the net return would be much higher.

**FIGURE 32.17**

A schematic illustration of one financial structure for a guaranteed savings arrangement of a cogeneration facility.

### 32.9.7 Final Comments on Financial Aspects

Financing arrangements are a crucial aspect of most cogeneration developments. These arrangements may range from simple to highly complex. They are affected by internal factors such as ownership arrangements, credit ratings, and risk tolerance. In addition, these financial aspects are affected by external factors such as the financial and credit markets, tax laws, and cogeneration regulations. A variety of initial financial arrangements have been outlined in this section to illustrate the nature of these arrangements. Much more detailed arrangements are possible and often necessary, but these are beyond the scope of this chapter.

## 32.10 Case Studies

Case studies will be presented. One is a state hospital where a small gas turbine was installed, and the other is a utility application that generates power and sells steam to a local paper mill.

### 32.10.1 The Austin State Hospital Case Study

The Austin State Hospital was a facility operated by the Texas Mental Health and Mental Retardation (MHMR) state agency. It was one of 15 sites selected for a potential cogeneration site and was analyzed by Texas A&M's Energy Systems Laboratory (ESL) in 1985. A large laundry and cafeteria provided most of the thermal loads needed for the project, but there were also significant heat loads during the winter. In 1985, the ESL study

recommended that gas turbines totaling 1.5 MW be installed, at an estimated cost of \$1.5 million. An engineering study was then initiated in 1986–1987, and steam data was taken to determine the steam loads more accurately. The consulting engineering study recommended a 1 MW system at an estimated cost of \$1.3 million. A \$1.5 million grant application was submitted to and approved by Department of Energy (DOE). Specifications were prepared, the project was bid, and all bids came in too high. The project was then stalled for nearly 2 years until additional funding was secured and a long-term gas contract could be signed with the Texas General Land Office (GLO). The project was rebid in 1990, and a contractor was selected (Caton et al. 1991).

The 1 MW gas turbine, heat-recovery steam generator, and controls were completed in May 1992, at a cost of over \$1.8 million, or slightly more than \$1800/kW. The system supplies steam to the Austin State Hospital complex and provides base-load electricity for the facility. The cogeneration system was projected to save \$225,000 per year, for a simple payback of 8 years. A long-term gas contract with the GLO assured the long-term economics of the system. The GLO established a maximum gas cost escalation rate of 5% per year for the duration of the payback period. Because DOE was providing a \$1.5 million grant for the system, the benefit to the state of Texas was large. The state contribution of \$300,000 would be paid back in less than 2 years. Table 32.3 summarizes 2 years of operation of the cogeneration system. The system was monitored by the ESL at Texas A&M University.

Shortly after the installation of the cogeneration system was completed (in May 1992), lightning struck the transformer and power line into the Austin State Hospital and burned

**TABLE 32.3**

Energy Usage for the Austin State Hospital Cogeneration System

Date	Purchased Electricity (kWh/month)	Cogenerated Electricity (kWh/month)	Total Electricity (kWh/month)	HRSG Heating (MMBtu/month)
August 1992	994,909	629,714	1,624,623	3851

**TABLE 32.4**

Summary of Savings Calculations for the Austin State Hospital (1992 Dollars)

Electrical energy cost		\$0.02609/kWh
Average demand cost		\$11.69/kW
Natural gas fuel cost (August 1992–June 1994)		\$3.19/MCF
	<b>Energy usage (per year)</b>	<b>Savings</b>
a. Electricity	14,599,766 kWh	\$198,209
b. Demand (avoided)	23,190 kW	\$141,183
c. Heating (HRSG)	106,477 Mbtu	\$229,565
d. Maintenance of conventional boiler at \$1.10/klb of steam (not required)		\$57,496
	Total savings	\$626,452
<b>Energy costs for the cogeneration system</b>	<b>Expenses (per year)</b>	
Natural gas for the gas turbine	\$332,394	
Standby charge	30,600	
Maintenance of the cogeneration system (\$0.004/kWh)	30,365	
Maintenance of HRSG (\$1.00/klb)	52,261	
Total costs	\$445,620	
Net savings	\$181,000/year	

out many of the controls of the cogeneration system. This caused several weeks of downtime during that summer. Additional start-up problems were attributed to the waste heat system. Overall, the cogeneration system performed exceptionally well, with a turbine/generator availability of 96.8% for a 2-year period (July 1992 through June 1994). This 96.8% availability includes downtime for scheduled maintenance. Excluding scheduled maintenance downtime, the turbine/generator availability was nearly 100%.

Problems with the waste-heat boiler reduced its availability to approximately 92% over the same period. This reduced the expected steam recovery below the assumed availability. This is not the reason, however, for the lower-than-projected savings. The city of Austin changed the type of electrical service and increased the demand charges in 1992. An extra standby charge added approximately \$30,000 annually to the bill. Without this charge, the cogeneration system would be saving nearly \$210,000 annually, almost exactly the annual amount predicted by the savings analysis. Table 32.4 is a summary based on actual metered data for the ASH cogeneration system for 23 months of operation (August 1992 through June 1994). The annual dollar savings are approximately \$181,000 per year, which gives a simple payback of approximately 10 years. Because the bulk of the money was provided by a Federal grant, the state portion has already been repaid. Therefore, the cogeneration project saved the state over \$180,000 annually based on 1992 electricity and gas prices. The Austin State Hospital cogeneration system was shut down after 10 years of operation. The gas turbine remained reliable throughout most of the period of operation. The waste-heat recovery system had many problems during its operating period. However, [Tables 32.3](#) and [32.4](#) give actual data and measured performance of a small-scale system.

### 32.10.2 Klamath Cogeneration Project—An Industrial/Utility Case Study

The Klamath cogeneration project (KCP) is a 484 MW natural-gas fired, combined cycle plant that was completed in 2001. This plant is an example of community and state

involvement that is prevalent in twenty-first century plants. State involvement came from the state of Oregon's Energy Facility Siting Council (EFSC), which approved the project based on reduced CO<sub>2</sub> emissions from the more efficient cogeneration system. Community involvement was also important because a nearby industry (wood processing facility) was to be a steam host for the cogeneration plant. The facility's boilers were to be shut down, thus reducing CO<sub>2</sub> emissions. Although there are other aspects of the overall project, the bottom line is a significant offset of CO<sub>2</sub> emissions, largely from the cogeneration project.

### 32.10.3 Project Overview

The original intent of the project was to generate 484 MW of electricity and supply 200,000 lb/h of steam to the wood processing plant. The Oregon EFSC approved the permitting based on shutting down the plant's boilers, which would guarantee an offset of 4,464,395 short tons of CO<sub>2</sub> over 30 years. Unfortunately, after the permitting was approved, the wood processing plant shut down one of their process lines, which reduced their steam needs to less than half on the original design.

Table 32.5 gives the steam supplied to the wood processing plant since 2001. Although the steam usage is increasing, the steam supplied to the plant is far short of the 200,000 lb/h required in the permitting. Thus, the Klamath cogeneration project will have to find another large steam host or purchase additional CO<sub>2</sub> offsets in order to meet the state of Oregon environmental requirements.

The city of Klamath Falls also had to guarantee the project's heat rate. If it fell short, then additional carbon offsets had to be provided to cover any shortfalls.

This case study is being provided to show the links between cogeneration projects and the environment. Even in a very strict environmental state such as Oregon, a highly efficient cogeneration project can be permitted and licensed to operate. It also points to a problem area discussed earlier, i.e., the need to have a thermal load for the excess steam. When the project was first initiated, there was a large steam host capable of accepting huge quantities of steam. The needs of the wood processing plant changed, however, requiring only one-third of the original steam, and this has created a problem for the cogeneration system. The economics could change dramatically if the success of the project hinged on selling 200,000 lb/h of steam, and the environmental impact by reducing the CO<sub>2</sub> offset could place severe environmental constraints on the city. At the end of 2004, the city was over three million tons of CO<sub>2</sub> short of achieving its offset goal.

**TABLE 32.5**

KCP Facility's Provision of Steam to Collins

Year	Months of Operation	Steam Sent to Collins (lb)	Hours of Operation (Approximately)	Flow Rate (lb/h)	CO <sub>2</sub> Offsets (Short Tons)
2001	July–December	181,288,984	3884	46,675	15,301
2002	January–December	533,655,766	8551	62,408	50,077

### 32.11 Small-Scale Cogeneration Applications in Buildings

Large-scale cogeneration systems have been shown to be very attractive in increasing thermal efficiency and reducing fuel costs and emissions. This technology also offers opportunities for cogeneration systems to be applied to commercial and residential buildings. Recent development of equipment such as microturbines, small-sized reciprocating engines, Stirling engines, and fuel cells makes cogeneration suitable for building use. Building-oriented, small-scale CHP is called *BCHP*. BCHP uses the waste heat for heating, cooling, and humidity control of buildings. The overall thermal efficiency of small-scale CHP can be as much as 85%–90%.

#### 32.11.1 Technology Status of Small-Scale CHP

Microscale CHP started in western Europe and Japan, and is gaining popularity in these countries. Driven by the potential market and advanced technology, the U.S. DOE and the U.S. EPA initiated the “CHP Challenge” in December 1998 to double the installed capacity of CHP systems in the U.S. by 2010. In 1998, the installed CHP capacity was 46 GW, and the goal set for 2010 is 92 GW. As of the end of December 2003, the installed capacity of CHP in the U.S. was approximately 71 GW. About 0.04% of this installed capacity is coming from systems with less than 100 kW of power output, and much less coming from systems with less than 10 kW of power output (Bernstein and Knoke 2004). However, with technology advances, the small-scale cogeneration systems are expected to experience greater growth in the near future.

Table 32.6 compares some of the important performance characteristics of the various types of small-scale systems.

Natural gas is the preferred fuel for the spark-ignition engines, but they can also run on propane or gasoline. Compression-ignition engines can operate on diesel fuel or heavy oil, or they can be set up in a dual-fuel configuration that burns primary natural gas with a small amount of diesel fuel. The engines used for micro-CHP units are normally designed as packaged units. The size of micro-CHP units, which use internal combustion engine as a prime mover, varies from 10 to 200 kW. The unit can be setup easily on-site. However, some drawbacks exist in the reciprocating-engine package units because they require regular maintenance, are noisy without proper noise abatement, and have potentially high emissions. They are not as attractive for residential applications.

Microturbines are a newly developed small-sized gas turbine with power generation from 25 to 250 kW. Like the larger gas turbines, the microturbine generator consists of a compressor, a combustion chamber, a one-stage turbine, and a generator. The rotating speed of the generator can be up to 10,000 rpm. The high-frequency electricity output is first rectified and then converted to 60 Hz. A rectifier and a transformer are invaluable devices in the generation set. Several companies are developing packaged microturbine CHP systems. The 30 and 60 kW units are already in the marketplace. The electricity efficiency of microturbines is about 25%–30%. The advantages of microturbine CHP are low noise and relatively low NO<sub>x</sub> emission. The disadvantages are low electricity efficiency and high cost. Microturbine CHP are suitable for taking a base-load of electricity, heating, and cooling because of their inflexibility in handling load changes.

The Stirling engines are small-scale engines ranging from 2 to 50 kW that are targeting the future residential CHP needs. The Stirling engine uses the Stirling cycle and is a reciprocating engine. However, unlike the internal-combustion engine, the Stirling engine

**TABLE 32.6**

Technical Features of Small-Scale CHP Devices

	Reciprocating Engines	Microturbines	Stirling Engines	PEM Fuel Cells
Electrical power (kW)	10–200	25–250	2–50	2–200
Electrical efficiency, full load (%)	24–45	25–30	15–35	40
Electrical efficiency, half load (%)	23–40	20–25	35	40
Total efficiency (%)	75–85	75–85	75–85	75–85
Heat/electrical power ratio	0.9–2	1.6–2	1.4–3.3	0.9–1.1
Output temperature level (°C)	85–100	85–100	60–80	60–80
Fuel	Natural or biogas, diesel fuel oil	Natural or biogas, diesel, gasoline, alcohols	Natural or biogas, LPG, several liquid or solid fuels	Hydrogen, gases, including hydrogen, methanol
Interval between maintenance (h)	5,000–20,000	20,000–30,000	5000	N/A
Investment cost (\$/kW)	800–1,500	900–1,500	1300–2000	2500–3500
Maintenance costs (¢/kW)	1.2–2.0	0.5–1.5	1.5–2.5	1.0–3.0

is an external-combustion engine. The working gases inside the engine cylinder are typically helium or hydrogen and never leave the engine. The combustion takes place outside the cylinder. The piston is driven by compression or expansion of working gases due to the alternating heating and cooling of the cylinder by external heat sources. The engine converts the temperature difference into electricity. The Stirling engine can run on various fuels, both gas fuels and solid fuels, due to its external combustion. The advantages of Stirling engines are its quiet operation, little maintenance, and low NO<sub>x</sub> emission. The disadvantages are relative lower electricity efficiency, typically about 25%–30%. When the Stirling engine is used as prime mover in micro-CHP systems, the total thermal efficiency is about the same level of other micro-CHP applications. Stirling-engine CHP packaged units are being developed. Several demonstration projects have shown the system efficiency can be over 90%.

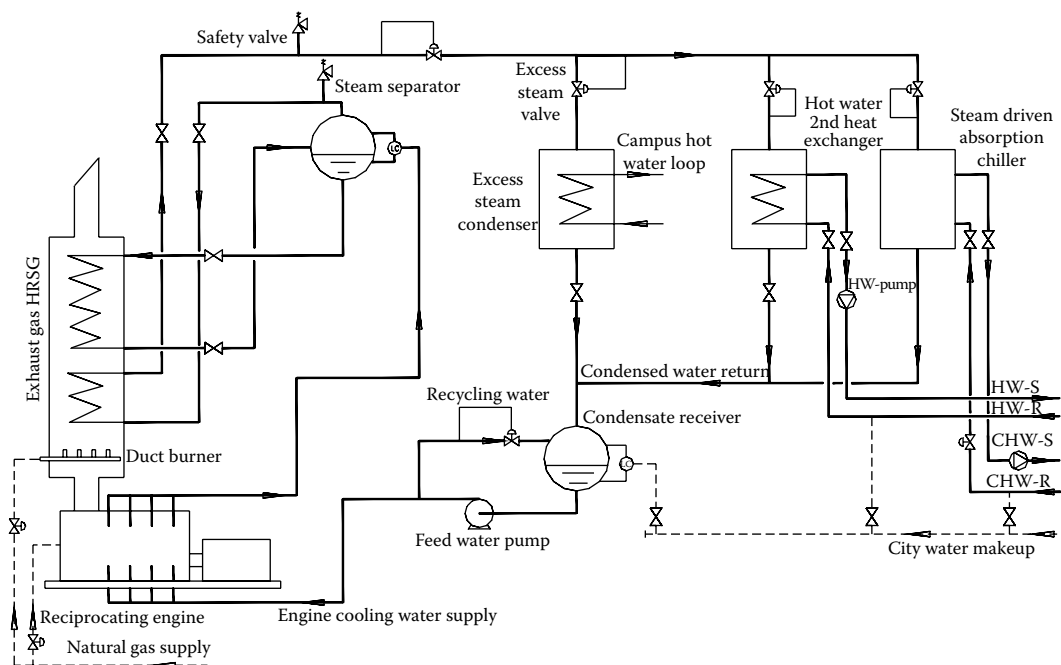

A fuel cell is an electrochemical device that produces electricity by an oxidation-reduction reaction between a fuel, typically hydrogen, and atmospheric oxygen. A fuel cell consists of an anode, a cathode, and an electrolyte. The fuel (hydrogen) is fed to the anode and releases electrons on the anode that are conducted to the cathode via an external circuit. The electron current can be utilized to generate electricity. The hydrogen protons diffuse through the electrolyte material to the cathode. Oxygen or air passes through the cathode in the fuel cell, where oxygen is reacted with the hydrogen proton to form water and release heat. A typical fuel cell system consists of three parts: a fuel reformer section, power generation section, and power conditioning section. The heat rejected from the fuel reformer and power generation section can be recovered and used to drive absorption chillers and heat exchanges to supply hot water and chilled water for building air conditioning systems. The fuel cell technologies can be classified as polymer electrolyte membrane (PEM), phosphoric acid fuel cell (PAFC), solid oxide fuel cell (SOFC), and molten carbonate fuel cell (MCFC),

according to their types of electrolyte. The PEM and PAFC are lower-temperature fuel cells, with operating temperatures of 200°F and 400°F, respectively. The SOFC and MCFC are high-temperature fuel cells with operating temperatures of 1750°F and 1200°F, respectively. The advantages of fuel cell technology are its high electrical efficiency, which can be as high as 45%–55%, and low emissions. Fuel cells are applicable for various purposes, based on the operating temperature levels of the cells. The major disadvantage of a fuel cell is the high price. In 2005, the 200 kW PAFC became available in the market.

### 32.11.2 Building Combined Heat and Power Systems

Commercial and residential buildings are responsible for about 37% of total U.S. primary energy consumption. Ninety-five percent of the commercial buildings are powered by electricity. Ninety-seven percent of these buildings use electricity for air conditioning. Approximately 73.9% of the electricity is generated from combustion of coal, petroleum, and natural gas in the U.S. Because many commercial buildings have a simultaneous need for electricity and thermal energy, there is a potential application for BCHP. The energy consumed by the BCHP system will be utilized at a higher efficiency than conventional means.

Modular CHP units or packaged systems have been developed in recent years to cater to the needs of buildings. Modular cogeneration systems are compact, and can be manufactured economically. These systems, ranging in size from 20 to 650 kW, produce electricity and hot water from engine waste heat. Figure 32.18 shows an IC-engine-driven BCHP system. The engine exhaust gases pass through the heat recovery steam generator, which generates superheated steam to drive the steam-driven absorption chiller and hot-water heat exchanger. The condensed water first passes through the engine to take away the engine heat, then passes through HRSG. This system makes use of engine exhaust heat

**FIGURE 32.18**  
IC-engine-driven microcogeneration system.

and engine cooling heat to supply hot water and chilled water for the building air conditioning system. It is usually better to size the systems to meet the basic electricity load and use an auxiliary boiler or duct burner to adjust CHP thermal output. Therefore, this type of BCHP can run continuously. The best CHP applications for buildings are hospitals or restaurants that have a year-round need for hot water or steam.

Microscale CHP systems using different prime movers are also being developed by several companies to satisfy the electricity and thermal need of residential buildings. These micro-CHP packages have a capacity of up to 16 kW, and are capable of providing most of the heating and electrical needs for a home. Currently, there are several micro-CHP demonstration units running, in which the prime movers vary as IC engine, microturbine, and fuel cell. The major barriers in commercializing these systems in the U.S. market are cost, reliability, and regulations.

### 32.11.3 Market Barriers and Drivers for Building CHP

Electricity deregulation has opened up the traditional power generation market for competition. On the scale of BCHP, deregulation takes the form of net metering in many states, which requires utilities to pay the customer retail price for the electricity exported to the grid. Deregulation, environmental concerns, and incentive programs of the government are the major market drivers for the installation of BCHP. However, several factors also affect the growth of installation of BCHP. These factors include the initial cost of buying and installing a micro-CHP system, maintenance costs, and environmental control requirements. Some electric utilities charge stand-by fees for the installation of micro-CHP so that the utilities may recover the costs of the stranded assets when customers turn to on-site generation. Customers using micro-CHP typically require a backup source of power to meet load requirements during outages or scheduled maintenance. The stand-by charge sometimes can kill a micro-CHP project.

Currently, the high cost is a major barrier preventing the installation of BCHP. High initial cost relative to the central station electric power generation can be a deterrent to the investment in micro-CHP. Although micro-CHP products normally have a higher efficiency compared to the traditional power generation, the cost of the electricity and heat generated by micro-CHP products highly depends on the cost of the micro-CHP products and the cost of fuel. Technology development will certainly reduce the price of the micro-CHP products in the future.

---

## 32.12 Future of Cogeneration

The future of cogeneration will include refined and better versions of the technology already described. In addition, several advanced cogeneration cycles are currently in various stages of development. These include (1) the Cheng cycle, (2) the Kalina cycle, and (3) coal gasification combined cycles.

### 32.12.1 Cheng Cycle

The Cheng cycle for optimizing the performance of gas-turbine cogeneration systems was first identified by Dr. Dan Yu Cheng in 1974. It uses the steam produced in the HRSG for reinjection into the combustion chamber to provide additional power from the gas turbine.

Because the gas turbine is a mass-flow device, combining the steam with the combustion gases will increase the total electrical power produced. This cycle has an advantage over the traditional combined cycle (Rankine cycle) because of its simplicity. There is no need for steam turbine condensers and pumps. Part of the steam produced in the HRSG can also be used for process steam. Following electrical loads or following process steam loads is possible using steam injection in the Cheng cycle. Substantial increases in both power output and generating efficiency are possible.

An added benefit from the steam injection is reduced  $\text{NO}_x$  emissions from the system. Strasser (1991) summarizes the results of several Cheng cycle installations in the U.S. and abroad, the oldest of which was an installation at San Jose State University in San Jose, California. That particular site had accumulated over 46,000 operating hours through November 1991.

### **32.12.2 Kalina Cycle**

The Kalina cycle has been proposed by Dr. Alex Kalina as a means of improving the overall efficiency of combined-cycle plants. Its application to cogeneration systems would be to replace the conventional Rankine cycle power generation with a more efficient Kalina cycle. Dr. Kalina proposed the use of an ammonia-water mixture as the working fluid instead of water. The advantages include a 10%–20% increased thermal efficiency over a Rankine cycle with the same boundary conditions.

Ibrahim and Kovach (1993) describe a power generation application using the Kalina cycle, and Zervos et al. (1992) describe a 3 MW demonstration plant that uses the Kalina cycle. The complexity of the plant increases with the use of the  $\text{NH}_3\text{--H}_2\text{O}$  mixture. The conventional boiler is replaced by a vapor generator, the steam turbine by a vapor turbine, and the condenser by a distillation/condensation system. In the DOE demonstration project (Zervos et al. 1992), the liquid ammonia concentration is 70% by weight as it leaves the distillation/condensation system and enters the simulated waste-heat boiler. The superheated vapor then enters a specially designed vapor turbine, which drives a generator and produces electrical power. The Kalina cycle demonstration project operates between 2000 and 20 psia with ammonia. Mixture concentrations vary from 30% to 70%. The vapor turbine inlet conditions include a pressure of 1600 psia, a temperature of 960°F, an enthalpy of 1221 Btu/lb, an ammonia concentration of 70%, and a flow rate of 31,000 lb/h. The distillation/condensation system consists of a low-pressure condenser, vaporizer, preheater, and pump; an intermediate pressure shell-and-tube heat exchanger, falling film evaporator, flash drum, and pump; and a high-pressure condenser, preheater, pump, and solids removal system. Obviously, the management of the distillation/condensation system is crucial to the operation of a Kalina cycle system.

The vapor turbine has to withstand the high-temperature corrosion of the ammonia-water mixture and is made of type-316 stainless steel. Pressurized steam is injected into the labyrinth seals to contain the ammonia-water mixture and prevent its leakage during the vapor expansion phase in the turbine. This demonstration plant using the Kalina cycle began operation in December 1991.

### **32.12.3 Coal Gasification Combined Cycle Applications**

The United States Clean Coal Technology (CCT) program was established in 1984 with the set-aside of \$750 million for research and development of commercial processes to

accelerate the use of clean coal technologies for power production. The Clean Air Act amendments of 1990 prescribed reductions in acid rain effects and emissions, aimed primarily at the electric utility industry. Coal gasification projects, as well as fluidized-bed combustion, have been the focus of the DOE CCT program (Hemenway et al. 1991).

The purpose of the coal gasification project is to produce a syngas that can be burned in a combustion turbine, hopefully at a price that is competitive with natural gas. The obstacles are coal cleanup, including desulfurization and particulate removal, development of components capable of operating at higher temperatures, disposal of solids and particulates from the process, high-temperature cleaning of the gas stream, and optimization of combustor design for the lower-temperature gas.

Sulfur removal is a must for these units to meet the standards of the Clean Air Act for electric power production. There are various approaches used to remove sulfur, including the addition of limestone or dolomite to the gasifier. Particulate cleanup is usually accomplished by a series of cyclone separators and particle filters. The tricky problem with the gas cleanup is that it should be accomplished in the heated gas stream that may at a temperature of 1000°F or more. Waste heat from the combustion turbine exhaust is routed through the HRSG for steam production. The steam may then be piped to a steam turbine to produce additional electrical power or used partly for process heating. If some stage in the gasification process requires a fixed temperature to be maintained, it is possible that additional steam could be produced in the gasifier that could also be used for process heating or for additional power production.

Ruth and Bedick (1992) summarize five major integrated gasification combined cycle (IGCC) applications sponsored by the DOE. All of the projects are scheduled for start-up/demonstration in the 1995–1996 calendar years. The five activities are (1) Combustion Engineering IGCC Repowering, (2) Tampa Electric IGCC, (3) Pinion Pine IGCC, (4) Toms Creek IGCC Demonstration, and (5) Wabash River Coal Gasification Repowering Project.

Of the five planned projects discussed by Ruth and Bedick, three have been built and are in operation. The Wabash (Indiana) plant is a repowering plant, another application of the IGCC technology—to replace aging coal-fired plants with more efficient and more environmentally friendly IGCC plants. The first “greenfield” (or new plant) is Tampa’s 313 MW facility, dedicated in 1997, received many awards for its gas cleaning technology (DOE Fossil Energy website 2006). In February 1997 there were nine IGCC plants operating worldwide, including three in the United States (The third U.S. plant is outside Reno, Nevada, the Pinion Pine IGCC project.). By 2000 nearly 4 Gigawatts (GW) were in use worldwide (Coal 21 website). Most of the commercial IGCC plants are in the 250–300 MW capacity, currently restricted by the size of the pressurized gasifiers. Since the gasifiers are pressure vessels, they cannot be fabricated on site, and transport restrictions currently limit size (IEA Clean Coal Centre).

Other authors have examined the economics of obtaining and marketing the by-products produced by the gasification process, including methanol, acetic acid, nitric acid, and formaldehyde, as a means of enhancing revenues (Bahmann et al. 1992). Several scenarios were analyzed for cost effectiveness depending on the type of coproduct produced. The IGCC research at the U.S. DOE and throughout the world is focused on high temperature gas cleanup and improved turbines, both of which will improve IGCC efficiency. There is still a huge emphasis on improved methods to remove harmful pollutants that are emitted from the IGCC process. A good overview of the current IGCC technology is a summary by Maurstad (2005).

---

### 32.13 Summary and Conclusions

The importance of cogeneration is monetary, environmental, and energy savings. Any facility that uses electrical power and has thermal energy needs is a candidate for cogeneration. Facilities that may be considered for cogeneration include those in the industrial, commercial, and institutional sectors. The technology for conventional cogeneration systems is for the most part available and exists over a range of sizes: from less than 100 kW to over 100 MW. The major equipment requirements include a prime mover, electrical generator, electrical controls, heat recovery systems, and other typical power plant equipment. These components are well developed, and the procedures to integrate these components into cogeneration systems are well established.

In addition to the economic and technical considerations, the application of cogeneration systems involves an understanding of the governmental regulations and legislation on electrical power production and on environmental impacts. With respect to electrical power production, certain governmental regulations were passed during the late 1970s, again in the 1990s, and in 2005 that remove barriers and provide incentives to encourage cogeneration development. Finally, no cogeneration assessment would be complete without an understanding of the financial arrangements that are possible.

This chapter has provided a brief survey of the important aspects necessary to understand cogeneration. Specifically, this chapter has included information on the technical equipment and components, technical design issues, regulatory considerations, economic evaluations, financial aspects, and future cogeneration technologies. The chapter included two case studies to illustrate the range of technologies available for cogeneration systems, the types of considerations involved in selecting a cogeneration system, and the overall economic and environmental evaluations that may be completed.

Cogeneration will continue to experience progressive growth because of its inherent efficiency over conventional power generation and thermal energy production. As distributed generation becomes more widespread, we will see advances in smaller systems, sized for single buildings, including residential applications.

---

### Acknowledgments

The author wishes to acknowledge the assistance of Gary Gong, PhD candidate at Texas A&M University, for his assistance with this chapter. Also, Dr. Jerald Caton of the Mechanical Engineering Department at Texas A&M University was a contributing author to the earlier chapter.

### 33.1 Overview of Storage Technologies

The availability of affordable and reliable electrical energy storage technologies is crucial to the worldwide effort to transform our electricity and transportation systems and break society's century-long dependence on fossil fuels.

Concerns about energy security and climate change are driving demand for renewable energy generation and storage systems as an alternative to current technologies. While grid energy generation using wind and solar technologies is becoming more common, the lack of cost-effective, high-capacity storage systems has severely limited the use of these technologies. Similarly, shortcomings in storage systems have limited the shift in transportation fuel from petroleum to electricity.<sup>1</sup> Because the current state of knowledge does not allow us to overcome these limitations, revolutionary advances in science and engineering are needed.<sup>2</sup>

The electric grid is undergoing a transformation that requires electricity storage in order to realize its objectives of low-carbon, reliable operation. Tomorrow's grid uses a highly diverse generation mix with inflexible (i.e., unpredictable) renewable energy sources in both centralized and distributed deployments. While battery-based storage would avoid reliability issues, the cost of batteries (~\$500/kWh for a Na–S battery) is five times that of other storage technologies.<sup>3</sup>

In parallel, widespread market penetration of electric vehicles (EVs) will require a five-fold cost reduction, from \$500–\$600/kWh to \$100–\$125/kWh. To achieve a 350-mile driving range, EV batteries also must operate at pack-level energy densities of 400 Wh/kg or more, rather than today's 80–100 Wh/kg.

Energy storage will play a more and more critical role in an efficient and renewable energy future, much more so than it does in today's fossil-based energy economy. There are two principal reasons that energy storage will grow in importance with increased development of renewable energy:

1. Many important renewable energy sources are intermittent, and generate when weather dictates, rather than when energy demand dictates.
2. Many transportation systems require energy to be carried with the vehicle.\*

\* This is almost always true for private transportation systems, and usually untrue for public transportation systems, which can rely on rails or overhead wires to transmit electric energy. However, some public transportation systems such as buses do not have fixed routes and also require portable energy storage.

Energy can be stored in many forms: as mechanical energy in rotating, compressed, or elevated substances, as thermal or electrical energy waiting to be released from chemical bonds, or as electrical charge ready to travel from positive to negative poles on demand.

Storage media that can take and release energy in the form of electricity have the most universal value, because electricity can efficiently be converted either to mechanical or heat energy, while other energy conversion processes are less efficient. Electricity is also the output of three of the most promising renewable energy technologies: wind turbines, solar thermal, and photovoltaics. Storing this electricity in a medium that naturally accepts electricity is favored, because converting the energy to another type usually has a substantial efficiency penalty.

Still, some applications can benefit from mechanical or thermal technologies. Examples are when the application already includes mechanical devices or heat engines that can take advantage of the compatible energy form, lower environmental impacts that are associated with mechanical and thermal technologies, or low cost resulting from simpler technologies or efficiencies of scale.

In this chapter, we group the technologies into five categories: direct electric, electrochemical, mechanical, direct thermal, and thermochemical. [Table 33.1](#) is a summary of all of the technologies covered. Each is listed with indicators of appropriate applications, which are further explained in Section 33.3.

---

### 33.2 Principal Forms of Stored Energy

The storage media discussed in this chapter can accept and deliver energy in three fundamental forms: electrical, mechanical, and thermal. Electrical and mechanical energies are both considered high-quality energy, because they can be converted to either of the other two forms with fairly little energy loss (e.g., electricity can drive a motor with only about 5% energy loss, or a resistive heater with no energy loss).

The quality of thermal energy storage depends on its temperature. Usually, thermal energy is considered low quality, because it cannot be easily converted to the other two forms. The theoretical maximum quantity of useful work  $W_{\max}$  (mechanical energy) extractable from a given quantity of heat  $Q$  is

$$W_{\max} = \frac{(T_1 - T_2)}{T_1 \times Q},$$

where

$T_1$  is the absolute temperature of the heat

$T_2$  is the surrounding, ambient absolute temperature

Any energy storage facility must be carefully chosen to accept and produce a form of energy consistent with either the energy source or the final application. Storage technologies that accept and/or produce heat should as a rule only be used with heat energy sources or with heat applications. Mechanical and electric technologies are more versatile, but in most cases, electric technologies are favored over mechanical, because electricity is more easily transmitted, because there is a larger array of useful applications, and because the construction cost is typically lower.

### 33.3 Applications of Energy Storage

In Table 33.1, each technology is classified by its relevance in one to four different, principal applications.

*Utility shaping* is the use of very large capacity storage devices in order to answer electric demand, when a renewable resource is not producing sufficient generation. An example would be nighttime delivery of energy generated by a solar thermal plant during the prior day.

*Power quality* is the use of very responsive storage devices (capable of large changes in output over very short timescales) to smooth power delivery during switching events, short outages, or plant run-up. Power quality applications can be implemented at central generators, at switchgear locations, and at commercial and industrial customers' facilities. Uninterruptible power supplies (UPS) are an example of this category.

*Distributed grid* technologies enable energy generation and storage at customer locations, rather than at a central (utility) facility. The distributed grid is an important, enabling concept for photovoltaic technologies, which are effective at a small scale and can be installed on private homes and commercial buildings. When considered in the context of photovoltaics, the energy storage for the distributed grid is similar to the utility shaping application insofar that both are solutions to an intermittent, renewable resource, but distributed photovoltaic generation requires small capacities in the neighborhood of a few tens of MJ, while utility shaping requires capacities in the TJ range.\* Renewable thermal resources (solar and geothermal) can also be implemented on a distributed scale, and require household-scale thermal storage tanks. For the purposes of this chapter, district heating systems are also considered a distributed technology.

*Automotive* applications include battery-electric vehicles (EVs), hybrid gasoline-electric vehicles (HEVs), plug-in hybrid electric vehicles (PHEVs), and other applications that require mobile batteries larger than those used in today's internal combustion engine cars. A deep penetration of automotive batteries also could become important in a distributed grid. Large fleets of EVs or PHEVs that are grid-connected when parked would help enable renewable technologies, fulfilling utility shaping and distributed grid functions as well as their basic automotive function.

Additional energy storage applications exist, most notably portable electronics and industrial applications. However, the four applications described here make up the principal components that will interact in a significant way with the global energy grid.

---

### 33.4 Specifying Energy Storage Devices

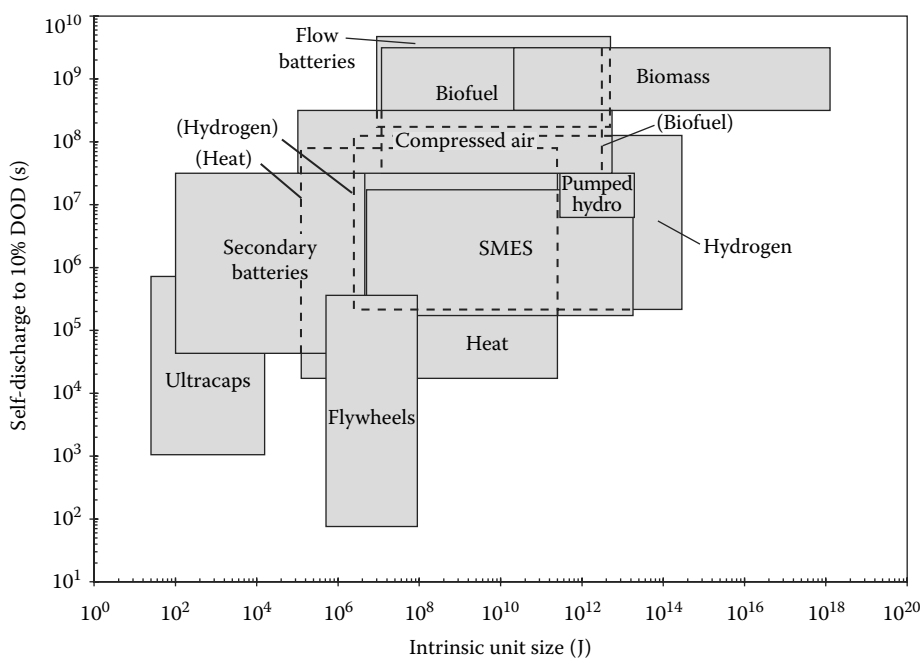

Every energy storage technology, regardless of category, can be roughly characterized by a fairly small number of parameters. Self-discharge time, unit size, and efficiency serve to differentiate the various categories. Within a category, finer selections of storage technology can be made by paying attention to cycle life, specific energy, specific power, energy density, and power density.

*Self-discharge time* is the time required for a fully charged, noninterconnected storage device to reach a certain depth of discharge (DOD). DOD is typically described as a percentage of the storage device's useful capacity, so that, for instance, 90% DOD means 10% of the device's energy capacity remains. The relationship between self-discharge time and DOD is rarely linear, so self-discharge times must be measured and compared at a uniform DOD. Acceptable self-discharge times vary greatly: from a few minutes for some power quality applications to years for devices designed to shape annual power production.

*Unit size* describes the intrinsic scale of the technology, and is the least well defined of the parameters listed here. If the unit size is small compared to the total required capacity

---

\* Storage capacities in this chapter are given in units of MJ, GJ and TJ. 1 MJ = 0.28 kWh, 1 GJ = 280 kWh, and 1 TJ = 280 MWh.

**FIGURE 33.1**

All storage technologies, mapped by self-discharge time and unit size. Not all hidden lines are shown. Larger self-discharge times are always more desirable, but more or less important depending on the application. Intrinsic unit size does not have a desirability proportional to its value, but rather must be matched to the application.

of a project, complexity and supply shortages can increase the cost relative to technologies with a larger unit size. Some technologies have a fairly large unit size that prohibits small-scale energy storage.

Figure 33.1 maps all of the technologies discussed in this chapter, according to their unit size and 10% self-discharge time. The gamut of technologies available covers many orders of magnitude on each axis, illustrating the broad choice available. Utility shaping applications require a moderate self-discharge time and a large unit size; power quality applications are much less sensitive to self-discharge time but require a moderate unit size. Distributed grid and automotive applications both require a moderate self-discharge time and a moderate unit size.

*Efficiency* is the ratio of energy output from the device to the energy input. Like energy density and specific energy, the system boundary must be carefully considered when measuring efficiency. It is particularly important to pay attention to the form of energy required at the input and output interconnections, and to include the entire system necessary to attach to those interconnections. For instance, if the system is to be used for shaping a constant-velocity, utility wind farm, then presumably, both the input and output will be AC electricity. When comparing a battery with a fuel cell in this scenario, it is necessary to include the efficiencies of an AC-to-DC rectifier for the battery, an AC-powered hydrogen generation system for the fuel cell system, and DC-to-AC converters associated with both systems.

Efficiency is related to self-discharge time. Technologies with a short self-discharge time will require constant charging in order to maintain a full charge; if discharge occurs much

later than charge in a certain application, the apparent efficiency will be lower, because a significant amount of energy is lost in maintaining the initial, full charge.

*Cycle life* is the number of consecutive charge–discharge cycles a storage installation can undergo while maintaining the installation's other specifications within certain, limited ranges. Cycle life specifications are made against a chosen DOD depending on the application of the storage device. In some cases, for example, pressurized hydrogen storage in automobiles, each cycle will significantly discharge the hydrogen canister and the appropriate DOD reference might be 80% or 90%. In other cases, for example, a battery used in a HEV, most discharge cycles may consume only 10% or 20% of the energy stored in the battery. For most storage technologies, cycle life is significantly larger for shallow discharges than deep discharges, and it is critical that cycle life data be compared across a uniform DOD assumption.

*Specific energy* is a measure of how heavy the technology is. It is measured in units of energy per mass, and in this chapter, we will always report this quantity in MJ/kg. The higher the specific energy, the lighter the device. Automotive applications require high specific energies; for utility applications, specific energy is relatively unimportant, except where it impacts construction costs.

*Energy density* is a measure of how much space the technology occupies. It is measured in units of energy per volume, and in this chapter, we will always report this quantity in megajoule per liter (MJ/L). The higher the energy density, the smaller is the device. Again, this is most important for automotive applications, and rarely important in utility applications. Typical values for energy density associated with a few automotive-scale energy technologies are listed in Table 33.2, together with cycle life and efficiency data.

Energy density and specific energy estimates are dependent on the system definition. For example, it might be tempting to calculate the specific energy of a flow battery technology by dividing its capacity by the mass of the two electrolytes. But it is important to also include the mass of the electrolyte storage containers, and of the battery cell for a fair and comparable estimate of its specific energy. Thus, the energy density and specific energy are dependent on the size of the specific device; large devices benefit from efficiency of scale with a higher energy density and specific energy.

*Specific power* and *power density* are the power correlates to specific energy and energy density.

**TABLE 33.2**

Nominal Energy Density, Cycle Life, and Efficiency of Automotive Storage Technologies

	Energy Density (MJ/L)	Cycle Life at 80% DOD <sup>a</sup>	Electric Efficiency (%)
Ultracapacitors	0.2	50,000	95
Li-ion batteries	1.8	2,000	85
NiMH batteries	0.6	1,000	80
H <sub>2</sub> at 350 bar	3.0	n/a <sup>b</sup>	47
H <sub>2</sub> at 700 bar	5.0	n/a	45
Air at 300 bar	<0.1	n/a	37
Flywheels	<0.1	20,000	80
Ethanol	23.4	n/a	n/a

Note: Electric efficiencies are calculated for electric-to-electric conversion and momentary storage.

<sup>a</sup> Depth of discharge.

<sup>b</sup> Not applicable.

### 33.5 Specifying Fuels

A *fuel* is any (relatively) homogenous substance that can be combusted to produce heat. Though the energy contained in a fuel can always be extracted through combustion, other processes may be used to extract the energy (e.g., reaction in a fuel cell). A fuel may be gaseous, liquid, or solid. All energy storage technologies in the thermochemical category store energy in a fuel. In the electrochemical category, electrolytic hydrogen is a fuel.

A fuel's *lower heating value (LHV)* is the total quantity of sensible heat released during combustion of a designated quantity of fuel. For example, in the simplest combustion process, that of hydrogen,

or for the slightly more complex combustion of methane,

In this chapter, the quantity of fuel is always expressed as a mass, so that LHV is a special case of specific energy. Like specific energy, LHV is expressed in units of MJ/kg in this chapter.

*Higher heating value (HHV)* is the LHV, plus the latent heat contained in the water vapor resulting from combustion.\* For the examples of hydrogen and methane, this means

and

The latent heat in the water vapor can be substantial, especially for the hydrogen-rich fuels typical in renewable energy applications. Table 33.3 lists LHVs and HHVs of fuels

**TABLE 33.3**

Properties of Fuels

	Chemical Formula	Density (g/L)	LHV (MJ/kg)	HHV (MJ/kg)
Methanol	CH <sub>3</sub> OH	794	19.9	22.7
Ethanol	C <sub>2</sub> H <sub>5</sub> OH	792	26.7	29.7
Methane	CH <sub>4</sub>	0.68	49.5	54.8
Hydrogen	H <sub>2</sub>	0.085	120	142
Dry syngas, airless process <sup>a</sup>	40H <sub>2</sub> + 21CO + 10CH <sub>4</sub> + 29CO <sub>2</sub>	0.89	11.2	12.6
Dry syngas, air process <sup>a</sup>	25H <sub>2</sub> + 16CO + 5CH <sub>4</sub> + 15CO <sub>2</sub> + 39N <sub>2</sub>	0.99	6.23	7.01

<sup>a</sup> Chemical formulae and associated properties of syngas are representative; actual composition of syngas will vary widely according to manufacturing process.

\* The concepts of sensible and latent heat are explained further in Section 33.9.

discussed in this chapter; in the most extreme case of molecular hydrogen, the HHV is some 18% higher than the LHV. Recovery of the latent heat requires controlled condensation of the water vapor; technologies for doing so are described in Chapter 13.

In this chapter, all heating values are reported as HHV rather than LHV. HHV is favored for two reasons. One, its values allow easier checking of energy calculations with the principle of energy conservation. Two, when examining technologies for future implementation, it is wise to keep an intention of developing methods for extracting as much of each energy source's value as possible.

## 33.6 Electrochemical Energy Storage

### 33.6.1 Secondary Batteries

A secondary battery allows electrical energy to be converted into chemical energy, stored, and converted back to electrical energy. Batteries are made up of three basic parts: a negative electrode, positive electrode, and an electrolyte (Figure 33.2). The negative electrode gives up electrons to an external load, and the positive electrode accepts electrons from the load. The electrolyte provides the pathway for charge to transfer between the two electrodes. Chemical reactions between each electrode and the electrolyte remove electrons from the positive electrode and deposit them on the negative electrode. This can be written as an overall chemical reaction that represents the states of charging and discharging of a battery. The speed at which this chemical reaction takes place is related to the *internal resistance* that dictates the maximum power at which the batteries can be charged and discharged.

**FIGURE 33.2**

Schematic of a generalized secondary battery. Directions of electron and ion migration shown are for discharge, so that the positive electrode is the cathode and the negative electrode is the anode. During charge, electrons and ions move in the opposite directions and the positive electrode becomes the anode, while the negative electrode becomes the cathode.

Some batteries suffer from the *memory effect* in which a battery exhibits a lower discharge voltage under a given load than is expected. This gives the appearance of lowered capacity but is actually a voltage depression. Such a voltage depression occurs when a battery is repeatedly discharged to a partial depth and recharged again. This builds an increased internal resistance at this partial DOD, and the battery appears as a result to only be dischargeable to the partial depth. The problem, if and when it occurs, can be remedied by deep discharging the cell a few times. Most batteries considered for modern renewable applications are free from this effect, however.

### 33.6.1.1 Lead-Acid

Lead-acid is one of the oldest and most mature battery technologies. In its basic form, the lead-acid battery consists of a lead (Pb) negative electrode, a lead dioxide (PbO<sub>2</sub>) positive electrode, and a separator to electrically isolate them. The electrolyte is dilute sulfuric acid (H<sub>2</sub>SO<sub>4</sub>), which provides the sulfate ions for the discharge reactions. The chemistry is represented by

(In all battery chemistries listed in this chapter, left-to-right indicates battery discharge and right-to-left indicates charging.)

There are three main types of lead-acid batteries: the flooded cell, the sealed gel cell, and the sealed absorbed glass mat (AGM) lead-acid battery. The wet cell has a liquid electrolyte, which must be replaced occasionally to replenish the hydrogen and oxygen that escape during the charge cycle. The sealed gel cell has a silica component added to the electrolyte to stiffen it. The AGM design uses a fiberglass-like separator to hold electrolyte in close proximity to the electrodes, thereby increasing efficiency. For both the gel and AGM configurations, there is a greatly reduced risk of hydrogen explosion and corrosion from disuse. These two types do require a lower charging rate, however. Both the gel cells and the AGM batteries are sealed and pressurized so that oxygen and hydrogen, produced during the charge cycle, are recombined into water.

The lead-acid battery is a low-cost and popular storage choice for power quality applications. Its application for utility shaping, however, has been very limited due to its short cycle life. A typical installation survives 1500 deep cycles at a maximum.<sup>4</sup> Yet, lead-acid batteries have been used in a few commercial and large-scale energy management applications. The largest one is a 140 GJ system in Chino, California, built in 1988. Lead-acid batteries have a specific energy of only 0.18 MJ/kg, so they would not be a viable automobile option apart from providing the small amount of energy needed to start an engine. It also has a poor energy density at around 0.25 MJ/L. The advantages of the lead-acid battery technology are low cost and high power density.

### 33.6.1.2 Lithium Ion

Lithium ion and lithium polymer batteries, while primarily used in the portable electronics market, are likely to have future use in many other applications. The cathode in these batteries is a lithiated metal oxide (LiCoO<sub>2</sub>, LiMO<sub>2</sub>, etc.), and the anode is made of graphitic carbon with a layer structure. The electrolyte consists of lithium salts (such as LiPF<sub>6</sub>) dissolved in organic carbonates; an example of Li-ion battery chemistry is

When the battery is charged, lithium atoms in the cathode become ions and migrate through the electrolyte toward the carbon anode where they combine with external electrons and are deposited between carbon layers as lithium atoms. This process is reversed during discharge.

The lithium polymer variation replaces the electrolyte with a plastic film that does not conduct electricity but allows ions to pass through it. The 60°C operating temperature requires a heater, reducing overall efficiency slightly.

Lithium ion batteries have a high energy density of about 0.72 MJ/L and have low internal resistance; so, they will achieve efficiencies in the 90% range and above. They have an energy density of around 0.72 MJ/kg. Their high energy efficiency and energy density make lithium-ion batteries excellent candidates for storage in all four applications we consider here: utility shaping, power quality, distributed generation, and automotive.

### 33.6.1.3 Nickel–Cadmium

Nickel–cadmium (NiCd) batteries operate according to the chemistry

NiCd batteries are not common for large stationary applications. They have a specific energy of about 0.27 MJ/kg, an energy density of 0.41 MJ/L, and an efficiency of about 75%. Alaska's Golden Valley Electric Association commissioned a 40 MW/290 GJ nickel–cadmium battery in 2003 to improve reliability and to supply power for essentials during outages.<sup>5</sup> Resistance to cold and relatively low cost were among the deciding factors for choosing the NiCd chemistry.

Cadmium is a toxic heavy metal and there are concerns relating to the possible environmental hazards associated with the disposal of NiCd batteries. In November 2003, the European Commission adopted a proposal for a new battery directive that includes recycling targets of 75% for NiCd batteries. However, the possibility of a ban on rechargeable batteries made from nickel–cadmium still remains, and hence, the long-term viability and availability of NiCd batteries continues to be uncertain. NiCd batteries can also suffer from *memory effect*, where the batteries will only take full charge after a series of full discharges. Proper battery management procedures can help to mitigate this effect.

### 33.6.1.4 Nickel Metal Hydride

The nickel metal hydride (NiMH) battery operates according to the chemistry

where M represents one of a large variety of metal alloys that serve to take up and release hydrogen. NiMH batteries were introduced as a higher energy density and more environmentally friendly version of the nickel–cadmium cell. Modern NiMH batteries offer up to 40% higher energy density than nickel–cadmium. There is potential for yet higher energy density, but other battery technologies (lithium ion in particular) may fill the same market sooner.

NiMH is less durable than nickel–cadmium. Cycling under heavy load and storage at high temperature reduces the service life. NiMH suffers from a higher self-discharge

rate than the nickel–cadmium chemistry. NiMH batteries have a specific energy of 0.29 MJ/kg, an energy density of about 0.54 MJ/L, and an energy efficiency about 70%. These batteries have been an important bridging technology in the portable electronics and hybrid automobile markets. Their future is uncertain, because other battery chemistries promise higher energy storage potential and cycle life.

### 33.6.1.5 Sodium–Sulfur

A sodium–sulfur (NaS) battery consists of a liquid (molten) sulfur positive electrode and liquid (molten) sodium negative electrode, separated by a solid beta-alumina ceramic electrolyte (Figure 33.3). The chemistry is as follows:

When discharging, positive sodium ions pass through the electrolyte and combine with the sulfur to form sodium polysulfides.  $x$  in the equation is 5 during early discharging, but once free sulfur has been exhausted, a more sodium-rich mixture of polysulfides with lower average values of  $x$  develops. This process is reversible as charging causes sodium polysulfides in the positive electrode to release sodium ions that migrate back through the electrolyte and recombine as elemental sodium. The battery operates at about 300°C. NaS batteries have a high energy density of around 0.65 MJ/L and a specific energy of up to 0.86 MJ/kg. These numbers would indicate an application in the automotive sector, but warm-up time and heat-related accident risk make its use there unlikely. The efficiency of this battery chemistry can be as high as 90% and would be suitable for bulk storage applications while simultaneously allowing effective power smoothing operations.<sup>6</sup>

**FIGURE 33.3**

Sodium–sulfur battery showing discharge chemistry. The sodium (Na) and sulfur (S) electrodes are both in a liquid state and are separated by a solid, beta-alumina ceramic electrolyte that allows only sodium ions to pass. Charge is extracted from the electrolytes with metal contacts; the positive contact is the battery wall.

### 33.6.1.6 Zebra

Zebra is the popular name for the sodium nickel chloride battery chemistry:

Zebra batteries are configured similarly to sodium–sulfur batteries (see [Figure 33.3](#)), and also operate at about 300°C. Zebra batteries boast a greater than 90% energy efficiency, a specific energy of up to 0.32 MJ/kg, and an energy density of 0.49 MJ/L.<sup>7</sup> Its tolerance for a wide range of operating temperature and high efficiency, coupled with a good energy density and specific energy, make its most probable application the automobile sector, and as of 2003, Switzerland's MES-DEA is pursuing this application aggressively.<sup>8</sup> Its high energy efficiency also makes it a good candidate for the utility sector.

### 33.6.2 Flow Batteries

Most secondary batteries use electrodes both as an interface for gathering or depositing electrons, and as a storage site for the products or reactants associated with the battery's chemistry. Consequently, both energy and power density are tied to the size and shape of the electrodes. Flow batteries store and release electrical energy by means of reversible electrochemical reactions in two liquid electrolytes. An electrochemical cell has two compartments, one for each electrolyte, physically separated by an ion-exchange membrane. Electrolytes flow into and out of the cell through separate manifolds and undergo chemical reaction inside the cell, with ion or proton exchange through the membrane and electron exchange through the external electric circuit. The chemical energy in the electrolytes is turned into electrical energy and vice versa for charging. They all work in the same general way but vary in chemistry of electrolytes.<sup>9</sup>

There are some advantages to using the flow battery over a conventional secondary battery. The capacity of the system is scaleable by simply increasing the amount of solution. This leads to cheaper installation costs, as the systems get larger. The battery can be fully discharged with no ill effects and has little loss of electrolyte over time. Because the electrolytes are stored separately and in large containers (with a low surface area to volume ratio), flow batteries show promise to have some of the lowest self-discharge rates of any energy storage technology available.

Poor energy densities and specific energies remand these battery types to utility-scale power shaping and smoothing, though they might be adaptable for distributed generation use. There are three types of flow batteries that are closing in on commercialization: vanadium redox, polysulfide bromide, and zinc bromide. There is a fourth type of flow battery in early stages of R&D that may enable a significant increase in energy density over aqueous systems by enabling operation in a wider voltage window than allowed by water: nonaqueous flow batteries.

#### 33.6.2.1 Vanadium Redox

The vanadium redox flow battery (VRB) was pioneered at the University of New South Wales, Australia, and has shown potentials for long cycle life and energy efficiencies of over 80% in large installations.<sup>10</sup> The VRB uses compounds of the element vanadium in both electrolyte tanks. The reaction chemistry at the positive electrode is

and at the negative electrode is

Using vanadium compounds on both sides of the ion-exchange membrane eliminates the possible problem of cross-contamination of the electrolytes and makes recycling easier.<sup>11</sup> As of 2005, two small, utility-scale VRB installations are operating: one 2.9 GJ unit on King Island, Australia, and one 7.2 GJ unit in Castle Valley, Utah.

### 33.6.2.2 Polysulfide Bromide

The polysulfide bromide battery (PSB) utilizes two salt solution electrolytes, sodium bromide (NaBr) and sodium polysulfide ( $\text{Na}_2\text{S}_x$ ). PSB electrolytes are separated in the battery cell by a polymer membrane that only passes positive sodium ions. Chemistry at the positive electrode is

and at the negative electrode is

The PSB battery is being developed by Canada's VRB Power Systems, Inc.<sup>12</sup> This technology is expected to attain energy efficiencies of approximately 75%.<sup>13</sup> Though the salt solutions themselves are only mildly toxic, a catastrophic failure by one of the tanks could release highly toxic bromine gas. Nevertheless, the Tennessee Valley Authority released a finding of no significant impact for a proposed, 430 GJ facility and deemed it safe.<sup>14</sup>

### 33.6.2.3 Zinc Bromide

In each cell of a zinc bromide (ZnBr) battery, two different electrolytes flow past carbon-plastic composite electrodes in two compartments separated by a microporous membrane. Chemistry at the positive electrode follows the equation:

and at the negative electrode:

During discharge, Zn and Br combine into zinc bromide. During charge, metallic zinc is deposited as a thin film on the negative electrode. Meanwhile, bromine evolves as a dilute solution on the other side of the membrane, reacting with other agents to make thick bromine oil that sinks down to the bottom of the electrolytic tank. During discharge, a pump mixes the bromine oil with the rest of the electrolyte. The zinc bromide battery has an energy efficiency of nearly 80%.<sup>15</sup>

Exxon developed the ZnBr battery in the early 1970s. Over the years, many GJ-scale ZnBr batteries have been built and tested. Meidisha demonstrated a 1 MW/14 GJ ZnBr battery in 1991 at Kyushu Electric Power Company. Some GJ-scale units are now available preassembled, complete with plumbing and power electronics.

#### 33.6.2.4 Nonaqueous Redox Flow

Current flow battery technologies depend on aqueous electrodes, a choice that limits energy densities to <40 Wh/L as a consequence of low solubilities of redox species and operating voltages that are bounded by water electrolysis.<sup>16</sup> Employing nonaqueous solvents offers a wider window of electrochemical stability that enables cell operation at dramatically higher potentials. Higher cell voltage (>3 V) leads to higher energy density, and typically to higher roundtrip efficiency as well, which together reduce the total cost of energy. Compared to aqueous flow systems, fewer stack layers, lower flow velocities, smaller tanks, and fewer ancillaries are required, which significantly reduces hardware costs and enhances system reliability. In order to capitalize on the inherent benefits of nonaqueous redox flow, several fundamental science challenges must be overcome.

Nonaqueous flow batteries fall into two broad classes of early investigation: solution phase systems, in which electroactive materials are dissolved in the electrolyte,<sup>17,18</sup> and suspensions of active intercalant hosts, which are essentially fluidized versions of standard solid-state electrodes found in current lithium ion batteries.<sup>19,20</sup>

#### 33.6.3 Electrolytic Hydrogen

Diatomic, gaseous hydrogen ( $H_2$ ) can be manufactured with the process of electrolysis; an electric current applied to water separates it into components  $O_2$  and  $H_2$ . The oxygen has no inherent energy value, but the HHV of the resulting hydrogen can contain up to 90% of the applied electric energy, depending on the technology.<sup>21</sup> This hydrogen can then be stored, and later combusted to provide heat or work, or power a fuel cell (see Chapter 27).

The gaseous hydrogen is low density and must be compressed to provide useful storage. Compression to a storage pressure of 350 bar, the value usually assumed for automotive technologies, consumes up to 12% of the hydrogen's HHV if performed adiabatically, though the loss approaches a lower limit of 5% as the compression approaches an isothermal ideal.<sup>22</sup> Alternatively, the hydrogen can be stored in liquid form, a process that costs about 40% of HHV using current technology, and that at best would consume about 25%. Liquid storage is not possible for automotive applications, because mandatory boil-off from the storage container cannot be safely released in closed spaces (i.e., garages).

Hydrogen can also be bonded into metal hydrides using an absorption process. The energy penalty of storage may be lower for this process, which requires pressurization to only 30 bar. However, the density of the metal hydride can be between 20 and 100 times the density of the hydrogen stored. Carbon nanotubes have also received attention as a potential hydrogen storage medium.<sup>23</sup> Hydrogen storage technologies are covered in more detail in Chapter 53.

---

### 33.7 Direct Electric Storage

#### 33.7.1 Ultracapacitors

A capacitor stores energy in the electric field between two oppositely charged conductors. Typically, thin conducting plates are rolled or stacked into a compact configuration with a dielectric between them. The dielectric prevents arcing between the plates and allows the plates to hold more charge, increasing the maximum energy storage.

The ultracapacitor—also known as supercapacitor, electrochemical capacitor, or electric double layer capacitor (EDLC)—differs from a traditional capacitor in that it employs a thin electrolyte, in the order of only a few angstroms, instead of a dielectric. This increases the energy density of the device. The electrolyte can be made of either an organic or an aqueous material. The aqueous design operates over a larger temperature range, but has a smaller energy density than the organic design. The electrodes are made of a porous carbon that increases the surface area of the electrodes and further increases energy density over a traditional capacitor.

Ultracapacitors' ability to effectively equalize voltage variations with quick discharges makes them useful for power quality management and for regulating voltage in automotive systems during regular driving conditions. Ultracapacitors can also work in tandem with batteries and fuel cells to relieve peak power needs (e.g., hard acceleration) for which batteries and fuel cells are not ideal. This could help extend the overall life and reduce life-time cost of the batteries and fuel cells used in HEV and EV. This storage technology also has the advantage of very high cycle life of greater than 500,000 cycles and a 10–12 year lifespan.<sup>24</sup> The limitations lie in the inability of ultracapacitors to maintain charge voltage over any significant time, losing up to 10% of their charge per day.

### 33.7.2 SMES

A superconducting magnetic energy storage (SMES) system is well suited in storing and discharging energy at high rates (high power.) It stores energy in the magnetic field created by direct current in a coil of cryogenically cooled, superconducting material. If the coil were wound using a conventional wire such as copper, the magnetic energy would be dissipated as heat due to the wire's resistance to the flow of current. The advantage of a cryogenically cooled, superconducting material is that it reduces electrical resistance to almost zero. The SMES recharges quickly and can repeat the charge–discharge sequence thousands of times without any degradation of the magnet. A SMES system can achieve full power within 100 ms.<sup>25</sup> Theoretically, a coil of around 150–500 m radius would be able to support a load of 18,000 GJ at 1000 MW, depending on the peak field and ratio of the coil's height and diameter.<sup>26</sup> Recharge time can be accelerated to meet specific requirements, depending on system capacity.

Because no conversion of energy to other forms is involved (e.g., mechanical or chemical), the energy is stored directly and round-trip efficiency can be very high.<sup>5</sup> SMES systems can store energy with a loss of only 0.1%; this loss is due principally to energy required by the cooling system.<sup>6</sup> Mature, commercialized SMES is likely to operate at 97%–98% round-trip efficiency and is an excellent technology for providing reactive power on demand.

---

## 33.8 Mechanical Energy Storage

### 33.8.1 Pumped Hydro

Pumped hydro is the oldest and largest of all of the commercially available energy storage technologies, with existing facilities up to 1000 MW in size. Conventional pumped hydro uses two water reservoirs, separated vertically. Energy is stored by moving water from the

lower to the higher reservoir, and extracted by allowing the water to flow back to the lower reservoir. Energy is stored according to the fundamental physical principle of potential energy. To calculate the stored energy in joules, use the formula:

$$E_s = Vdgh,$$

where

V is the volume of water raised ( $\text{m}^3$ )

d is the density of water ( $1000 \text{ kg/m}^3$ )

g is the acceleration of gravity ( $9.8 \text{ m/s}^2$ )

h is the elevation difference between the reservoirs (m) and is often referred to as the *head*

Though pumped hydro is by nature a mechanical energy storage technology, it is most commonly used for electric utility shaping. During off-peak hours, electric pumps move water from the lower reservoir to the upper reservoir. When required, the water flow is reversed to generate electricity. Some high dam hydro plants have a storage capability and can be dispatched as pumped hydro storage. Underground pumped storage, using flooded mine shafts or other cavities, is also technically possible but probably prohibitively expensive. The open sea can also be used as the lower reservoir if a suitable upper reservoir can be built at close proximity. A 30 MW seawater pumped hydro plant was first built in Yanbaru, Japan, in 1999.

Pumped hydro is most practical at a large scale with discharge times ranging from several hours to a few days. There is over 90 GW of pumped storage in operation worldwide, which is about 3% of global electric generation capacity.<sup>27</sup> Pumped storage plants are characterized by long construction times and high capital expenditure. Its main application is for utility shaping. Pumped hydro storage has the limitation of needing to be a very large capacity to be cost effective, but can also be used as storage for a number of different generation sites.

Efficiency of these plants has greatly increased in the last 40 years. Pumped storage in the 1960s had efficiencies of 60% compared with 80% for new facilities. Innovations in variable speed motors have helped these plants to operate at partial capacity, and greatly reduced equipment vibrations, increasing plant life.

### 33.8.2 Compressed Air

A relatively new energy storage concept that is implemented with otherwise mature technologies is compressed air energy storage (CAES). CAES facilities must be coupled with a combustion turbine, so they are actually a hybrid storage/generation technology.

A conventional gas turbine consists of three basic components: a compressor, combustion chamber, and an expander. Power is generated when compressed air and fuel burned in the combustion chamber drive turbine blades in the expander. Approximately 60% of the mechanical power generated by the expander is consumed by the compressor supplying air to the combustion chamber.

A CAES facility performs the work of the compressor separately, stores the compressed air, and, at a later time, injects it into a simplified combustion turbine. The simplified turbine includes only the combustion chamber and the expansion turbine. Such a simplified turbine produces far more energy than a conventional turbine from the same fuel, because there is potential energy stored in the compressed air. The fraction of output energy

beyond what would have been produced in a conventional turbine is attributable to the energy stored in compression.

The net efficiency of storage for a CAES plant is limited by the heat energy loss occurring at compression. The overall efficiency of energy storage is about 75%.<sup>28</sup>

CAES compressors operate on grid electricity during off-peak times, and use the expansion turbine to supply peak electricity when needed. CAES facilities cannot operate without combustion, because the exhaust air would exit at extremely low temperatures, causing trouble with brittle materials and icing. If 100% renewable energy generation is sought, biofuel could be used to fuel the gas turbines. There might still be other emissions issues, but the system could be fully carbon neutral.

The compressed air is stored in appropriate underground mines, caverns created inside salt rocks or possibly in aquifers. The first commercial CAES facility was a 290 MW unit built in Hundorf, Germany, in 1978. The second commercial installation was a 110 MW unit built in McIntosh, Alabama, in 1991. The third commercial CAES is a 2700 MW plant under construction in Norton, Ohio. This nine-unit plant will compress air to about 100 bar in an existing limestone mine 2200 ft (766 m) underground.<sup>29</sup> The natural synergy with geological caverns and turbine prime movers dictates that these be on the utility scale.

### 33.8.3 Flywheels

Most modern flywheel energy storage systems consist of a massive rotating cylinder (comprised of a rim attached to a shaft) that is supported on a stator by magnetically levitated bearings that eliminate bearing wear and increase system life. To maintain efficiency, the flywheel system is operated in a low vacuum environment to reduce drag. The flywheel is connected to a motor/generator mounted onto the stator that, through some power electronics, interacts with the utility grid.

The energy stored in a rotating flywheel, in joules, is given by

$$E = \frac{1}{2}I\omega^2,$$

where

$I$  is the flywheel's moment of inertia ( $\text{kg}\cdot\text{m}^2$ )

$\omega$  is its angular velocity ( $1/\text{s}^2$ )

$I$  is proportional to the flywheel's mass, so energy is proportional to mass and the square of speed. In order to maximize energy capacity, flywheel designers gravitate toward increasing the flywheel's maximum speed rather than increasing its moment of inertia. This approach also produces flywheels with the higher specific energy.

Some of the key features of flywheels are low maintenance, a cycle life of better than 10,000 cycles, a 20-year lifetime, and environmentally friendly materials. Low speed, high mass flywheels (relying on  $I$  for energy storage) are typically made from steel, aluminum, or titanium; high speed, low mass flywheels (relying on  $\omega$  for energy storage) are constructed from composites such as carbon fiber.

Flywheels can serve as a short-term ride-through before long-term storage comes online. Their low energy density and specific energy limit them to voltage regulation and UPS capabilities. Flywheels can have energy efficiencies in the upper 90% range, depending on frictional losses.

### 33.9 Direct Thermal Storage

Direct thermal technologies, though they are storing a lower grade of energy (heat, rather than electrical or mechanical energy), can be useful for storing energy from systems that provide heat as a native output (e.g., solar thermal, geothermal), or for applications where the energy's commodity value is heat (e.g., space heating, drying).

While thermal storage technologies can be characterized by specific energy and energy density like any other storage technology, they can also be characterized by an important, additional parameter, the delivery temperature range. Different end uses have more or less allowance for wide swings of the delivery temperature. Also, some applications require a high operating temperature that only some thermal storage media are capable of storing.

Thermal storage can be classified into two fundamental categories: sensible heat storage and latent heat storage. Applications that have less tolerance for temperature swings should utilize a latent heat technology.

Input to and output from heat energy storage is accomplished with heat exchangers. The following discussion focuses on the choice of heat storage materials; the methods of heat exchange will vary widely depending on properties of the storage material, especially its thermal conductivity. Materials with higher thermal conductivity will require a smaller surface area for heat exchange. For liquids, convection or pumping can reduce the need for a large heat exchanger. In some applications, the heat exchanger is simply the physical interface of the storage material with the application space (e.g., phase change drywall, see the following).

#### 33.9.1 Sensible Heat

Sensible heat is the heat that is customarily and intuitively associated with a change in temperature of a massive substance. The heat energy  $E_s$  stored in such a substance is given by

$$E_s = (T_2 - T_1)cM,$$

where

$c$  is the specific heat of the substance (J/kg-°C)

$M$  is the mass of the substance (kg)

$T_1$  and  $T_2$  are the initial and final temperatures, respectively (°C)

The specific heat  $c$  is a physical parameter measured in units of heat per temperature per mass: substances with the ability to absorb heat energy with a relatively small increase in temperature (e.g., water) have a high specific heat, while those that get hot with only a little heat input (e.g., lead) have a low specific heat. Sensible heat storage is best accomplished with materials having a high specific heat.

##### 33.9.1.1 Liquids

Sensible heat storage in a liquid is with very few exceptions accomplished with water. Water is unique among chemicals in having an abnormally high specific heat of 4186 J/kg-K, and furthermore has a reasonably high density. Water is also cheap and safe. It is the preferred choice for most nonconcentrating solar thermal collectors.

Liquids other than water may need to be chosen if the delivery temperature must be higher than 100°C, or if the system temperature can fall below 0°C. Water can be raised to temperatures higher than 100°C, but the costs of storage systems capable of containing the associated high pressures are usually prohibitive. Water can be mixed with ethylene glycol or propylene glycol to increase the useful temperature range and prevent freezing.

When a larger temperature range than that afforded by water is required, mineral, synthetic, or silicone oils can be used instead. The trade-offs for the increased temperature range are higher cost, lower specific heat, higher viscosity (making pumping more difficult), flammability, and, in some cases, toxicity.

For very high temperature ranges, salts are usually preferred, which balance a low specific heat with a high density and relatively low cost. Sodium nitrate has received the most prominent testing for this purpose, in the U.S. Department of Energy's *Solar Two* project located in Barstow, California.

Liquid sensible heat storage systems are strongly characterized not just by the choice of heat transfer fluid, but also by the system architecture. Two-tank systems store the cold and hot liquids in separate tanks (Figure 33.4). Thermocline systems use a single tank with cold fluid entering or leaving the bottom of the tank and hot fluid entering or leaving the top (Figure 33.5). Thermocline systems can be particularly low cost, because they minimize the required tank volume, but require careful design to prevent mixing of the hot and cold fluid.

One particularly interesting application of the thermocline concept is nonconvecting, salinity-gradient solar ponds, which employ the concept in reverse. Solar ponds are both an energy collection and energy storage technology. Salts are dissolved in the water to introduce a density gradient, with the densest (saltiest) water on the bottom and lightest (freshest) on top. Solar radiation striking the dark bottom of the pond heats the densest water, but convection of the heated water to the top cannot occur, because the density gradient prevents it. Salinity-gradient ponds can generate and store hot water at temperatures approaching 95°C.<sup>30</sup>

**FIGURE 33.4**

Two-tank thermal storage system; hot water is shown in gray and cold water is shown in white. When the heat source is producing more output than required for the load, valve H is turned to deposit hot liquid in the tank. When it is producing less than required for the load, the valve is turned to provide supplemental heat from the storage tank. Note that each tank must be large enough to hold the entire fluid capacity of the system.

**FIGURE 33.5**

Thermocline storage tank. Thermocline storage tanks are tall and narrow to encourage the gravity-assisted separation of hot and cold fluid, and include design features (especially at the input/output connectors) to prevent mixing in the stored fluid.

### 33.9.1.2 Solids

Storage of sensible heat in solids is usually most effective when the solid is in the form of a bed of small units, rather than a single mass. The reason is that the surface-to-volume ratio increases with the number of units, so that heat transfer to and from the storage device is faster for a greater number of units. Energy can be stored or extracted from a thermal storage bed by passing a gas (such as air) through the bed. Thermal storage beds can be used to extract and store the latent heat of vaporization from water contained in flue gases.

Though less effective for heat transfer, monolithic solid storage has been successfully used in architectural applications and solar cookers.

### 33.9.2 Latent Heat

Latent heat is absorbed or liberated by a phase change or a chemical reaction, and occurs at a constant temperature. A phase change means the conversion of a homogenous substance among its various solid, liquid, or gaseous phases. One very common example is boiling water on the stovetop: though a substantial amount of heat is absorbed by the water in the pot, the boiling water maintains a constant temperature of 100°C. The latent heat  $E_s$  stored through a phase change is

$$E_s = lM,$$

where

$M$  is the mass of material undergoing a phase change (kg)

$l$  is the latent heat of vaporization (for liquid–gas phase changes) or the latent heat of fusion (for solid–liquid phase changes), in units of energy per mass (J/kg)

Conservation of energy dictates that the amount of heat absorbed in a given phase change is equal to the amount of heat liberated in the reverse phase change.

Though we use the term *phase change* to refer only to straightforward freezing and melting (Section 33.9.2.1), many sources use the term *phase change materials (PCMs)* to refer to any substance storing latent heat (including those described in Sections 33.9.2.2 and 33.9.2.3 as well).

### 33.9.2.1 Phase Change

Practical energy storage systems based on a material phase change are limited to solid–solid and solid–liquid phase changes. Changes involving gaseous phases are of little interest due to the expense associated with containing a pressurized gas, and difficulty of transferring heat to and from a gas.

Solid–solid phase changes occur when a solid material reorganizes into a different molecular structure in response to temperature. One particularly interesting example is lithium sulfate ( $\text{Li}_2\text{SO}_4$ ) that undergoes a change from a monoclinic structure to a face-centered cubic structure at  $578^\circ\text{C}$ , absorbing  $214 \text{ J/g}$  in the process, more than most solid–liquid phase changes.<sup>31</sup>

Some common chemicals, their melting points, and heats of fusion are listed in Table 33.4. Fatty acids and paraffins received particular attention in the 1990s as candidate materials for the heat storage component of phase change drywall, a building material designed to absorb and release heat energy near room temperature for the purpose of indoor temperature stabilization.<sup>32</sup> In this application, solids in the drywall maintain the material's structural integrity even though the PCMs are transitioning between solid and liquid states.

**TABLE 33.4**

Melting Points and Heats of Fusion for Solid–Liquid Phase Changes

	Melting Point ( $^\circ\text{C}$ )	Heat of Fusion ( $\text{J/g}$ )
Aluminum bromide	97	42
Aluminum iodide	191	81
Ammonium bisulfate	144	125
Ammonium nitrate	169	77
Ammonium thiocyanate	146	260
Anthracene	96	105
Arsenic tribromide	32	37

### 33.9.2.2 Hydration–Dehydration Reactions

In this process, a salt or similar compound forms a crystalline lattice with water below a *melting point* temperature, and at the melting point, the crystal dissolves in its own water of hydration. Sodium sulfate ( $\text{Na}_2\text{SO}_4$ ) is a good example, forming a lattice with ten molecules of water per molecule of sulfate ( $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ ) and absorbing 241 J/g at 32°C.<sup>33</sup>

Hydration–dehydration reactions have not found significant application in renewable energy systems, though they too have been a candidate for phase change drywall.

### 33.9.2.3 Chemical Reaction

A wide variety of reversible chemical reactions are available that release and absorb heat (e.g., Ref. [34]). The principal feature of this category of latent heat storage technologies is the ability to operate at extremely high temperatures, in some cases over 900°C. Extremely high temperature applications have focused primarily on fossil and advanced nuclear applications; to date, none of these chemical methods of heat storage have been deployed in commercial renewable energy applications.

## 33.10 Thermochemical Energy Storage

This section provides an overview of biomass storage technologies from an energetic perspective only. Additional details on biomass fuels are presented in Chapters 39, 49, and 50.

### 33.10.1 Biomass Solids

Plant matter is a storage medium for solar energy. The input mechanism is photosynthesis conversion of solar radiation into biomass. The output mechanism is combustion of the biomass to generate heat energy.

Biologists measure the efficiency of photosynthetic energy capture with the metric *net primary productivity* (NPP), which is usually reported as a yield in units similar to dry Mg/ha-yr (dry metric tons per hectare per year.) However, to enable comparisons of biomass with other solar energy storage technologies, it is instructive to estimate a *solar efficiency* by multiplying the NPP by the biomass heating value (e.g., MJ/dry Mg) and then dividing the result by the average insolation at the crop's location (e.g., MJ/ha-yr). The solar efficiency is a unitless value describing the fraction of incident solar energy ultimately available as biomass heating value. Most energy crops capture between 0.2% and 2% of the incident solar energy in heating value of the biomass; Table 33.5 shows examples of solar efficiencies estimated for a number of test crops.

The principal method for extracting useful work or electricity from biomass solids is combustion. Hence, the solar efficiencies listed in Table 33.5 need to be multiplied by the efficiency of any associated combustion process to yield a net solar efficiency. For example, if a boiler-based electric generator extracts 35% of the feedstock energy as electricity, and the generator is sited at a switchgrass plantation achieving 0.30% solar capture efficiency on a mass basis, the electric plant has a net solar efficiency of  $0.30\% \times 35\% = 0.11\%$ . Because biomass is a very low efficiency collector of solar energy, it is very land-intensive compared to photovoltaic or solar thermal collectors, which deliver energy at solar efficiencies

TABLE 33.5

Primary Productivity and Solar Efficiency of Biomass Crops

Location	Crop	Yield (Dry Mg/ha-Year)	Average Insolation (W/m <sup>2</sup> )	Solar Efficiency (%)
Alabama	Johnsongrass	5.9	186	0.19
Alabama	Switchgrass	8.2	186	0.26
Minnesota	Willow and hybrid poplar	8–11	159	0.30–0.41
Denmark	Phytoplankton	8.6	133	0.36

over 20% (see Chapters 43 and 47 for a full discussion). However, the capacity of land to store standing biomass over time is extremely high, with densities up to several hundred Mg/ha (and therefore several thousand GJ/ha), depending on the forest type. Standing biomass can serve as very long-term storage, though multiple stores need to be used in order to accommodate fire risk. For short-term storage, woody biomass may be dried, and is frequently chipped or otherwise mechanically treated to create a fine and homogenous fuel suitable for burning in a wider variety of combustors.

### 33.10.2 Ethanol

Biomass is a more practical solar energy storage medium if it can be converted to liquid form. Liquids allow for more convenient transportation and combustion, and enable

extraction on demand (through reciprocating engines) rather than through a less dispatchable, boiler- or turbine-based process. This latter property also enables its use in automobiles.

Biomass grown in crops or collected as residue from agricultural processes consists principally of cellulose, hemicellulose, and lignin. The sugary or starchy by-products of some crops such as sugarcane, sugar beet, sorghum, molasses, corn, and potatoes can be converted to ethanol through fermentation processes, and these processes are the principal source of ethanol today. Starch-based ethanol production is low efficiency, but does succeed in transferring about 16% of the biomass heating value to the ethanol fuel.<sup>35</sup>

When viewed as a developing energy storage technology, ethanol derived from cellulose shows much more promise than the currently prevalent starch-based ethanol.<sup>36</sup> Cellulosic ethanol can be manufactured with two fundamentally different methods: either the biomass is broken down to sugars using a hydrolysis process, and then the sugars are subjected to fermentation, or the biomass is gasified (see the following), and the ethanol is subsequently synthesized from this gas with a thermochemical process. Both processes show promise to be far cheaper than traditional ethanol manufacture via fermentation of starch crops, and will also improve energy balances. For example, it is estimated that dry sawdust can yield up to 224 L/Mg of ethanol, thus recovering about 26% of the HHV of the sawdust.<sup>37</sup> Since the ethanol will still need to be combusted in a heat engine, the gross, biomass-to-useful-work efficiency will be well below this. In comparison, direct combustion of the biomass to generate electricity (per the discussion in Section 33.10.1) makes much more effective use of the biomass as an energy storage medium. Hence, the value of ethanol as an energy storage medium lies mostly in the convenience of its liquid (rather than solid) state.

### 33.10.3 Biodiesel

As starch-based ethanol is made from starchy by-products, most biodiesel is generated from oily by-products. Some of the most common sources are rapeseed oil, sunflower oil, and soybean oil. Biodiesel yields from crops like these range from about 300 to 1000 kg/ha-year, but the crop as a whole produces about 20 Mg/ha-year, meaning that the gross solar capture efficiency for biodiesel from crops ranges between 1/20 and 1/60 the solar capture efficiency of the crop itself. Because of this low solar capture efficiency, biomass cannot be the principal energy storage medium for transportation needs.<sup>38</sup>

Biodiesel can also be manufactured from waste vegetable or animal oils; however, in this case, the biodiesel is not functioning *per se* as a solar energy storage medium, so it is not further treated in this work.

### 33.10.4 Syngas

Biomass can be converted to a gaseous state for storage, transportation, and combustion (or other chemical conversion).<sup>39</sup> Gasification processes are grouped into three different classes: *pyrolysis* is the application of heat in anoxic conditions; *partial oxidation* is combustion occurring in an oxygen-starved environment; *reforming* is the application of heat in the presence of a catalyst. All three processes form *syngas*, a combination of methane, carbon monoxide, carbon dioxide, and hydrogen. The relative abundances of the gaseous products can be controlled by adjusting heat, pressure, and feed rates. The HHV of the resulting gas can contain up to 78% of the original HHV of the feedstock, if the feedstock is dry.<sup>40</sup> Compositions and heating values of two example syngases are listed in [Table 33.3](#).

The equivalent of up to 10% of the gas HHV will be lost when the gas is pressurized for transportation and storage. Even with this loss, gasification is a considerably more efficient method than ethanol manufacture for transferring stored solar energy to a nonsolid medium.

### 34.1 Introduction

Global prosperity depends upon efficient and affordable energy. Without a major shift in the way energy systems are planned, built, and operated, the world will invest trillions of dollars in conventional electric infrastructure over the next 20 years to meet expected growth.<sup>32,33</sup>

The future electric system will incorporate information technology in revolutionary ways, much as information technology has transformed other aspects of business because, fundamentally, “bits are cheaper than iron.” The impact of the information age on the electric system will allow nations to realize the benefits already achieved by leading-edge industries that use real-time information, distributed e-business systems and market efficiencies to minimize the need for inventory and infrastructure and to maximize productivity, efficiency, and reliability.

With the help of information technologies, the creation of a distributed, yet integrated, system will empower consumers to participate in energy markets—the key to stabilizing prices. Market participants from utilities to new third parties to consumers will

create value by developing and deploying solutions that cross enterprise and regulatory boundaries. At the same time, this transformation of the energy system addresses the urgent need to enhance national security. A distributed, network-based electric system will reduce single-point vulnerabilities and allow the grid to become “self-healing” by incorporating autonomic system reconfiguration in response to human-caused or natural disruptions.

Deploying information technology in a highly connected world will maximize the use of existing assets and minimize the need for new assets. To do this, the future electric system will

- Provide the incentive for customer and third-party assets to collaborate with existing grid assets to control costs and improve reliability by revealing the true time- and location-dependent value of electricity
- Provide the basis for collaboration by allowing the revealed values to be shared in real time by leveraging broadband communications that are rapidly becoming ubiquitous
- Provide the means to take advantage of the opportunities for collaboration and capture value in return through rapid advances in distributed controls and e-business applications

Much of the challenge and opportunity presented by these solutions is that their value proposition often involves crossing enterprise and regulatory boundaries. This means that nontechnical challenges must be addressed to support policy changes and business models that allow new technology and operational practices to flourish.

Information technology will profoundly transform the planning and operation of the power grid, just as it has changed business, education, and entertainment. It will form the “nervous system” that integrates new distributed technologies—demand response, distributed generation, and storage—with traditional grid generation, transmission, and distribution assets to share responsibility for managing the grid as a collaborative “society” of devices.<sup>35–38</sup>

---

## **34.2 Technology Advancements for Electricity Delivery**

The following sections describe new technologies, or concepts that are becoming more economically feasible, for application to improved operation of the electric system. These are summarized in three general categories: distributed resources, transmission and distribution resources, information and communications technology, and control, applications, and operational paradigms.

### **34.2.1 Distributed Resources**

Distributed resources are physical, capital assets that generate, store, or consume electric power at the fringes of the electric delivery system. Traditionally, these resources have not been broadly considered or deployed as transmission and distribution assets; however, significant efforts are underway to take advantage of such existing resources, and to

provide motivation for future installations that can further benefit the system.<sup>34</sup> This section describes several of the resources that fall into this category.

*End use control:* Manual or automated control of end use systems to reduce or defer electric power use is an important element in active measures for enhancing delivery operations. Automatic load shedding (under-frequency, under-voltage), operator-initiated interruptible load, demand-side management programs, voltage reduction, and other load curtailment strategies have long been an integral part of coping with unforeseen contingencies as a last resort, and/or as a means of assisting the system during high-stress, overloaded conditions. Advances in load control technology will allow end use systems to play a more active role in the day-to-day operations of the electric system as well as create a more graceful response to emergency conditions.

*Intelligent building systems:* Intelligent building systems are emerging in factories, commercial buildings, and now residential facilities. These systems save energy by increasing efficient operations. Coordinated utilization of cooling, heating, and electricity in these establishments can significantly reduce energy consumption. Operated in a system that supports price-responsive demand programs, intelligent building systems can locally optimize operations to the benefit of larger system concerns.

*System-sensitive appliances:* System-sensitive appliances are emerging with the ability to measure and respond to frequency or voltage conditions or to react to simple signals, such as energy prices or emergency conditions. Washers, dryers, HVAC units, and other devices now come equipped with onboard intelligent systems that have the potential to respond to energy signals (see Section 34.3).

*Distributed generation (DG):* Fuel cells, microturbines, reciprocating engines, and small renewable generation such as wind and solar power, are increasingly being deployed across the system. DG can supply local load or sell into the system and offers owners self-determination. As these distributed resources increase in number, they can become a significant resource for reliable system operations. Their vast numbers teamed with end use systems adds a further dimension to the advantages of controllable load discussed above.

*Combined-heating power (CHP):* Combined-heating-power and buildings-cooling-heating-power (BCHP) are systems that combine distributed fuel-fired generation with equipment that recovers waste heat for heating or cooling at the for a building, facility, or district, maximizing the utilization of fuel.

*Renewable generation:* Renewable generation includes small wind-power, photovoltaic solar, and other renewable generation systems connected at the distribution level. Note that large wind farms are similar to central generation in that they do not displace the need for transmission and distribution assets. Unlike distributed fuel-fired generation, renewable generation is difficult to dispatch coincident with the needs of the grid, unless a storage system is involved.

*Local energy storage:* Systems that store energy locally for the benefit of end use systems can also be aggregated to the benefit of larger system operation concerns.

*Electric storage:* Systems that store electricity for later discharge include traditional batteries, flow batteries, supercapacitors, flywheels, and extend to uninterruptible power supplies modified to support local system operations.

*Thermal storage:* These systems store energy used for heat or cooling, usually in the form of hot or chilled water or ice, for later use in a building or an industrial process. The ability to “charge” to or “draw” from these resources provides flexibility to the timing of electricity use.

*Direct DC end use:* Returning to the days of Edison, equipment within customer premises are emerging that distribute and use DC power directly (instead of converting it from AC with attendant cost and inefficiencies) such as computers and electronic equipment, fans, pumps and other equipment with variable speed drives, battery chargers, and uninterruptible power supplies. DC distribution is especially useful if onsite generation inherently involves DC power directly or at an intermediate stage, such as from photovoltaics, microturbines, and fuel cells.

*Local voltage regulation:* Transformers, capacitors, or power electronics equipment that maintains voltage at the customer meter at a specified nominal level, can reduce wasted consumption from over-voltage while allowing higher-than-nominal distribution voltages to increase system throughput during times of peak demand.

*Advanced energy efficiency:* Investments in improved equipment, building structure, or industrial processes can reduce the quantity of electricity consumed yet provide equivalent service. Efficiency benefits occur with sensitivity to the end use being served, but are indifferent to the needs of the grid.

### 34.2.2 Transmission and Distribution Resources

The transmission and distribution (T&D) system of the future must not only have increased capacity to support the market demand for energy transactions, it must also be flexible to adapt to alterations in energy delivery patterns. These patterns change at various timescales: hourly, daily, weekly, and seasonally. The delivery system must also adapt to operation patterns dictated by the evolving geographical distribution of load and generation. As generation siting and dispatch decision making become less predictable and demand-side resources play a larger role in system operations, new technologies that afford transmission and distribution planners a wider range of alternatives for deployment of power become more attractive. This section discusses some of the newer hardware technologies that are being researched and deployed to reinforce grid operations. The list presented is not exhaustive.<sup>39–41</sup>

*Conductors:* The siting of the new transmission will continue to be a major challenge. Getting the most out of existing rights of way minimizes the need for new lines and rights of way and can minimize the societal concerns associated with visual pollution and high-energy EMFs.

*Advanced composite conductors:* Usually, transmission lines contain steel-core cables that support strands of aluminum wires that are the primary conductors of electricity. New cores developed from composite materials are proposed to replace the steel core. A new core consisting of composite glass-fiber materials shows promise as stronger than steel-core aluminum conductors while being 50% lighter in weight with up to 2.5 times less sag. The reduced weight and higher strength equate to greater current-carrying capability. This technology can be integrated in the field by most existing reconductoring equipment.

*High-temperature superconducting (HTSC) technology:* The conductors in HTSC devices operate at extremely low resistances. They require refrigeration (generally liquid nitrogen) to supercool ceramic superconducting materials. The technology is applicable to transmission lines, transformers, reactors, capacitors, and current limiters. HTSC cable occupies less space (AC transmission lines bundle three phase together; transformers and other equipment occupy smaller footprint for same level of capacity). Exposure to EMFs can be reduced with buried cables and this also counteracts visual pollution issues. Transformers can reduce or eliminate cooling oils that, if spilled, can damage the environment. For now, the maintenance costs remain high.

*Below-surface cables:* The underground cable advancements are employing fluid-filled polypropylene paper laminate (PPL) and extruded dielectric polyethylene (XLPE) cable technologies. Other approaches, such as gas-insulated transmission lines (GIL), are being researched and hold promise for future applications. Although there have been significant improvements in the technology, manufacturing costs remain high.

*T&D configurations:* Advances are being made in the configuration of transmission lines. New design processes coupled with powerful computer programs can optimize the height, strength, and positioning of transmission towers, insulators, and associated equipment in order to meet engineering standards appropriate for the conductor (e.g., distance from ground and tension for a given set of weather parameters).

*Tower and pole design tools:* A set of tools is emerging to analyze upgrades to existing transmission facilities or the installation of new facilities to increase their power-transfer capacity and reduce maintenance. Unused potential can be discovered in existing facilities to enhance upgrades, whereas new facilities can be engineered to closer design tolerances. Visualization techniques are adding the regulatory and public review cycles.

*Modular equipment:* One way to gain flexibility for changing market and operational situations is to develop standards for the manufacture and integration of modular equipment. This can reduce overall the time and expense for transmission systems to adapt to the changing economic and reliability landscape.

*T&F system devices:* Implemented throughout the system, these devices include capacitors, phase shifters, static VAR compensators (SVCs), thyristor-controlled series capacitors (TCSC), thyristor-controlled dynamic brakes, and other similar devices. Used to adjust system impedance, these devices can increase the delivery system's transfer capacity, support bus voltages by providing reactive power, or enhance dynamic or transient stability.

*HVDC:* With active control of real and reactive power transfer, HVDC can be modulated to damp oscillations or provide power-flow dispatch independent of voltage magnitudes or angles (unlike conventional AC transmission). HVDC runs independent of system frequency and can control the amount of power sent through the line. This latter benefit is the same as for FACTS devices discussed below. The high cost of converter equipment and its maintenance limits the application; however, as these costs continue to drop, the number of implementations will rise. Proposals have been made for DC application at the distribution level. The military continues to advance the technology in shipboard systems and mobile land-based facilities.

*Flexible AC transmission system (FACTS):* FACTS devices use power electronics to adjust the apparent impedance of the system. Capacitor banks are applied at loads and substations to provide capacitive reactive power to offset the inductive reactive power typical of most power system loads and transmission lines. With long inter-tie transmission lines, series capacitors are used to reduce the effective impedance of the line. By adding thyristors to both of these types of capacitors, actively controlled reactive power is available using static VAR compensators and thyristor-controlled series compensators, which are shunt-and series-controlled capacitors, respectively. The thyristors are used to adjust the total impedance of the device by switching individual modules. Unified power-flow controllers (UPFCs) also fall into this category. Phase shifters are transformers configured to change the phase angle between buses; they are particularly useful for controlling the power flow on the transmission network. Adding thyristor control to the various tap settings of the phase-shifting transformer, permits continuous control of the effective phase angle (and thus control of power flow). As with HVDC, the power electronics used in these devices are expensive in price and maintenance, but costs are dropping.

*T&D energy storage:* The traditional function of an energy storage device is to save production costs by holding cheaply generated off-peak energy that can be dispatched during peak consumption periods. By virtue of its attributes, energy storage can also provide effective power system control with modest incremental investment. Different dispatch modes can be superimposed on the daily cycle of energy storage, with additional capacity reserved for the express purpose of providing these control functions. Storage at the bulk system level also benefits the integration of intermittent renewable resources such as wind and solar power. The loss of efficiency between converting electricity into and out of storage is an important consideration in deploying these resources.

*Batteries:* Large battery systems use converters to transform the DC in the storage device to the AC of the power grid. Converters also operate in the opposite direction to recharge the batteries. Battery converters use power electronics that, by the virtue of their ability to change the power exchange rapidly, can be utilized for a variety of real-time control applications ranging from enhancing transient stability to preconditioning the area control error for automatic generator control enhancement. The expense of manufacturing and maintaining batteries has limited their impact in the industry.

*Superconducting magnetic energy storage (SMES):* SMES uses cryogenic technology to store energy by circulating current in a superconducting coil. SMES devices are efficient and compact because of their superconductive properties. As with the superconducting equipment mentioned above, SMES entails costs for the cooling system, special protection, and the specialized skills required to maintain the device.

*Pumped hydro and compressed air storage:* Pumped hydro consists of large ponds with turbines that can be run in either pump or generation modes. During periods of light load (e.g., night) excess, inexpensive capacity drives the pumps to fill the upper pond. During heavy-load periods, the water generates electricity into the grid. Compressed air storage uses the same principle except that large, natural underground vaults are used to store air under pressure during light-load periods. Pumped hydro, like any hydro generation project, requires significant space and has corresponding ecological impact. Compressed air storage systems require special geological formations.

*Flywheels:* Flywheels spin at high velocity to store energy. As with pumped hydro or compressed air storage, the flywheel is connected to a motor that either accelerates the flywheel to store energy or draws energy to generate electricity. Superconductivity technology can also be deployed to increase efficiency.

### 34.2.3 Information and Communications Technology

Automation and the ability to coordinate intelligent systems across wide areas are transforming all areas of our economy. The electric system is leveraging advances in generally available information and communication resources to enhance its operational effectiveness and incorporate new participants at the fringes of the system in operations.

*Communication media:* Wireless, power line carrier, cable, fiber, and other forms of broadband communication to delivery system components and end use premises is beginning to carry the information needed to implement new applications such as, consumption data, sensor data on grid conditions, and e-commerce information including service offerings, prices, contract terms, and incentives.

*Information security:* Technology that provides secure and reliable communications is essential to prevent intrusion by unauthorized parties or those without a need or right to know specific information.

*Privacy and authentication:* Grid operators, consumers and businesses all demand technology that ensures the privacy of information is maintained and the identity of participants is unambiguous.

*E-commerce transactions:* Technology that manages a multitude of small financial transactions in an auditable and traceable way will provide the financial incentive for day-to-day, moment-by-moment collaboration of end users with the grid (e.g., micropayments).

*Real-time monitoring:* The capability of the electricity grid is restricted through a combination of the limitations on individual devices and the composite capacity of the system. Improving monitoring to determine these limits in real time and to measure the system state directly can increase grid capability.

*Power-system device sensors:* Advancement in sensor technology is enabling dynamic ratings on the use of T&D resources. This includes the measurement of conductor sag, transformer coil temperature, and underground cable monitoring and diagnostics.

*System-state sensors:* Technology advancements are improving the operational view of large regions of the power network. Power-system monitors collect essential signals (key power flows, bus voltages, alarms, etc.) from local monitors and make them available to site operation functions. This provides regional surveillance over important parts of the control system to verify system performance in real time. Sample rates and data quality is increasing as costs decrease. For example, phasor measurement units (PMUs) are synchronized digital transducers that stream data, in real time, to phasor data concentrators (PDC). The general functions and topology for this network resemble those for dynamic monitor networks. Data quality for phasor technology is trustworthy, and secondary processing of the acquired phasor information can provide a broad range of signal types.

*Advanced meters:* Electric usage meters at customer premises are being replaced with technology that not only measures the energy usage, but also provides flexible interval energy monitoring and real-time power measurement to address needs such as peak usage, and power quality.

---

### 34.3 Control, Applications, and Operational Paradigms

The technologies summarized in the previous sections can be integrated into the electric system in a cooperative manner to address many applications: existing, proposed, and yet to be invented. There are many potential applications; some emerging ones are listed below and organized by end use, distribution, transmission, electricity service provider, and market operations.

#### 34.3.1 End Use Operations and Planning

The management of end use resources in factories, commercial buildings, and residential facilities offer arguably the greatest area for advancement and contribution to system operations. Some important applications include the following:

- *Customer information gateways:* Information portals that support two-way communications, including real-time price signals and long-term contracts, across the customer enterprise boundary to suppliers, grid operators, and other third parties.
- *Demand response and energy management systems:* Controls that optimize the scheduling of energy use by appliances, equipment, and processes to minimize overall costs for electricity and respond to incentives from the service providers to curtail loads at times of peak demand or grid distress.
- *System-sensitive appliances, equipment, and processes:* Controls that autonomously sense disturbances in grid frequency and voltage, directing end use devices to immediately curtail their demand for periods of up to a few minutes (or, conversely, turning things like heating elements on to soak up momentary fluctuations of excess power) to prevent or arrest cascading blackouts. They also delay device restart after a voltage collapse or a blackout, easing service restoration by preventing the surge in demand from devices that have been without power for a while.
- *Autonomous agents for power purchases:* Software serving as the trading agent on behalf of customers, searching market opportunities and arranging for the lowest cost suppliers, including subsequently auditing power bills to ensure fair play.

#### 34.3.2 Distribution Operations and Planning

- *Automated meter reading:* A smart meter allows the customer and their suppliers to access the electric meter to enable automated meter reading for billing and other purposes as well as access to consumption data by end use energy management systems.
- *Distribution automation:* Advanced distribution grid management systems that optimize supply voltage, manage peak demands by reconfiguring feeders to switch customers from one supply point to another, minimize the number of customers

affected by outages, and accelerate outage restoration. This includes advanced protection schemes that adapt protection device settings based on operating conditions.

- *Fault location and isolation:* Use advanced sensing and communications to better identify the location of faults, then invoke distribution automation capabilities to reconfigure feeders, safely reenergize as much of the affected region as possible, and inform work crews to repair the problem. Diagnostics and fault location tools for underground cables represent an important aspect of this area.
- *Distribution capacity marketplaces:* Software that projects the need for new distribution capacity, posting the cost of required upgrades and allowing customers and third parties to offer distributed resource projects (such as distributed generation, efficiency, and demand response) to defer or avoid construction; then operating those resources through local market signals or incentives to manage net demand at the capacity constraint.
- *Distributed generation for reactive power support and other ancillary services:* Software that manages customer-owned distributed generators to support the power grid by supplying reactive power in addition to real power and other ancillary services like spinning and nonspinning reserves, via direct dispatch based on prearranged contracts or indirect dispatch through markets or incentives.

### 34.3.3 Transmission Operations and Planning

- *Transactive control for transmission grids:* Systems for trading real-time transmission rights, analogous to automated stock market trading systems, that allow market signals to cause suppliers and load serving entities to shift or curtail wheeling of power from one region to another, effectively reconfiguring the power grid in real time in response to a potential or pending crisis.
- *Substation automation:* Device-level intelligence combines with high-speed, reliable communications to improve operations effectiveness. For example, transformer tap changes will coordinate with capacitor banks to perform voltage or reactive power control functions. More and better quality information is used locally for adaptive relay protection schemes that change their settings based on present system configuration information. Information exchanged between neighboring substations can be used to further coordinate system protection schemes and economic operation.
- *Regional control:* On a regional level, remedial action schemes can adaptively arm themselves based on updated information from several points in the system. Regional control centers can also coordinate the transmission operating configuration based on gathering better information from the field. For example, the results from system studies, such as contingency analysis and optimal power flow can make use of dynamic line ratings that are regularly updated based on weather forecasts and sag measurements from the field.

### 34.3.4 Electricity Service Provider Operations and Planning

- *Differentiating customer service levels:* Systems that integrate demand response, distribution automation, and local distributed generation to supply premium reliability service to customers that require it, providing digital quality power to those willing to pay a premium without “gold-plating” the system for other customers satisfied with current service.

- *Emergency end use curtailment:* Communications and control software that broadcasts emergency status information and leverages demand response capabilities to ration power to customers on a prearranged basis, providing power for critical customers and end uses while curtailing less critical demand to match the available supply; the intent is for everyone to have some power in a crisis rather than using rolling blackouts, for instance.

### 34.3.5 Market Operations and Forecasting

- *Market operations:* Software that operates markets and incentives that engage distributed resources and demand response to manage peak demands and ancillary services in supply, transmission, and local distribution systems.
- *Load forecasters:* Algorithms that provide continually updated, adaptive predictions of the demand for electricity at various levels in the system ranging from end use to distribution and transmission, as it responds to changes in conditions such as weather and price; based on techniques ranging from statistical methods and neural networks to engineering model parameter estimation.

---

## 34.4 System-Sensitive Appliances

The abundance of information, including price signals and grid conditions, will allow demand-response technologies to play a significant role in a virtual energy infrastructure. Consider that regardless of time of day or even time of year, about 20% of the load on the electric system is from consumer appliances that cycle on and off, such as heating, air conditioning, water heaters, and refrigerators. At the same time, generators also maintain steady operating reserves on “hot standby” that are equivalent to about 13% of the total load on the system in case problems suddenly arise. Why not find a way to reduce the demand of these appliances in times when operators would typically be dipping into the expensive cushion?

The (Grid Friendly™ controller) low-cost sensors embedded in appliances can sense grid conditions by monitoring the frequency of the system and provides automatic demand response in times of disruption. Within each interconnected operating region, a disturbance reflected in the system frequency is a universal indicator of serious imbalance between supply and demand that, if not relieved, can lead to a blackout. A simple computer chip installed in end use appliances can reduce the appliance’s electricity demand for a few minutes or even a few seconds to allow the grid to stabilize. The controllers can be programmed to autonomously react in fractions of a second when a disturbance is detected whereas power plants can take minutes to come up to speed.<sup>42</sup>

As these controllers penetrate the appliance marketplace, important control issues must be addressed. For example, the control approach must deactivate appliances in a graduated manner so as not to “shock” the grid by dropping more load than necessary to rebalance supply and demand.<sup>43</sup> They must also be reactivated after the crisis in a similarly smooth fashion. It may be highly desirable to organize this response as a hierarchy ordered from the least to the highest priority end uses—from the least critical functions, such as air conditioning, to the most critical functions, such as communications, traffic control, water, sewage,

and fuel pumps. Then, if a crisis persists, grid operators can allocate power to end uses simply by maintaining grid frequency at small increments below the normal range. Managing demand in the power grid in an “all-or-nothing” fashion will no longer be necessary.

By integrating the controllers with appliances at the factory, costs can be reduced to a few dollars per appliance. Done properly, consumers will not even notice the short interruption (by turning off the compressor in a refrigerator, but leaving the light on, for example). In the process, consumers become an integral part of power-grid operations and could even be rewarded for their participation in helping prevent a widespread outage. Therefore, without the need for any formal communications capability, appliances are transformed from being part of the problem to part of the solution. They now act as assets that form a much quicker and better safety net under the power grid, freeing up power plants from standby duty to increase competition, lower prices and meet future load growth. Moreover, because they act autonomously, no communication system is required beyond the power grid itself. However, when a communication system becomes available, the “smarts” are already on board the appliances to do much more sophisticated negotiation and control, such as reducing peak loads.

---

## 34.5 Markets + Control = The Transactive Network

Transactive (e.g., contract) networks and agent-based systems present an opportunity to implement process controls in which highly optimized control (both local and global) is an inherent attribute of the strategy rather than an explicitly programmed feature. The premise of transaction-based control is that interactions between various components in a complex energy system can be controlled by negotiating immediate and contingent contracts on a regular basis in lieu of standard on/off command and control. Each device is given the ability to negotiate deals with its peers, suppliers and customers in order to maximize revenues while minimizing costs. This is best illustrated by an example.

### 34.5.1 The End Use Facilities Marketplace

A typical building might have several chillers that supply a number of air handlers with chilled water on demand. If several air handlers require the full output of one chiller, and another air handler suddenly also requires cooling, traditional building control algorithms simply startup a second chiller to meet the demand and the building's electrical load ratchets upward accordingly.

A transaction-based building control system behaves differently. Instead of honoring an absolute demand for more chilled water, the air handler requests such service in the form of a bid (expressed in dollars), increasing its bid in proportion to its “need” (divergence of the zone temperature from its setpoint). The chiller controls, with knowledge of the electric rate structure, can easily express the cost of service as the cost of the kWh to run the additional chiller plus the incremental kW demand charge. If the zone served by this air handler just began to require cooling, its “need” is not very great at first, and so it places a low value on its bid for service and the additional chiller stays off until the level of need increases. Meanwhile, if another air handler satisfies its need for cooling, the cost of chilled water immediately drops below the bid price because a second chiller is no longer required, and the air handler awaiting service receives chilled water.

This is analogous to air traffic control where a limited resource is managed by scheduling demand into time slots. Alternatively, a peer-to-peer transaction can take place in which an air handler with greater need for service displaces (literally outbids) another whose thermostat is nearly satisfied.

In this way, the contract-based control system accomplishes several things. First, it inherently limits demand by providing the most “cost-effective” service. In doing this, it inherently prioritizes service to the most important needs before serving less important ones. Second, it decreases energy consumption by preventing the operation of an entire chiller to meet a small load, where it operates inefficiently.

Third, contract-based controls inherently propagate cost impacts up and down through successive hierarchical levels of the system being controlled (in this example, a heating/cooling system). The impacts on the utility bill, which are easily estimated for the chiller operation, are used as the basis for expressing the costs of air handler and zone services. Using cost as a common denominator for control makes expression of what is effectively a multilevel optimization much simpler to express than an engineered solution would be. It allows controls to be expressed in local, modular terms while accounting for their global impact on the entire system.

In effect, the engineering decision-making process is subsumed by a market value-based decision-making process that injects global information conveyed by market activity (i.e., asks, bids, immediate and contingent contracts, closings, and defaults) into the local engineering parameters that govern the behavior of individual systems over multiple timescales.

### **34.5.2 The Distribution Marketplace**

One of the most critical, yet difficult, parts of the value chain to reveal is the value of new or expanded distribution capacity. When distribution utilities determine a need to add or increase the capacity of a substation, it is typical for the costs to range from \$100/kW to \$200/kW, or even higher in less common cases such as urban centers.<sup>44</sup> Although this is generally not enough value to fund a distributed-generation project that may cost \$800/kW, for example, it nevertheless is a substantial fraction of the needed investment. When added to other values seen by the customer, such as backup power and reduced demand and energy charges, plus values for grid support and displaced central generation at the transmission and wholesale levels, the project may be attractive to the customer, the utility, or a third party if all these values can be accumulated or shared.

This suggests a role for a new distribution-level marketplace. The distribution utility that traditionally deals with operations and planning now has an additional function—operating a local marketplace or incentive structure where these values are revealed. By posting long-term upgrade costs as an opportunity notice to customers and third parties to bid alternative investments, such opportunities will reveal themselves.

For example, if a single distributed generator is located at a substation or feeder to displace an upgrade, then sooner or later it will go down just when the load is peaking on a hot summer day. To maintain the initial level of reliability, multiple, smaller units must be installed, or load management contracts must be signed with enough customers to back up the resource occasionally. Direct load curtailment contracts are one way to do this, using technology such as transactive control to make it seamless, automatic, and minimally disruptive. A market-like economic dispatch based on a local congestion surcharge is another way to let these resources compete for the right to serve peak loads at minimal cost. In either case, the distribution marketplace becomes a focal point for the transformation.

### 34.5.3 The Transmission Marketplace

The transmission power grid and wholesale markets can potentially be operated in an analogous, transactive fashion that provides a mechanism for the “self-healing” features that are the key to increasing the reliability of the grid while minimizing the infrastructure cost involved. A scenario best illustrates this concept. In today’s wholesale market, a large customer shopping for a long-term contract for power finds an energy service provider offering the minimal cost contract guaranteeing generation and transmission of power to the local distribution utility on its behalf. When a crisis occurs that suddenly disrupts the grid and severely constricts the transmission capacity of the corridor being used, the frequency disruption immediately triggers frequency-sensitive appliances throughout the entire region to temporarily rebalance supply and demand. This allows time for an automated power-trading system, analogous to an automated stock market trading scheme, to reconfigure the system in response to the crisis.

To do this, the energy management system immediately posts an emergency congestion surcharge on the constrained pathway. This surcharge triggers the energy service provider to issue a short-term subcontract to a generator in another location to use a different transmission pathway to deliver power on behalf of the customer. In effect, this is what grid operators do today, reconfiguring the grid and voiding power wheeling contracts with a telephone and paperwork. However, the fact that the August 14, 2003 blackout in the Eastern Interconnection, once begun,<sup>45</sup> rolled from Ohio to New York in 9 s serves as a reminder that information technology is essential for reacting with the speed necessary to arrest such events.

The key is tapping into the remarkable property of markets to reorganize themselves efficiently and the speed of high technology to effect that reorganization. Although engineers speak of “control” and economists speak of “markets,” in the future power grid, these concepts will merge and blend to form a transactive network that effectively forms the central nervous system of an adaptive, evolving system.

---

## 34.6 Renewable Energy Sources Integration

Broadly defined, renewable energy sources include wind, solar (solar photovoltaic (PV) and solar thermal), biomass, hydroelectric, ocean and river currents, waves, and tides. However, only wind, solar, and biomass sources are largely unconstrained by resource location. Thus, these renewable energy sources are ideally suited as distributed sources within the future electric system. Biomass-derived fuels can power conventional and emerging external and internal combustion engines. Thus, this renewable source brings the additional value of regulated/controllable power output and benefits in the form of voltage and reactive power support, spinning reserve, and improved power quality. In short, biomass-derived fuels can simply replace conventional fossil-based fuels in powering conventional power generator units such as diesel generator sets. However, both solar and wind energy sources can also bring many of these additional values.

Both solar and wind energy have, to date, been considered to be intermittent sources (when energy storage is absent). However, as these power sources become accepted as conventional components of the power generation mix and are used more effectively, there has come the recognition that these resources are best described as “variable” and that furthermore the outputs are relatively highly predictable. In addition, the parallel

development of reliable, intelligent, low-cost, electronic-based voltage-source power converters has brought the ability of solar and wind generators to supply both high-quality power and reactive power support. Therefore, wind and solar power generators should now be included in the distributed power generator resource category.

The integration of ubiquitous communications and integrated distributed control now allows distributed generation, and particularly renewable power sources to utilize loads (especially thermostatic loads) to “firm up” intermittent sources making them collectively a more reliable resource. Additionally, opportunities for distributed renewables to participate in real-time emission management and provide grid support such as reactive power, cold load pickup during restoration, and backup for nearby critical loads provide benefits that can be realized economically.

Renewable power generators can be assigned effective load-carrying capability (ELCC) (or capacity credit) values. These values can be established when the deployment configuration, integration, and dispatch of these resources, along with other distributed resources, is optimized within a specific distribution or transmission system. For example, it has been shown that had a dependable capacity of 5000 MW of PV been installed in the California ISO region in 2000, the peak load on June 15, 2000 could have been reduced by 3000 MW. This would have cut by one-half the number of equivalently sized natural-gas-driven combustion gas turbines needed to ensure system reserve capacity.<sup>46</sup> Although PV power is only available during daylight hours, the annual average ELCC estimated for PV power plants distributed throughout California has nonetheless been calculated to be 64% of the PV plant rating. Furthermore, when the California system electric load is driven by the sun, the ELCC exceeds 80%. Thus a 5 MW PV system would be considered a summer peaking power source of 4 MW.

Wind-power output in many locations also has a definite diurnal pattern. However, analyses of real operating data currently underway in both the United States and Europe show that the very favorable geographic diversity effect (due to many wind turbines scattered throughout a relatively large geographical area), along with the significant advances in short-term wind forecasting, can permit electric power system planners and operators to assign high values of ELCC and capacity factor to wind-power systems.<sup>47</sup>

In short, the intelligent deployment, integration, and operation of wind and solar energy sources within the future electric system enable renewable power resources to be categorized as distributed power generation assets without qualification, bringing with them many of the values of the traditional distributed power generation sources (such as diesel generators and gas turbine generators) that can be exploited within the system, renewable power to provide ancillary benefits such as grid reactive support, and additional societal benefits to be realized such as real-time emissions management.

**35.1 Introduction**

Smart grid refers to a set of technology using control and automation to advance power systems operation. The goals of smart grid explored in this chapter are (1) to integrate renewable energy into grid through power electronic devices, (2) to flexibly route power through power electronic control, (3) to accommodate uncertainty of generation through enhancing controllability of loads—energy storage is a means in enhancing load controllability, and (4) to enhance grid operation technology through phasor measurement unit (PMU). In the following sections, the earlier-mentioned goals and technology will be elaborated. Section 35.2 focuses on power electronic technology for renewable energy grid integration and high-voltage direct current (HVDC)-based flexible power routing. Section 35.3 focuses on load controllability. Section 35.4 discusses the state-of-the-art technology in grid operation.

**35.2 Renewable Energy Integration and Flexible Power Routing**

Power electronic technology makes renewable energy such as wind and solar integration possible. In the 1980s, wind turbines made of induction generators were directly connected to the grid. These wind turbines operate when wind speed is greater than the nominal wind speed and have power rating around 100 kW. The state-of-the-art wind turbines are variable-speed constant-frequency types, meaning that they can operate at variable wind speed and generate constant-frequency electricity. Such technology reduces mechanical stress and improves the power rating. Today, wind turbines have power rating

up to 5 MW. State-of-the-art wind turbines such as types 3 and 4 wind turbines are all connected to the grid through power electronic interfaces [1].

Photovoltaic (PV) panels are connected to the grid through power electronic interfaces. These interfaces can either single phase or three phase, be one stage (a DC to AC inverter) or two stages (a DC to DC converter and a DC to AC inverter). Power electronic technology also makes flexible power routing possible through HVDC technology.

The following subsections will elaborate on these two applications: power-electronic-enabled grid integration and power-electronic-enabled flexible power routing.

### 35.2.1 Power-Electronic-Enabled Grid Integration

Power electronic converters can be viewed as frequency transformers. They are able to convert electricity from one format to another, including (1) DC to AC, (2) AC to DC, and (3) AC to AC. For example, the direct output from a PV panel is DC electricity. To connect the PV panel to the single-phase 120 V distribution line, a DC to AC inverter is needed. In the scenarios of (2), AC electricity can be rectified to DC through a converter and be transmitted as DC electricity. Such is the case of HVDC. A permanent magnet synchronous generator-based wind turbine generates very low-frequency AC electricity. This low-frequency electricity will pass through back-to-back converters (an AC-to-DC converter and a DC-to-AC inverter connected through a DC link) to be connected to the grid of 60 Hz.

The power electronic interfaces usually are power or voltage control enabled. The AC side output active power and reactive power can be controlled through converters. For converters interfacing renewable energies, active power order usually follows maximum power point extracting to have maximum energy output. On the other hand, inverters have the ability to generate or consume reactive power. Therefore, inverters can regulate AC system voltages through reactive power generation or consumption.

With many PV and power factor capacitors installed in distribution systems, system voltage/Var regulation becomes a coordinated optimization problem to meet the system voltage requirement while generating maximum benefit. Such operation requires the PVs to regulate their reactive power outputs to have minimum line flow loss.

In a very short timescale, such as tens of seconds, PV voltage can drop sharply due to cloud. This requires the system to have fast voltage recovery capability. And it can be achieved either through redesign PV voltage control functionality or through voltage control using other devices such as battery.

### 35.2.2 Power-Electronic-Enabled Flexible Power Routing

AC power flows follow Kirchhoff's laws, and the flow on transfer path is dependent on physical parameters such as line length. The most simplified expression for power flow on a line can be expressed as  $P_{ij} = V_i V_j / X_{ij} \sin \delta_{ij}$ , where  $V_i$  and  $V_j$  are voltage magnitudes of the node buses,  $X_{ij}$  is the reactance of the line, and  $\delta_{ij}$  is the phase angle difference between the two node voltage phasors. In order to be able to control power flow, phase shifters are used in industry to change the phase angle difference [2]. Unified power flow controller (UPFC) was also built and applied in American Electric Power (AEP) [3]. A UPFC can change both the node voltage magnitude and the node voltage phase angle.

High-voltage DC links are used for long-distance power transfer [4]. The applications include links built to bring Canadian hydropower to Minnesota (Nelson River—MN) and Oregon hydropower to California. The major advantage of HVDC is its energy efficiency. Compared to AC power transfer, DC power transfer requires less current carrying

through the line for the same amount of active power due to the omission of reactive power. Therefore, line loss will be greatly reduced.

Conventional HVDC technology, line current commuted (LCC) technology, relies on thyristor devices, which can be switched on every one cycle. LCC-HVDC is suitable for large-scale power transfer ( $>1000$  MW). It requires large filters to get rid of low-order harmonics due to thyristor switching. In addition, LCC-HVDC always absorbs reactive power and requires a strong grid to support reactive power.

With the advance of insulated gate bipolar transistor (IGBT) switches, voltage source converter (VSC) HVDC technology becomes popular for wind integration [5]. Such technology is suitable for several hundred MW power transfer. Since IGBT switching is at kilohertz, the size of filters is very small. In addition, VSC-HVDC can operate in four quadrants in terms of PQ (real power [P] and reactive power [Q]). Therefore, VSC-HVDC can absorb or generate both real power and reactive power, and it can be used for black-start.

In terms of flexible power routing, HVDC technology is built for power flow control and can realize such requirement. For example, the LCC-HVDC is operated based on power order. The rectifier of an LCC-HVDC will adjust the thyristor firing angle based on a power order. The VSC-HVDC is also equipped with power order control.

Smart grid requires fast and flexible power routing. For example, in an area with ample renewable generation supply, it is necessary to route the power to a metropolitan area or an area with energy storage. In addition, due to the variant nature of renewable energy, it is also required to be very fast. HVDC technology can fulfill both requirements. Multiterminal HVDC is also a technology under investigation for fast and flexible power routing.

---

### 35.3 Load Controllability

In conventional power systems, operation usually refers to switch on/off and dispatch generators, while loads are considered as uncontrollable. One of the goals of smart grid technology is to make loads controllable through adding communication infrastructure to connect loads and make load controllable.

Traditionally, loads consist of only passive power consumers. With the advance of distributed generation and energy storage, loads become active power consumer. Loads can decide when to consume and how much to consume. For example, a home equipped with a smart meter and interruptible loads such as washing machine or air-conditioners can make decision whether to switch on/off washing machine or air-conditioner.

Two types of load control are discussed in the following subsections: (1) direct load control is conducted by utilities and (2) demand response program lets loads make their own decisions.

#### 35.3.1 Direct Load Control

In direct load control, loads allow utilities to directly control their appliances or equipment. Utilities favor peak shaping to avoid the need to build new power plants. The following is an example of peak shaving through energy storage system. A 1.6 kW PV system is connected to the distribution system along with a 5 kW, 4 h battery system. The peak hours are in the afternoon around 2 pm. The control strategy of the utility is as follows: before 2 pm, all PV power will be used to charge the battery, and the net exchange between the grid and the PV/battery system is zero. After 2 pm, the battery will be discharged to supply the grid.

**FIGURE 35.1**  
PV/battery system power output.

The output power from the battery can be a constant. Or the net output from the PV/battery system can be a constant. After the peak hours, the discharge process of the battery will stop. Figure 35.1 presents a real-world PV/battery output power for several days.

### 35.3.2 Demand Response Program

In this section on demand response program, let us look at an example of demand response of microgrids from Ref. [6]. In this example, the microgrids and the utility exchange limited information, and they make their own decisions while updating the information exchange. In the end, they are expected to reach agreement. Both the utility and microgrids will achieve optimal goals. Figure 35.2 presents a scheme of information exchange between the utility and microgrids.

In this figure, the microgrids send the bidding price for real power ( $\lambda^p$ ) and reactive power ( $\lambda^q$ ) to the utility. The utility decides how much power to export based on the bidding price. The microgrids receive the information of power amount and again compute the bidding prices and send them to utility. After iterations, the prices and the power amount are expected to be constant.

The optimization problems for the utility and the microgrid are described as follows:

1. *Utility optimization:* At iteration  $k$ , the utility solves (35.1) given price vectors  $(\lambda_i^p(k), \lambda_i^q(k))$  at the first iteration or updated ones to determine the importing power vector  $(P_{imp}, Q_{imp})$ . Then, the vectors  $P_{imp}$  and  $Q_{imp}$  are announced to the communities. The procedure to solve utility optimal power flow (OPF) problem is the same as that in the subgradient method.

**FIGURE 35.2**  
Information flow of lower- and upper-bound switching (LUBS) algorithm.

The utility also computes the utility cost  $C_u(k)$  at  $k$ th iteration.

$$\begin{aligned}
 \min \quad & \sum_{i \in N-A} C_i(P_{gi}) + \sum_{i \in A} [\lambda_i^p P_{imp_i} + \lambda_i^q Q_{imp_i}] \\
 \text{subject to} \quad & \forall i \in N, \quad \forall j \in B \\
 & P_{gi} - P_{Li} - P_i(V, q) = 0 \\
 & Q_{gi} - Q_{Li} - Q_i(V, q) = 0 \\
 & V_i^m \leq V_i \leq V_i^M \\
 & P_{gi}^m \leq P_{gi} \leq P_{gi}^M \\
 & Q_{gi}^m \leq Q_{gi} \leq Q_{gi}^M \\
 & S_j(V, \theta) - S_j^M \leq 0 \\
 & P_{imp_i}^m \leq P_{imp_i} \leq P_{imp_i}^M \quad \forall i \in A \\
 & Q_{imp_i}^m \leq Q_{imp_i} \leq Q_{imp_i}^M \quad \forall i \in A
 \end{aligned} \tag{35.1}$$

where

$C(\cdot)$  is the cost function, superscripts  $M$  and  $m$  denote upper and lower bounds  
 $P_g, Q_g, P_L$ , and  $Q_L$  are the vectors of bus real and reactive power injection, and real and reactive loads

$P(V, \theta)$  and  $Q(V, \theta)$  are the power injection expressions in terms of bus voltage magnitude and phase angles

$S(V, \theta)$  is the vector of line complex power flow

2. *Community optimization and price updating*: Once the communities receive the importing (exporting) power vectors from the utility, they will determine the local generator output and announce the prices back to the utility.

The optimization problem is presented as follows:

$$\begin{aligned}
 & \min \quad C_i(P_{gi}) \\
 & \text{subject to} \quad P_{gi} - P_{Li} = P_{imp,i} \\
 & \quad \quad \quad P_{gi}^m \leq P_{gi} \leq P_{gi}^M \\
 & \quad \quad \quad Q_{gi}^m \leq Q_{gi} \leq Q_{gi}^M
 \end{aligned} \tag{35.2}$$

Generally, the community connected to the bus  $i \in A$  seeks the prices  $(\lambda_i^{p*}, \lambda_i^{q*})$  of  $(P_{imp,i}, Q_{imp,i})$ . These prices are the Lagrangian multipliers related to the equality constraints. When the limits are not bounding, the prices are the same as the marginal prices of the generators.

In a special case where the communities only have generation units and fixed loads,  $(\lambda_i^{p*}, \lambda_i^{q*})$  are their marginal costs corresponding to  $(P_{imp,i}, Q_{imp,i})$ . For example, if the cost function of a generation unit is quadratic,  $C_i(P_{gi}) = 0.5\alpha_i P_{gi}^2 + \beta_i P_{gi} + \gamma_i$ . Then, the active power price is equal to  $\lambda_i^{p*} = \alpha_i(P_{imp,i} + P_{Li}) + \beta_i$ . The cost of the community  $i$  is denoted as  $C_{ci}$ .

## 35.4 PMU Technology

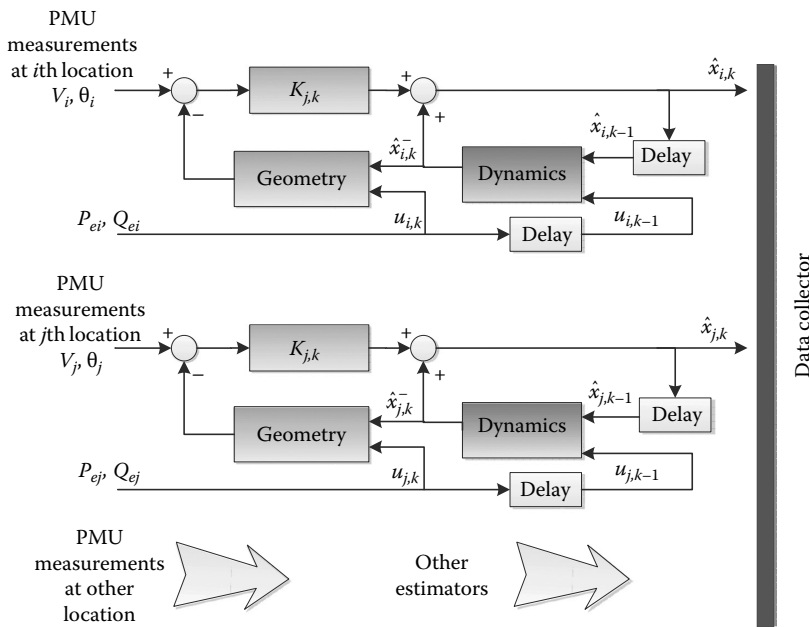

In grid operation, a set of technology advances to enhance power system operation, including synchrophasor measurement unit (PMU) applications, to enhance situation awareness. DOE-initiated Smart Grid Investment Grant was launched in early 2010 to modernize the power grid. The topic areas of the grant include device manufacturing, customer systems, advanced metering infrastructure, electric distribution systems, and electric transmission systems. In the area of electric transmission systems, projects primarily involve installing PMU, adding smart grid functions to devices, and enhancing visualization tools.

PMU devices compute voltage and current phasor and frequency and transmit the information to a control center at 30 Hz. Applications of PMU data include state estimation, prediction and prevention, and dynamic model verification. Compared to the conventional state estimation where measurements such as active power, reactive power, and voltage magnitudes are collected, PMUs give voltage and current phasor including phase angles directly. The information can be used to estimate every node's voltage phasors. Such process is a linear estimation process instead of nonlinear estimation process. The PMU data can be used to complement the current state-estimation system and have better estimation results.

PMU data can also be used for electromechanical dynamic model estimation. The frequency range of electromechanical modes is usually less than 2 Hz. To identify those dynamics, 30 Hz PMU sampling data is sufficient. With the PMU data be classified as

**FIGURE 35.3**

(a) Model decoupling using  $V$  and  $\theta$  as inputs and  $P_e$  and  $Q_e$  as measurements. (b) Model decoupling using  $P_e$  and  $Q_e$  as inputs and  $V$  and  $\theta$  as measurements.

**FIGURE 35.4**

Kalman filtering technology using PMU data.

input and output, two general approaches can be applied for system identification: extended Kalman filter (EKF) and least square error-based estimation. The USF SPS group has conducted research in system identification through PMU data in Refs. [7,8].

Figure 35.3 presents the input and output data. Figure 35.4 presents the EKF scheme for model estimation.

## 35.5 Conclusion

This chapter presents a set of smart grid technology in renewable energy grid integration, fast and flexible power routing, load control, and system situation awareness. Power electronic technology is used to interface renewable energy sources and energy storage

devices as well as power delivery. Power electronic makes fast and flexible power routing possible. Compared to the conventional power systems where loads are uncontrollable, one of the goals of smart grid is to increase load controllability. This is achieved by installing distributed generators and energy storage devices at the load sides. Through either direct load control or demand response program, peak shaving and other economic benefits can be achieved. In the transmission systems, PMU technology is employed to enhance situation awareness. State estimation and dynamic model validation can be improved through PMU technology.

### 36.1 Introduction

Solar energy is the world's most abundant permanent source of energy. The amount of solar energy intercepted by the planet Earth is a tiny fraction of the solar radiation emitted by the sun. However, even that tiny amount is 5000 times greater than the sum of all other inputs (terrestrial nuclear, geothermal, and gravitational energies and lunar gravitational energy).

**FIGURE 36.1**  
Relationship between the sun and the earth.

The sun is a  $13.9 \times 10^5 \text{ km}$  diameter sphere comprising many layers of gases, which are progressively hotter toward its center. The outermost layer, from which energy is radiated into the solar system, is approximately at an equivalent blackbody temperature of 5,760 K (10,400° R). The rate of energy emission from the sun is  $3.8 \times 10^{23} \text{ kW}$ . Of this total, only a tiny fraction, approximately  $1.7 \times 10^{14} \text{ kW}$ , is intercepted by the earth, which is located about 150 million km from the sun (Figure 36.1). Of this amount, 30% is reflected to space, 47% is converted to low-temperature heat and reradiated to space, and 23% powers the evaporation/precipitation cycle of the biosphere. Less than 0.5% is represented in the kinetic energy of the wind and waves and in photosynthetic storage in plants.

Total terrestrial radiation is only about one-third of the extraterrestrial total during a year, and 70% of that falls on the oceans. However, the remaining  $1.5 \times 10^{17} \text{ kWh}$  that falls on land is a prodigious amount of energy—about 6000 times the total energy usage of the United States in 2009. Only a small fraction of this total can be used because of physical and socioeconomic constraints.

## 36.2 Sun–Earth Geometric Relationship

Figure 36.2 shows the annual orbit of the earth around the sun. The distance between the earth and the sun changes throughout the year, the minimum being  $1.471 \times 10^{11} \text{ m}$  at winter solstice (December 21) and the maximum being  $1.521 \times 10^{11} \text{ m}$  at summer solstice (June 21). The year-round average earth–sun distance is  $1.496 \times 10^{11} \text{ m}$ . The amount of solar radiation intercepted by the earth, therefore, varies throughout the year, the maximum being on December 21 and the minimum on June 21.

The axis of the earth's daily rotation around itself is at an angle of  $23.45^\circ$  to the axis of its ecliptic orbital plane around the sun. This tilt is the major cause of the seasonal variation of the solar radiation available at any location on the earth. The angle between the earth–sun line (through their centers) and the plane through the equator is called the *solar declination*,  $\delta_s$ . The declination varies between  $-23.45^\circ$  on December 21 and  $+23.45^\circ$  on June 21. Stated another way, the declination has the same numerical value as the latitude at which the sun is directly overhead at solar noon on a given day. The tropics of Cancer ( $23.45^\circ \text{ N}$ ) and Capricorn ( $23.45^\circ \text{ S}$ ) are at the extreme latitudes where the sun is overhead at least once a year as shown in Figure 36.2. The Arctic and Antarctic circles are defined as those latitudes above which the sun does not rise above the horizon plane at least once per year. They are located, respectively, at  $66\frac{1}{2}^\circ \text{ N}$  and

**FIGURE 36.2**

(a) Motion of the earth about the sun and (b) location of tropics. Note that the sun is so far from the earth that all the rays of the sun may be considered as parallel to one another when they reach the earth.

$66\frac{1}{2}^\circ$  S. Declinations north of the equator (summer in the northern hemisphere) are positive; those south, negative. The solar declination may be estimated by the relation\*

$$\delta_s = 23.45^\circ \sin[360(284 + n)/365]^\circ, \quad (36.1)$$

where  $n$  is the day number during a year with January 1 being  $n = 1$ . Approximate values of declination\* may also be obtained from Table 36.1 or Figure 36.3. For most calculations, the declination may be considered constant during any given day.

For the purposes of this book, the Ptolemaic view of the sun's motion provides a simplification to the analysis that follows. It is convenient to assume the earth to be fixed and to describe the sun's apparent motion in a coordinate system fixed to the earth with its origin at the site of interest. Figure 36.4 shows an apparent path of the sun to an observer. The position of the sun can be described at any time by two angles, the altitude and azimuth

\* A more accurate relation is  $\sin \delta_s = \sin(23.45^\circ) \sin[360(284 + n)/365]^\circ$ . Because the error is small, Equation (2.23) is generally used.

<sup>a</sup> Since each year is 365.25 days long, the precise value of declination varies from year to year. *The American Ephemeris and Nautical Almanac*, published each year by the U.S. Government Printing Office, contains precise values for each day of each year.

**FIGURE 36.3**  
Graph to determine the solar declination.

**FIGURE 36.4 (Continued)**

Sun paths for the summer solstice (6/21), the equinoxes (3/21 and 9/21), and the winter solstice (12/21) for a site at 40° N: (c) solar altitude and azimuth angles.

angles, as shown in Figure 36.4c. The *solar altitude angle*,  $\alpha$ , is the angle between a line collinear with the sun's rays and the horizontal plane. The *solar azimuth angle*,  $a_s$ , is the angle between a due south line and the projection of the site to sun line on the horizontal plane. The sign convention used for the azimuth angle is positive west of south and negative east of south. The *solar zenith angle*,  $z$ , is the angle between the site to sun line and the vertical at the site:

$$z = 90^\circ - \alpha. \quad (36.2)$$

The solar altitude and azimuth angles are not fundamental angles. Hence, they must be related to the fundamental angular quantities *hour angle*, *latitude*, and *declination*. The three angles are shown in Figure 36.5. The solar hour angle  $h_s$  is based on the nominal time of 24 h required for the sun to move 360° around the earth or 15° per hour. Therefore,  $h_s$  is defined as

$$h_s = (15^\circ/\text{h}) \cdot (\text{Hours from local solar noon}) = \frac{\text{Minutes from local solar noon}}{4 \text{ min/degree}}. \quad (36.3)$$

Again, values east of due south, that is, morning values, are negative; and values west of due south are positive.

The latitude angle  $L$  is the angle between the line from the center of the earth to the site and the equatorial plane. The latitude may be read from an atlas and is considered positive north of the equator and negative south of the equator.

**FIGURE 36.5**

Definition of solar hour angle  $h_s$ , solar declination  $\delta_s$ , and latitude  $L$ ;  $Q$  site of interest.

### 36.2.1 Solar Time and Angles

The sun angles are obtained from the local solar time, which differs from the local standard time (LST). The relationship between the local solar time and the LST is

$$\text{Solar time} = \text{LST} + \text{ET} + (l_{st} - l_{local}) \cdot 4 \text{ min/degree}, \quad (36.4)$$

where

$\text{ET}$  is the equation of time, which is a correction factor that accounts for the irregularity of the speed of earth's motion around the sun

$l_{st}$  is the standard time meridian

$l_{local}$  is the local longitude

$\text{ET}$  may be estimated from [Table 36.1](#) or [Figure 36.6](#) or calculated from the following empirical equation:

$$\text{ET}(\text{in min}) = 9.87 \sin 2B - 7.53 \cos B - 1.5 \sin B, \quad (36.5)$$

where  $B = 360(n - 81)/360^\circ$ .

The solar altitude angle,  $\alpha$ , can be found from the application of the law of cosines to the geometry of [Figures 36.4c](#) and 36.5 and simplification as

$$\sin \alpha = \sin L \sin \delta_s + \cos L \cos \delta_s \cos h_s. \quad (36.6)$$

Using a similar technique, the solar azimuth angle,  $a_s$ , can be found as

$$\sin a_s = \cos \delta_s \sin h_s / \cos \alpha. \quad (36.7)$$

At local solar noon,  $h_s = 0$ ; therefore,  $\alpha = 90 - |L - \delta_s|$ , and  $a_s = 0$ .

**FIGURE 36.6**  
Equation of time.

In calculating the solar azimuth angle from Equation 36.7, a problem occurs whenever the absolute value of  $a_s$  is greater than  $90^\circ$ . A computational device usually calculates the angle as less than  $90^\circ$  since  $\sin a_s = \sin(180 - a_s)$ . The problem can be solved in the following way:

For  $L > \delta_s$ , the solar times when the sun is due east ( $t_E$ ) or due west ( $t_W$ ) can be calculated by  $t_E$  or  $t_W = 12:00 \text{ noon} \mp (\cos^{-1}[\tan \delta_s / \tan L])^0 / (15^\circ/\text{h})$  (– for  $t_E$ , + for  $t_W$ ).

For solar times earlier than  $t_E$  or later than  $t_W$ , the sun would be north (south in the southern hemisphere) of the east-west line and the absolute value of  $a_s$  would be greater than  $90^\circ$ , which may be calculated as  $a_s = + \text{ or } -(180^\circ - |a_s|)$ .

For  $L \leq \delta_s$ , the sun remains north (south in the southern hemisphere) of the east-west line and the true value of  $a_s$  is greater than  $90^\circ$ .

*Sunrise and sunset* times can be estimated by finding the hour angle for  $\alpha = 0$ . Substituting  $\alpha = 0$  in Equation 19.6 gives the hour angles for sunrise ( $h_{sr}$ ) and sunset ( $h_{ss}$ ) as

$$h_{ss} \text{ or } h_{sr} = \pm \cos^{-1}[-\tan L \cdot \tan \delta_s]. \quad (36.8)$$

It should be emphasized that Equation 36.8 is based on the center of the sun being at the horizon. In practice, sunrise and sunset are defined as the times when the upper limb of the sun is on the horizon. Because the radius of the sun is  $16'$ , the sunrise would occur when  $\alpha = -16'$ . Also, at lower solar elevations, the sun will appear on the horizon when it is actually  $34'$  below the horizon. Therefore, for apparent sunrise or sunset,  $\alpha = -50'$ .

Knowledge of the solar angles is helpful in the design of passive solar buildings, especially the placement of windows for solar access and the roof overhang for shading the walls and windows at certain times of the year.

### 36.2.2 Sun-Path Diagram

The projection of the sun's path on the horizontal plane is called a *sun-path diagram*. Such diagrams are very useful in determining shading phenomena associated with solar collectors, windows, and shading devices. As shown earlier, the solar angles ( $\alpha$ ,  $a_s$ ) depend

upon the hour angle, declination, and latitude. Since only two of these variables can be plotted on a 2D graph, the usual method is to prepare a different sun-path diagram for each latitude with variations of hour angle and declination shown for a full year. A typical sun-path diagram is shown in Figure 36.7 for 30° N latitude.

Sun-path diagrams for a given latitude are used by entering them with appropriate values of declination  $\delta_s$  and hour angle  $h_s$ . The point at the intersection of the corresponding  $\delta_s$  and  $h_s$  lines represents the instantaneous location of the sun. The solar altitude can then be read from the concentric circles in the diagram, the azimuth, from the scale around the circumference of the diagram.

**FIGURE 36.7**

Sun-path diagram for 30° N latitude showing altitude and azimuth angles.

### 36.2.3 Shadow-Angle Protractor

The shadow-angle protractor used in shading calculations is a plot of solar altitude angles, projected onto a given plane, versus solar azimuth angle. The projected altitude angle is usually called the *profile angle*  $\gamma$ . It is defined as the angle between the normal to a surface and the projection of the sun's rays on a vertical plane normal to the same surface. The profile angle is shown in Figure 36.8a with the corresponding

**FIGURE 36.8**

(a) Sketch showing the profile angle  $\gamma$  and the corresponding solar altitude angle  $\alpha$  for a window shading device and (b) the shadow-angle protractor. (Libby-Owens-Ford Glass Co. With permission.)

solar altitude angle. The profile angle, which is always used in sizing shading devices, is given by

$$\tan \gamma = \sec a \tan \alpha, \quad (36.9)$$

where  $a$  is the solar azimuth angle with respect to the wall normal.

Figure 36.8b shows the shadow-angle protractor to the same scale as the sun-path diagram in Figure 36.7. It is used by plotting the limiting values of profile angle  $\gamma$  and azimuth angle  $a$ , which will start to cause shading of a particular point. The shadow-angle protractor is usually traced onto a transparent sheet so that the shadow map constructed on it can be placed over the pertinent sun-path diagram to indicate the times of day and months of the year during which shading will take place. The use of the shadow-angle protractor is best illustrated by an example.

### Example 36.1

A solar building with a south-facing collector is sited to the north-northwest of an existing building. Prepare a shadow map showing what months of the year and what part of the day point C at the base of the solar collector will be shaded. Plan and elevation views are shown in Figure 36.9. Latitude =  $40^\circ$  N.

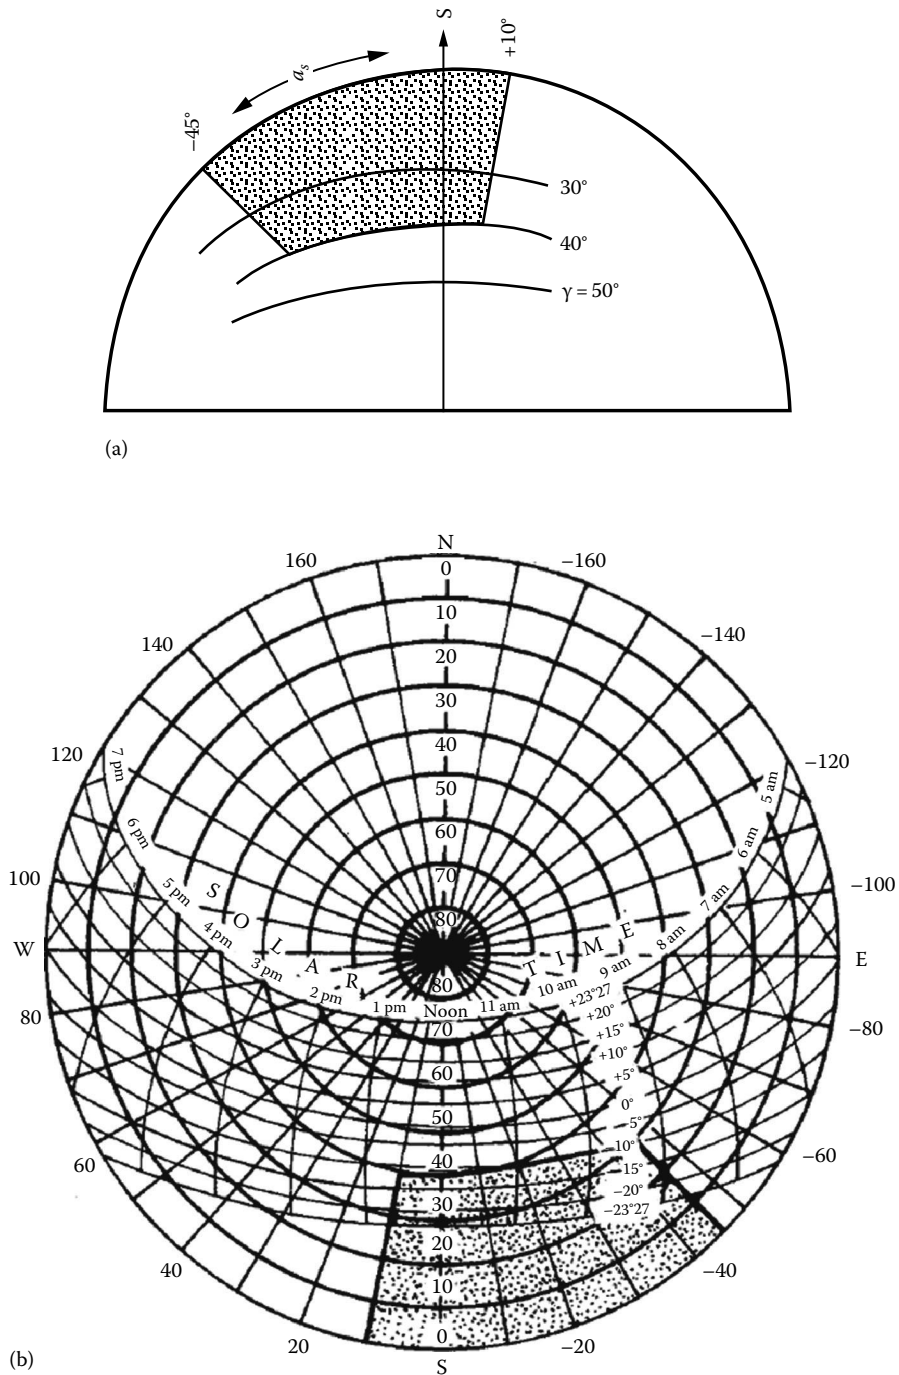

### Solution

The limiting profile angle for shading is  $40^\circ$  and the limiting azimuth angles are  $-45^\circ$  and  $+10^\circ$  as shown in Figure 36.9. These values are plotted on the shadow-angle protractor (Figure 36.10a). The shadow map, when superimposed on the sun-path

**FIGURE 36.9**

Elevation (a) and plan (b) view of proposed solar building and existing building, which may shade solar collector at point C.

**FIGURE 36.10**

(a) Shadow map constructed for the example shown in Figure 2.13 and (b) shadow map superimposed on the sun-path diagram.

diagram (Figure 36.10b), shows that point C will be shaded during the following times of day for the periods shown:

Declination	Date	Time of Day
$-23^{\circ}27'$	Dec 22	8:45 AM–12:40 PM
$-20^{\circ}$	Jan 21, Nov 22	8:55 AM–12:35 PM
$-15^{\circ}$	Feb 9, Nov 3	9:10 AM–12:30 PM

In summary, during the period from November 3 to February 9, point C will be shaded between 3 and 4 h. It will be shown later that this represents about a 50% loss in collector performance for point C, which would be unacceptable for a collector to be used for heating a building in winter.

### 36.3 Solar Radiation

Detailed information about solar radiation availability at any location is essential for the design and economic evaluation of a solar energy system. Long-term measured data of solar radiation are available for a large number of locations in the United States and other parts of the world. Where long-term measured data are not available, various models based on available climatic data can be used to estimate the solar energy availability. Solar energy is in the form of electromagnetic radiation with the wavelengths ranging from about  $0.3 \mu\text{m}$  ( $10^{-6} \text{ m}$ ) to over  $3 \mu\text{m}$ , which correspond to ultraviolet (less than  $0.4 \mu\text{m}$ ), visible ( $0.4$  and  $0.7 \mu\text{m}$ ), and infrared (over  $0.7 \mu\text{m}$ ). Most of this energy is concentrated in the visible and the near-infrared wavelength range (see Figure 36.11). The incident solar radiation,

**FIGURE 36.11**

Extraterrestrial solar radiation spectral distribution. Also shown are equivalent blackbody and atmosphere-attenuated spectra.

sometimes called *insolation*, is measured as irradiance, or the energy per unit time per unit area (or power per unit area). The units most often used are watts per square meter ( $\text{W/m}^2$ ), British thermal units per hour per square foot ( $\text{Btu/h-ft}^2$ ), and langleys per minute (calories per square centimeter per minute,  $\text{cal/cm}^2/\text{min}$ ).

### 36.3.1 Extraterrestrial Solar Radiation

The average amount of solar radiation falling on a surface normal to the rays of the sun outside the atmosphere of the earth (extraterrestrial) at mean earth–sun distance ( $D_0$ ) is called the *solar constant*,  $I_0$ . Measurements by NASA indicated the value of the solar constant to be  $1353 \text{ W/m}^2$  ( $\pm 1.6\%$ ),  $429 \text{ Btu/h-ft}^2$ , or  $1.94 \text{ Cal/cm}^2/\text{min}$  (langleys/min). This value was revised upward by Fröhlich et al. [7] to  $1377 \text{ W/m}^2$  or  $437.1 \text{ Btu/h-ft}^2$  or  $1.974 \text{ langleys/min}$ , which was the value used in compiling SOLMET data in the United States [37,38]. At present, there is no consensus on the value of the solar constant. Recently, new measurements have found the value of the *solar constant* to be  $1366.1 \text{ W/m}^2$ . A value of  $1367 \text{ W/m}^2$  is also used by many references.

The variation in seasonal solar radiation availability at the surface of the earth can be understood from the geometry of the relative movement of the earth around the sun. Since the earth's orbit is elliptical, the earth–sun distance varies during a year, the variation being  $\pm 1.7\%$  from the average. Therefore, the extraterrestrial radiation,  $I$ , also varies by the inverse square law as follows:

$$I = I_0 \left( \frac{D_0}{D} \right)^2, \quad (36.10)$$

where

$D$  is the distance between the sun and the earth

$D_0$  is the yearly mean earth–sun distance ( $1.496 \times 10^{11} \text{ m}$ )

The  $(D_0/D)^2$  factor may be approximated as [42]

$$\begin{aligned} (D_0/D)^2 = & 1.00011 + 0.034221 \cos(x) + 0.00128 \sin(x) \\ & + 0.000719 \cos(2x) + 0.000077 \sin(2x), \end{aligned} \quad (36.11)$$

where

$$x = \frac{360(n-1)}{365^\circ}, \quad (36.12)$$

and  $n$  = day number (starting from January 1 as 1). The following approximate relationship may also be used without much loss of accuracy:

$$I = I_0 [1 + 0.034 \cos(360n/365.25)^\circ]. \quad (36.13)$$

**FIGURE 36.12**

Effect of the time of year on the ratio of extraterrestrial radiation to the nominal solar constant.

Figure 36.12 also shows the relationship of the extraterrestrial solar radiation to the solar constant. For many solar energy applications, such as photovoltaics and photocatalysis, it is necessary to examine the distribution of energy within the solar spectrum. Figure 36.11 shows the spectral irradiance at the mean earth–sun distance for a solar constant of  $1366.1 \text{ W/m}^2$  as a function of wavelength. The data are also presented in Table 36.2 and their use is illustrated in the following example.

### Example 36.2

Calculate the fraction of extraterrestrial solar radiation within the visible part of the spectrum, that is, between  $0.40$  and  $0.70 \mu\text{m}$ .

### Solution

The first column in Table 36.2 gives the wavelength. The second column gives the averaged solar spectral irradiance in a band centered at the wavelength in the first column. The fourth column,  $D_\lambda$ , gives the percentage of solar total radiation at wavelengths shorter than the value of  $\lambda$  in the first column. At a value of  $0.40 \mu\text{m}$ , 8.12% of the total radiation occurs at shorter wavelengths. At a wavelength of  $0.70 \mu\text{m}$ , 47.25% of the radiation occurs at shorter wavelengths. Consequently, 39.13% of the total radiation lies within the band between  $0.40$  and  $0.70 \mu\text{m}$ , and the total energy received outside the earth's atmosphere within that spectral range is  $535 \text{ W/m}^2$  during equinoxes.

## 36.4 Estimation of Terrestrial Solar Radiation

As extraterrestrial solar radiation,  $I$ , passes through the atmosphere, a part of it is reflected back into space, a part is absorbed by air and water vapor, and some gets scattered by molecules of air, water vapor, aerosols, and dust particles (Figure 36.13). The part of solar radiation that reaches the surface of the earth with essentially no change in direction is

TABLE 36.2

Extraterrestrial Solar Irradiance

Note: Solar constant =  $1366.1 \text{ W}/\text{m}^2$ .

<sup>a</sup>  $E_\lambda$  is the solar spectral irradiance.

<sup>b</sup>  $D_\lambda$  is the percentage of the solar constant associated with wavelengths shorter than  $\lambda$ .

called *direct* or *beam radiation*. The scattered diffuse radiation reaching the surface from the sky is called the *sky diffuse radiation*.

Although extraterrestrial radiation can be predicted with certainty,\* radiation levels on the earth are subject to considerable uncertainty resulting from local climatic interactions. The most useful solar radiation data are based on long-term (30 years or more) measured average values at a location, which unfortunately are not available for most locations in the world. For such locations, an estimating method (theoretical model) based on some measured climatic parameter may be used. This chapter describes several ways of estimating terrestrial solar radiation; all have large uncertainties (as much as  $\pm 30\%$ ) associated with them.

### 36.4.1 Atmospheric Extinction of Solar Radiation

As solar radiation  $I$  travels through the atmosphere, it is attenuated due to absorption and scattering. If  $K$  is the local extinction coefficient of the atmosphere, the

**FIGURE 36.13**

Attenuation of solar radiation as it passes through the atmosphere.

beam solar radiation at the surface of the earth can be written according to Bouger's law as

$$I_{b,N} = I_e^{-\int k dx}, \quad (36.14)$$

where  $I_{b,N}$  is the instantaneous beam solar radiation per unit area normal to the sun's rays and  $x$  is the length of travel through the atmosphere. If  $L_0$  is the vertical thickness of the atmosphere and

$$\int_0^{L_0} K dx = k, \quad (36.15)$$

the beam normal solar radiation for a solar zenith angle of  $z$  will be

$$I_{b,N} = I_e^{-k \sec z} = I_e^{-k / \sin \alpha} = I_e^{-km}, \quad (36.16)$$

where  $m$  is a dimensionless path length of sunlight through the atmosphere, sometimes called the *air mass ratio* (Figure 36.14):

$$m = \frac{\overline{BP}}{AP} \approx \frac{1}{\cos z} \approx \frac{1}{\sin \alpha}. \quad (36.17)$$

**FIGURE 36.14**

Air mass definition; air mass  $m = BP/AP = \text{cosec } \alpha$ , where  $\alpha$  is the altitude angle. The atmosphere is idealized as a constant thickness layer.

The following equation gives a more accurate value of air mass according to Kasten and Young (1989):

$$m \approx \frac{1}{\sin \alpha + 0.50572 (6.07995 + \alpha)^{-1.6364}} \quad (36.18)$$

where  $\alpha$  is expressed in degrees. When solar altitude angle is  $90^\circ$  (sun is overhead),  $m = 1$ .

### 36.4.2 Clear Sky Radiation Model

Gueymard and Thevenard (2009) have described a model that can be used to model solar radiation for clear days for a large number of locations in the world. This model was developed for ASHRAE to calculate the solar heat gain for fenestration; therefore, they named it the ASHRAE clear sky model. This is a simple model that was developed based on a large number of simulations using sophisticated spectral simulations using the spectral model of the atmospheric radiative transfer of sunshine (SMARTS) spectral code developed by Gueymard (2000, 2005b, 2008a) and validating with ground-based measurements. Based on the detailed simulations, Gueymard developed a simple two-band solar irradiance model, the reference evaluation of solar transmittance, 2 (REST2), that can model clear sky solar irradiance very accurately. The proposed model was developed in two steps:

1. Solar transmittance of clear sky was modeled based on two spectral bands, the first band from 290 to 700 nm, characterized by absorption by molecules and aerosols, and the second band from 700 to 4000 nm, characterized by absorption by water vapor and  $\text{CO}_2$ . The two-band clear sky radiation model was used to calculate clear sky solar irradiance for a large number of *typical* cases and compared with the data covering a large part of the world. [Figure 36.15](#) shows the global sites used in the validation.
2. The second step consisted in developing a condensed model depending on only two monthly parameters described later in this section.

**FIGURE 36.15**

World sites of interest used in the model. (From Gueymard, C.A. and Thevenard, D., *Solar Energy*, 82, 272, 2009.)

According to the ASHRAE model, the beam and diffuse components are calculated as

$$I_{b,N} = I(e^{-\tau_b m^b}), \quad (36.19)$$

$$I_{d,h} = I(e^{-\tau_d m^d}), \quad (36.20)$$

where

$I_{b,N}$  is the beam normal irradiance per unit area normal to the sun rays

$I_{d,h}$  is the diffuse horizontal irradiance per unit area on a horizontal surface

$I$  is the extraterrestrial normal irradiance

$m$  is the air mass

$\tau_b, \tau_d$  are the beam and diffuse optical depths ( $\tau_b$  and  $\tau_d$  are more correctly termed pseudo-optical depths, because optical depth is usually employed when the air mass coefficient is unity)

$b, d$  are the beam and diffuse air mass exponents

Values of  $\tau_b$  and  $\tau_d$  are location-specific and vary during the year. They embody the dependence of clear sky solar radiation upon local conditions, such as elevation, precipitable water content, and aerosols. Their average values are tabulated for the 21st day of each month for all the locations in the tables of climatic design conditions (*ASHRAE Handbook*, 2009 Fundamentals).

Air mass exponents  $b$  and  $d$  are correlated to  $\tau_b$  and  $\tau_d$  through the following empirical relationships:

$$b = 1.219 - 0.043 \tau_b - 0.151 \tau_d - 0.204 \tau_b \cdot \tau_d \quad (36.21)$$

$$d = 0.202 + 0.852 \tau_b - 0.007 \tau_d - 0.357 \tau_b \cdot \tau_d. \quad (36.22)$$

**FIGURE 36.16**

Solar radiation on a horizontal surface.

This radiation model describes a simple parameterization of a sophisticated broadband radiation model and provides accurate predictions of  $I_{b,N}$  and  $I_{d,h}$  even at sites where the atmosphere is very hazy or humid most of the time.

Solar radiation on a horizontal surface is given by (Figure 36.16)

$$I_h = (I_{b,N} \sin \alpha + I_{d,h}). \quad (36.23)$$

### 36.4.3 Solar Radiation on a Tilted Surface

Solar radiation on an arbitrary tilted surface having a tilt angle of  $\beta$  from the horizontal and an azimuth angle of  $a_w$  (assumed + west of south), as shown in Figure 36.17, is the sum of components consisting of beam ( $I_{b,c}$ ), sky diffuse ( $I_{d,c}$ ), and ground-reflected solar radiation ( $I_{r,c}$ ):

$$I_c = I_{b,c} + I_{d,c} + I_{r,c}. \quad (36.24)$$

**FIGURE 36.17**

Definitions of solar angles for a tilted surface.

If  $i$  is the *angle of incidence* of the beam radiation on the tilted surface, it is simple to show that the instantaneous beam radiation on the surface per unit area is

$$I_{b,c} = I_{b,N} \cos i. \quad (36.25)$$

From the geometry in [Figure 36.17](#), it can be shown that the angle of incidence  $i$  for the surface (angle between the normal to the surface and a line collinear with the sun's rays) is related to the solar angles as

$$\cos i = \cos \alpha \cos (a_s - a_w) \sin \beta + \sin \alpha \cos \beta. \quad (36.26)$$

The diffuse radiation on the surface ( $I_{d,c}$ ) can be obtained by multiplying the sky diffuse radiation on a horizontal surface by the view factor between the sky and the surface:\*

$$\begin{aligned} I_{d,c} &= I_{d,h} (I + \cos \beta) / 2 \\ &= I_{d,h} \cos^2(\beta/2). \end{aligned} \quad (36.27)$$

The ground-reflected solar radiation can be found from the total solar radiation incident on a horizontal surface and the ground reflectance  $\rho$  as

$$I_{r,c} = I_h \rho. \quad (36.28)$$

The part of  $I_r$  intercepted by the tilted surface can be found by multiplying the ground-reflected radiation by the view factor between the surface\* and the ground:

$$\begin{aligned} I_{r,c} &= \rho I_h (1 - \cos \beta) / 2 = \rho I_h \sin^2(\beta/2) \\ &= \rho (I_{b,h} \sin \alpha + I_{d,h}) \sin^2(\beta/2). \end{aligned} \quad (36.29)$$

For ordinary ground or grass,  $\rho$  is approximately 0.2, and for snow-covered ground, it can be taken as approximately 0.8.

### Example 36.3a

Find the instantaneous solar radiation at 12:00 noon Eastern Standard Time on a solar collector surface ( $\beta = 30^\circ$ ,  $a_w = +10^\circ$ ) on February 1st in Tampa, FL.

### Solution

For Tampa International Ap,  $L = 2796$  N (+),  $L_{local} = 82.54$  W (+), and  $L_{ST} = 75$  W (+) for February 1st;  $n = 32$ .

The declination angles for this day are

$$\begin{aligned} \delta_s &= 23.45^\circ \sin \left[ \frac{360}{365} (284 + 32) \right] \\ \delta_s &= -17.51^\circ \end{aligned}$$

The local time is 12:00 PM. The solar time is given by

$$ST = LST + ET + (L_{st} - L_{local}) \cdot 4 \frac{\text{min}}{1^\circ}.$$

The equation of time is

$$B = \frac{360}{364}(32 - 81) = -48.46^\circ$$

$$ET(\text{min}) = 9.87(2 \times (-48.46^\circ)) - 7.53 \cos(-48.46^\circ) - 1.5 \sin(-48.46^\circ).$$

$$= -13.66 \text{ min.}$$

Then the solar time is

$$ST = 12:00 - 13.66 \text{ min} + (75^\circ - 82.54^\circ) \times 4 = 11:16 \text{ AM.}$$

The hour angle is

$$h_s = (ST - 12) \frac{15^\circ}{\text{h}} = (11.26 - 12) \frac{15^\circ}{\text{h}} = -11.1^\circ.$$

The solar altitude angle is

$$\sin \alpha = \cos \delta_s \cos L \cosh_s + \sin \delta_s \sin L$$

$$= \cos(-17.51^\circ) \cos(27.96^\circ) \cos(-11.1^\circ) + \sin(-17.51^\circ) \sin(27.96^\circ)$$

and

$$\alpha = 43.30^\circ.$$

The solar azimuth angles are defined by

$$\sin a_s = \cos \delta_s \frac{\sin h_s}{\cos \alpha} = \cos(-17.51^\circ) \frac{\sin(-11.1^\circ)}{\cos(43.30^\circ)}$$

and

$$a_s = -14.61^\circ.$$

We need to find out if  $|a_s|$  is greater than  $90^\circ$ .

For

$$L > \delta_s,$$

$$t_E = 12:00 - \left[ \cos^{-1} \left( \frac{\tan \delta_s}{\tan L} \right) \right] \frac{\text{h}}{15^\circ}$$

$$= 12:00 - \left[ \cos^{-1} \left( \frac{\tan(-17.51^\circ)}{\tan(27.96^\circ)} \right) \right] \frac{\text{h}}{15^\circ}.$$

$$= 3.5689 \text{ h}$$

Given that  $ST > t_E$ , the sun is south, and  $a_s = -14.61^\circ$ . The air mass is as follows

$$m = \frac{1}{\sin(43.30^\circ) + 0.50572(6.07995 + 43.30^\circ)^{-1.6364}}$$

$$= 1.4565.$$

The data for the Tampa International AP, FL, are shown in [Table 36.3](#).

**TABLE 36.3**

Data for Tampa International AP, FL

Lat, 27.96N; long, 82.54W; elev, 3 m												
Month	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec

$\tau_d$	2.531	2.403	2.271	2.272	2.029	2.07	1.95	2.01	2.19	2.356	2.488	2.512
$I_{b,N}$ , noon (W/m <sup>2</sup> )	902	908	899	895	831	823	793	805	836	861	876	882
$I_{d,h}$ , noon (W/m <sup>2</sup> )	94	113	134	137	174	167	188	175	143	116	97	93

Source: Data taken from *ASHRAE Handbook: Fundamentals*: SI Edition, American Society of Heating, Refrigeration and Air-Conditioning Engineers, Inc., 2009.

The *pseudo*-optical depths are tabulated for the 21st day of each month for all the locations in the tables of climatic design. Values for other days of the year should be found by interpolation. For this example, by using linear interpolation between January and February, the *pseudo*-optical depths are

$$\tau_b = 0.35109$$

$$\tau_d = 2.48558.$$

The parameters for air mass are as follows:

$$b = 1.219 - 0.043\tau_b - 0.151\tau_d - 0.204\tau_b\tau_d = 0.6506$$

$$d = 0.202 - 0.852\tau_b - 0.007\tau_d - 0.357\tau_b\tau_d = -0.4261.$$

The extraterrestrial solar radiation is given by

$$\begin{aligned}
 I &= I_0 \left[ 1 + 0.034 \cos \left( \frac{360n}{365.25} \right)^\circ \right] \\
 &= 1366.1 \left[ 1 + 0.034 \cos \left( 360 \times \frac{32}{365.26} \right)^\circ \right] = 1406 \text{ W/m}^2.
 \end{aligned}$$

The direct solar radiation component is

$$\begin{aligned}
 I_{b,N} &= Ie^{-\tau_b m^b} \\
 &= 1406 \exp(-0.35109 \cdot 1.4565^{0.6506}) \\
 &= 898 \text{ W/m}^2.
 \end{aligned}$$

The diffuse solar radiation on a horizontal surface is

$$\begin{aligned}
 I_{d,h} &= Ie^{-\tau_d m^d} \\
 &= 1406 \exp(-2.48558 \cdot 1.4565^{-0.4261}) \\
 &= 169 \text{ W/m}^2.
 \end{aligned}$$

The instantaneous beam radiation on the surface per unit area is given by

$$I_{b,c} = I_{b,N} \cos i.$$

For this geometry, the cosine of the angle of incidence is

$$\begin{aligned} \cos i &= \cos \alpha \cos(a_s - a_w) \sin \beta + \sin \alpha \cos \beta \\ &= \cos(43.30^\circ) \cos(-14.61^\circ - (+10^\circ)) \sin(30^\circ) + \sin(43.30^\circ) \cos(30^\circ) \\ &= 0.9248. \end{aligned}$$

Then the beam radiation is

$$I_{b,c} = 898 \times 0.9248 = 830 \text{ W/m}^2.$$

The diffuse radiation on the collector surface will be

$$\begin{aligned} I_{d,c} &= I_{d,h} \cos^2\left(\frac{\beta}{2}\right) \\ &= 169 \cos^2\left(\frac{30^\circ}{2}\right) \\ &= 158 \text{ W/m}^2. \end{aligned}$$

The ground-reflected solar radiation is

$$I_{r,c} = \rho(I_{b,N} \sin \alpha + I_{d,h}) \sin^2\left(\frac{\beta}{2}\right).$$

Assuming that the solar collector is surrounded by ordinary ground or grass, then  $\rho \approx 0.2$ :

$$\begin{aligned} I_{r,c} &= 0.2(898 \sin(43.30^\circ) + 169.10) \sin^2\left(\frac{30^\circ}{2}\right) \\ &= 11 \text{ W/m}^2. \end{aligned}$$

Finally, the total radiation on a tilted collector surface is

$$I_c = I_{b,c} + I_{d,c} + I_{r,c} = 830 + 158 + 11 = 999 \text{ W/m}^2.$$

### Example 36.3b

Repeat the calculations in Example 36.3a for a north-facing solar collector ( $\beta = 30^\circ$ ,  $a_w = 10^\circ$ ) in Canberra, Australia (latitude =  $35^\circ - 18'$  S, longitude =  $149^\circ - 11'$  E, Standard Meridian =  $150^\circ$  E).

### Solution

As the day number has not been changed, the values of the  $\delta_s$  and ET remain the same:

$$\delta_s = -17.51^\circ$$

$$ET = -13.66 \text{ min.}$$

The local time is 12:00 PM. The solar time is given by

$$ST = 12:00 - 13.66 \text{ min} + (-150^\circ + 149.18^\circ) \times 4 \frac{\text{min}}{1^\circ} = 11:43 \text{ AM.}$$

The hour angle is

$$h_s = (ST - 12) \frac{15^\circ}{\text{h}} = (11.72 - 12) \frac{15^\circ}{\text{h}} = -4.2^\circ.$$

The solar altitude angle is

$$\begin{aligned} \sin \alpha &= \cos \delta_s \cos L \cosh_s + \sin \delta_s \sin L \\ &= \cos(-17.51^\circ) \cos(-35.3^\circ) \cos(-4.2^\circ) + \sin(-17.51^\circ) \sin(-35.3^\circ) \end{aligned}$$

and

$$\alpha = 71.82^\circ.$$

The solar azimuth angles are defined by

$$\sin a_s = \cos \delta_s \sin h_s / \cos \alpha = \cos(-17.51^\circ) \sin(-4.2^\circ) / \cos(71.82^\circ)$$

and

$$a_s = -12.93^\circ.$$

The air mass is as follows:

$$m = \frac{1}{\sin(71.82^\circ) + 0.50572(6.07995 + 71.82^\circ)^{-1.6364}} = 1.052.$$

The data for the Canberra airport are shown in Table 36.4.

By using linear interpolation between January and February, the *pseudo*-optical depths are

$$\tau_b = 0.3548$$

$$\tau_d = 2.4584.$$

**TABLE 36.4**

Data for Canberra Airport

Lat, 35.30S; long, 149.20E; elev, 580 m

Source: Data taken from: 2009 *ASHRAE Handbook: Fundamentals*: SI Edition, American Society of Heating, Refrigeration and Air-Conditioning Engineers, Inc.

The parameters for air mass are as follows:

$$b = 1.219 - 0.043\tau_b - 0.151\tau_d - 0.204\tau_b\tau_d = 0.6546$$

$$d = 0.202 - 0.852\tau_b - 0.007\tau_d - 0.357\tau_b\tau_d = -0.4289.$$

The extraterrestrial solar radiation is given by

$$I = I_0 \left[ 1 + 0.034 \cos \left( \frac{360n}{365.25} \right)^\circ \right] = 1406 \text{ W/m}^2.$$

The direct solar radiation component is

$$I = I_0 \left[ 1 + 0.034 \cos \left( \frac{360n}{365.25} \right)^\circ \right] = 1406 \text{ W/m}^2.$$

The diffuse solar radiation on a horizontal surface is

$$I_{d,h} = I e^{-\tau_d m^d}$$

$$= 1406 \exp(-2.4584 \times 1.0521^{-0.4289})$$

$$= 127 \text{ W/m}^2.$$

The cosine of the angle of incidence is

$$\cos i = \cos \alpha \cos(a_s - a_w) \sin \beta + \sin \alpha \cos \beta$$

$$= \cos(71.82^\circ) \cos(-12.93^\circ - (+10^\circ)) \sin(30^\circ) + \sin(71.82^\circ) \cos(30^\circ)$$

$$= 0.9665.$$

Then the beam radiation is

$$I_{b,c} = I_{b,N} \cos i$$

$$I_{b,c} = 974 \times 0.9665 = 941 \text{ W/m}^2.$$

The diffuse radiation on the collector surface will be

$$I_{d,c} = I_{d,h} \cos^2 \left( \frac{\beta}{2} \right)$$

$$= 127 \cos^2 \left( \frac{30^\circ}{2} \right)$$

$$= 118 \text{ W/m}^2.$$

The ground-reflected solar radiation is

$$I_{r,c} = \rho(I_{b,N} \sin \alpha + I_{d,h}) \sin^2 \left( \frac{\beta}{2} \right).$$

Assuming that the solar collector is surrounded by ordinary ground or grass, then  $\rho \approx 0.2$ :

$$\begin{aligned} I_{r,c} &= 0.2(974 \sin(71.82^\circ) + 127) \sin^2\left(\frac{30^\circ}{2}\right) \\ &= 14 \text{ W/m}^2. \end{aligned}$$

Finally, the total radiation on a tilted collector surface is

$$I_c = I_{b,c} + I_{d,c} + I_{r,c} = 941 + 118 + 14 = 1073 \text{ W/m}^2.$$

### 36.4.4 Monthly Solar Radiation Estimation Models

One of the earliest methods of estimating solar radiation on a horizontal surface was proposed by the pioneer spectroscopist Angström. It was a simple linear model relating average horizontal radiation to clear-day radiation and to the sunshine level, that is, percent of possible hours of sunshine. Since the definition of a clear day is somewhat nebulous, Page [34] refined the method and based it on extraterrestrial radiation instead of the ill-defined clear day:

$$\begin{aligned} \bar{H}_h &= \bar{H}_{o,h} \left( a + b \frac{\bar{n}}{\bar{N}} \right) \\ &= \bar{H}_{o,h} \left( a + b \frac{\overline{PS}}{100} \right) \end{aligned} \quad (36.30)$$

where

$\bar{H}_h$  and  $\bar{H}_{o,h}$  are the horizontal terrestrial and horizontal extraterrestrial radiation levels averaged for a month

$\overline{PS}$  is the monthly averaged percent of possible sunshine (i.e., hours of sunshine / maximum possible duration of sunshine  $\times 100$ )

$a$  and  $b$  are constants for a given site

$\bar{n}$  and  $\bar{N}$  are the monthly average numbers of hours of bright sunshine and day length, respectively

The ratio  $\bar{n}/\bar{N}$  is also equivalent to the monthly average percent sunshine ( $\overline{PS}$ ).  $\bar{H}_{o,h}$  can be calculated by finding  $H_{o,h}$  from Equation 36.31, using Equations 36.13 and 36.30, and averaging  $I_{o,h}$  for the number of days in each month:

$$H_{o,h} = \int_{t_{sr}}^{t_{ss}} I \sin \alpha dt. \quad (36.31)$$

Some typical values of  $a$  and  $b$  are given in Table 36.5 [26].

A number of researchers found Angström–Page-type correlations for specific locations that are listed in Table 36.6. Some of these include additional parameters such as relative humidity and ambient temperature. Correlations listed in the table may be used for the specific locations for which they were developed.

Another meteorological variable that could be used for solar radiation prediction is the opaque cloud cover recorded at many weather stations around the world. This quantity is

a measure of the percent of the sky dome obscured by opaque clouds. Because this parameter contains even less solar information than sunshine values, it has not been useful in predicting long-term solar radiation values. A subsequent section, however, will show that cloud cover, when used with solar altitude angle or air mass, is a useful estimator of hourly direct radiation.

### 36.5 Models Based on Long-Term Measured Horizontal Solar Radiation

Long-term measured solar radiation data are usually available as monthly averaged total solar radiation per day on horizontal surfaces. In order to use these data for tilted surfaces, the total solar radiation on a horizontal surface must first be broken down into beam and diffuse components. A number of researchers have proposed models to do that, prominent among them being Liu and Jordan, Collares-Pereira and Rabl, and Erbs, Duffie, and Klein.

Gopinathan [10]	40 locations around the world	$\frac{\bar{H}_h}{\bar{H}_{o,h}} = a + b \left( \frac{\bar{n}}{\bar{N}} \right)$ $a = -0.309 + 0.539 \cos L - 0.0639h + 0.290 \left( \frac{\bar{n}}{\bar{N}} \right)$ $b = 1.527 - 1.027 \cos L + 0.0926h - .359 \left( \frac{\bar{n}}{\bar{N}} \right)$

Note:  $\bar{N}'$ , maximum duration for which Campbell–Stokes recorder can be active, that is, solar elevation  $>5^\circ$ ;  $W_{at}$ , relative humidity  $\times (4.7923 + 0.3647T + 0.055T^2 + 0.0003 T^3)$ ;  $T$ , ambient temperature,  $^\circ\text{C}$ ;  $W_{at}$ , gm moisture/ $\text{m}^3$ ;  $h$ , elevation in km above sea level;  $L$ , latitude.

<sup>a</sup>  $\bar{H}_a$ ,  $\bar{H}_b$ ,  $\bar{H}_{o,h}$ ,  $\bar{D}_h$  are monthly averaged daily values.

### 36.5.1 Monthly Solar Radiation on Tilted Surfaces

In a series of papers, Liu and Jordan [21–25] have developed an essential simplification in the basically complex computational method required to calculate long-term radiation on tilted surfaces. This is called the Liu and Jordan (LJ) method. The fundamental problem in such calculations is the decomposition of long-term measured total horizontal radiation into its beam and diffuse components.

If the decomposition can be computed, the trigonometric analysis presented earlier can be used to calculate incident radiation on any surface in a straightforward manner. Liu and Jordan (LJ) correlated the diffuse-to-total radiation ratio  $(\bar{D}_h/\bar{H}_h)$  with the *monthly clearness index*  $\bar{K}_T$ , which is defined as

$$\bar{K}_T = \frac{\bar{H}_h}{\bar{H}_{o,h}}, \quad (36.32)$$

where

$\bar{H}_h$  is the monthly averaged terrestrial radiation per day on a horizontal surface

$\bar{H}_{o,h}$  is the corresponding extraterrestrial radiation, which can be calculated from Equation 36.31 by averaging each daily total for a month

The original LJ method was based upon the extraterrestrial radiation at midmonth, which is not truly an average.

The LJ correlation predicts the monthly diffuse ( $\bar{D}_h$ ) to monthly total  $\bar{H}_h$  ratio. It can be expressed by the following empirical equation:

$$\frac{\bar{D}_h}{\bar{H}_h} = 1.390 - 4.027\bar{K}_T + 5.531\bar{K}_T^2 - 3.108\bar{K}_T^3. \quad (36.33)$$

Note that the LJ correlation is based upon a solar constant value of 1394 W/m<sup>2</sup> (442 Btu/h-ft<sup>2</sup>), which was obtained from terrestrial observations, whereas the newer value, based on satellite data, is 1377 W/m<sup>2</sup> (437 Btu/h-ft<sup>2</sup>). The values of  $\bar{K}_T$  must be based on this earlier value of the solar constant to use the LJ method. Collares-Pereira and Rabl [4] conducted a study and concluded that although LJ's approach is valid, their correlations would predict significantly smaller diffuse radiation components. They also concluded that LJ were able to correlate their model with the measured data because they used the measured data that were not corrected for the shade ring (see solar radiation measurements). Collares-Pereira and Rabl also introduced the sunset hour angle  $h_{ss}$  in their correlation to account for the seasonal variation in the diffuse component. The Collares-Pereira and Rabl (C-P&R) correlation is

$$\frac{\bar{D}_h}{\bar{H}_h} = 0.775 + 0.347\left(h_{ss} - \frac{\pi}{2}\right) - \left[0.505 + 0.0261\left(h_{ss} - \frac{\pi}{2}\right)\right]\cos(2K_T - 1.8), \quad (36.34)$$

where  $h_{ss}$  is the sunset hour angle in radians. The C-P&R correlation agrees well with the correlations for India [3], Israel [43], and Canada [39] and is, therefore, preferred to Equation 36.33.

The monthly average beam component  $\bar{B}_h$  on a horizontal surface can be readily calculated by simple subtraction since  $\bar{D}_h$  is known:

$$\bar{B}_h = \bar{H}_h - \bar{D}_h. \quad (36.35)$$

It will be recalled on an instantaneous basis from Equations 36.23 and 36.25 and Figure 36.17 that

$$I_{b,N} = \frac{I_{b,h}}{\sin \alpha}, \quad (36.36)$$

$$I_{b,c} = I_{b,N} \cos i, \quad (36.37)$$

where  $I_{b,h}$  is the instantaneous horizontal beam radiation. Solving for  $I_{b,c}$ , the beam radiation on a surface,

$$I_{b,c} = I_{b,h} \left( \frac{\cos i}{\sin \alpha} \right). \quad (36.38)$$

The ratio in parentheses is usually called the beam radiation *tilt factor*  $R_b$ . It is a purely geometric quantity that converts instantaneous horizontal beam radiation to beam radiation intercepted by a tilted surface.

Equation 36.38 cannot be used directly for the long-term beam radiation  $\bar{B}_h$ . To be strictly correct, the instantaneous tilt factor  $R_b$  should be integrated over a month with the beam component  $I_{b,h}$  used as a weighting factor to calculate the beam tilt factor. However, the LJ method is used precisely when such short-term data as  $I_{b,h}$  are not available. The LJ recommendation for the monthly mean tilt factor  $\bar{R}_b$  is simply to calculate the monthly average of  $\cos i$  and divide it by the same average of  $\sin \alpha$ . In equation form for south-facing surfaces, this operation yields

$$\bar{R}_b = \frac{\cos(L - \beta) \cos \delta_s \sin h_{sr} + h_{sr} \sin(L - \beta) \sin \delta_s}{\cos L \cos \delta_s \sin h_{sr}(\alpha = 0) + h_{sr}(\alpha = 0) \sin L \sin \delta_s}, \quad (36.39)$$

where the sunrise hour angle  $h_{sr}(\alpha = 0)$  in radians is given by Equation 36.8 and  $h_{sr}$  is the  $\min \left[ |h_s(\alpha = 0)|, |h_s(i = 90^\circ)| \right]$ , respectively, which are evaluated at midmonth. Non-south-facing surfaces require numerical integration or iterative methods to determine  $\bar{R}_b$ . The long-term beam radiation on a tilted surface  $\bar{B}_c$  is then

$$\bar{B}_c = \bar{R}_b \bar{B}_h, \quad (36.40)$$

which is the long-term analog of Equation 36.27.

Diffuse radiation intercepted by a tilted surface differs from that on a horizontal surface, because a tilted surface does not view the entire sky dome, which is the source of diffuse radiation. If the sky is assumed to be an isotropic source of diffuse radiation, the instantaneous and long-term tilt factors for diffuse radiation,  $R_d$  and  $\bar{R}_d$ , respectively, are equal and are simply the radiation view factor from the plane to the visible portion of a hemisphere. In equation form,

$$R_d = \bar{R}_d = \cos^2 \frac{\beta}{2} = \frac{(1 + \cos \beta)}{2}. \quad (36.41)$$

In some cases where solar collectors are mounted near the ground, some beam and diffuse radiation reflected from the ground can be intercepted by the collector surface. The tilt factor  $\bar{R}_r$  for reflected total radiation ( $\bar{D}_h + \bar{B}_h$ ) is then calculated to be

$$\bar{R}_r = \frac{\bar{R}}{\bar{D}_h + \bar{B}_h} = \rho \sin^2 \frac{\beta}{2} = \frac{\rho(1 - \cos \beta)}{2}, \quad (36.42)$$

in which  $\rho$  is the diffuse reflectance of the surface south of the collector assumed uniform and of infinite extent.

For snow,  $\rho \cong 0.75$ ; for grass and concrete,  $\rho \cong 0.2$ . The total long-term radiation intercepted by a surface  $\bar{H}_c$  is then the total of beam, diffuse, and diffusely reflected components:

$$\bar{H}_c = \bar{R}_b \bar{B}_h + \bar{R}_d \bar{D}_h + \bar{R}_r (\bar{D}_h + \bar{B}_h). \quad (36.43)$$

Using Equations 36.41 and 36.42, we have

$$\bar{H}_c = \bar{R}_b \bar{B}_h + \bar{D}_h \cos^2 \frac{\beta}{2} + (\bar{D}_h + \bar{B}_h) \rho \sin^2 \frac{\beta}{2}, \quad (36.44)$$

in which  $\bar{R}_b$  is calculated from Equation 36.39.

#### Example 36.4

Using a value of  $\bar{H}_h$  as 16,215 kJ/m<sup>2</sup>/day for January in place of the long-term measured data for the North Central Sahara Desert at latitude 25° N, find the monthly averaged insolation per day on a south-facing solar collector tilted at an angle of 25° from the horizontal.

#### Solution

The following solution is for the month of January. Values for the other months can be found by following the same method:

$$\bar{H}_h = 16,215 \text{ kJ/m}^2/\text{day}.$$

From Table A2.2a,

$$\bar{H}_{o,h} = 23,902.$$

Therefore,

$$\bar{K}_T = \frac{\bar{H}_h}{\bar{H}_{o,h}} = 0.678.$$

$\delta_s$  and  $h_{sr}$  can be found for the middle of the month (January 16):

$$\begin{aligned} \delta_s &= 23.45^\circ \sin[360(284 + 16)/365]^\circ \\ &= -21.1^\circ, \end{aligned}$$

$$\begin{aligned} h_{sr}(\alpha = 0) &= -\cos^{-1}(-\tan L \tan \delta) \\ &= -79.6^\circ \quad \text{or} \quad -1.389 \text{ rad} \end{aligned}$$

and

$$h_{ss} = 1.389.$$

Using the C-P&R correlation,

$$\begin{aligned}\frac{\bar{D}_h}{H_h} &= 0.775 + 0.347(1.389 - 1.5708) - [0.505 + 0.0261(1.389 - 1.5708)]\cos(2 \times 0.678 - 1.8) \\ &= 0.212.\end{aligned}$$

Therefore,

$$\bar{D}_h = 0.212 \times 16,215 = 3,438 \text{ kJ/m}^2/\text{day}$$

and

$$\bar{B}_h = \bar{H}_h - \bar{D}_h = 12,777 \text{ kJ/m}^2/\text{day}$$

Insolation on a tilted surface can be found from Equation 36.43. We need to find  $\bar{R}_b$  from Equation 36.39.

Therefore,

$$\begin{aligned}\bar{R}_b &= \frac{\cos(0)\cos(-21.1^\circ)\sin(-79.6^\circ) - 1.389\sin(0)\sin(-21.1^\circ)}{\cos(25^\circ)\cos(-21.1^\circ)\sin(-79.6^\circ) - 1.389\sin(25^\circ)\sin(-21.1^\circ)} \\ &= 147.\end{aligned}$$

$$\bar{R}_d = \cos^2(25/2) = 0.953.$$

$$\begin{aligned}\bar{R}_r &= \rho \sin^2(\beta/2) \text{ (Assume } \rho = 0.2) \\ &= 0.2\sin^2(12.5^\circ) \\ &= 0.009.\end{aligned}$$

Therefore,

$$\begin{aligned}\bar{H}_c &= (1.47)(12,777) + 0.953(3,438) + 0.009(16,215) \\ &= 22,205 \text{ kJ/m}^2.\end{aligned}$$

### 36.5.2 Circumsolar or Anisotropic of Diffuse Solar Radiation

The models described in the earlier sections assume that the sky diffuse radiation is isotropic. However, this assumption is not true because of circumsolar radiation (brightening around the solar disk). Although the assumption of isotropic diffuse solar radiation does not introduce errors in the diffuse values on horizontal surfaces, it can result in errors of 10%–40% in the diffuse values on tilted surfaces. A number of researchers have studied the anisotropy of the diffuse solar radiation because of circumsolar radiation. Temps and Coulson [45] introduced an anisotropic diffuse radiation algorithm for tilted surfaces for

clear sky conditions. Klucher [20] refined the Temps and Coulson algorithm by adding a cloudiness function to it:

$$R_d = \frac{1}{2}(1 + \cos \beta)M_1M_2, \quad (36.45)$$

where

$$M_1 = 1 + F \sin^3(\beta/2), \quad (36.46)$$

$$M_2 = 1 + F \cos^2 i \sin^3(z), \quad (36.47)$$

$$F = 1 - \left( \frac{D_h}{H_h} \right)^2. \quad (36.48)$$

Examining  $F$ , we find that under overcast skies ( $D_h = H_h$ ),  $R_d$  in Equation 36.45 reduces to the isotropic term of LJ. The Klutcher algorithm reduces the error in diffuse radiation to about 5%.

In summary, monthly averaged, daily solar radiation on a surface is calculated by first decomposing total horizontal radiation into its beam and diffuse components using Equation 36.34 or 36.35. Various tilt factors are then used to convert these horizontal components to components on the surface of interest.

### 36.5.3 Hourly and Daily Solar Radiation on Tilted Surfaces

Accurate determinations of the hourly solar radiation received during the average day of each month are a prerequisite in different solar energy applications. In the early 1950s, Whillier introduced the *utilizability* method to analytically predict the performance of active solar collectors. This method used a simple formulation to estimate the mean hourly radiation during each hour of an average day of the month, based on the ratio of the hourly to daily irradiation received by a horizontal surface outside of the atmosphere. The long-term models provide the mean hourly distribution of global radiation over the average day of each average month.

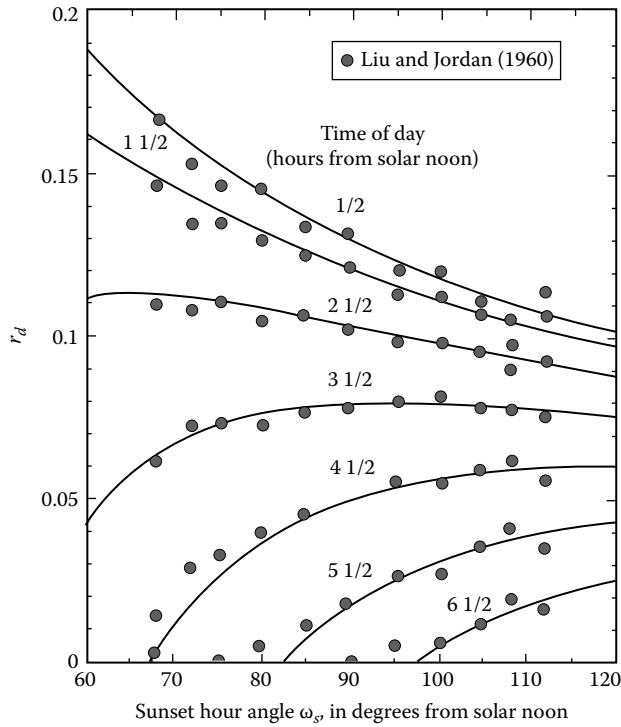

Three methods are described as follows:

#### 1. C-P&R model, CPR (Figure 36.18)

Given the long-term average daily total and diffuse irradiation on a horizontal surface  $\bar{H}_h$  and  $\bar{H}_d$ , it is possible to find the long-term average hourly irradiances  $\bar{I}_d$ ,  $\bar{I}_h$ , and  $\bar{I}_b$ .

The ratio of the hourly diffuse to the long-term average daily diffuse irradiation on a horizontal surface,  $r_d$ , is given by

$$r_d = \frac{I_d}{\bar{H}_d} = \frac{\pi}{24} \frac{\cos h_s - \cos h_{ss}}{\sin h_{ss} - \left( \frac{\pi}{180} \right) h_{ss} \cos h_{ss}}. \quad (36.49)$$

**FIGURE 36.18**

C-P&R model, CPR. (Adapted from Collares-Pereira, M. and Rabl, A., *Sol. Energ.*, 22, 155, 1979; Liu, B.H.Y. and Jordan, R.C., *Sol. Energ.*, 4, 1, 1960.)

The ratio of hourly total to the long-term average daily total irradiation on a horizontal surface,  $r_h$ , is given by

$$r_t = \frac{I_h}{H_h} = (a + b \cos h_s) r_d \quad (36.50)$$

with

$$a = 0.409 + 0.5016 \sin(h_{ss} - 60^\circ)$$

$$b = 0.6609 - 0.4767 \sin(h_{ss} - 60^\circ)$$

This fit satisfies, within 1% for all  $h_{ss}$ , the normalization condition:

$$\int_{-t_s}^{t_s} I_d dt = \overline{H_h} \quad (36.51)$$

## 2. C-P&R model modified by Gueymard, CPRG (Figure 36.19)

For the CPRG method, the ratio of hourly total to the long-term average daily total irradiation on a horizontal surface,  $r_h$ , is given by [52]

$$r_t = \frac{I_h}{H_h} = \frac{(a + b \cos h_s) r_d}{f_c} \quad (36.52)$$

**FIGURE 36.19**

C-P&R model modified by Gueymard [51]. (Adapted from Collares-Pereira, M. and Rabl, A., *Sol. Energ.*, 22, 155, 1979; Liu, B.H.Y. and Jordan, R.C., *Sol. Energ.*, 4, 1, 1960.)

with

$$f_c = a + kb \left[ \left( \frac{\pi}{180} \right) h_{ss} - \frac{1}{2} \sin 2h_{ss} \right]. \quad (36.53)$$

$$k = \left( 2 \left[ \sin h_{ss} - \left( \frac{\pi}{180} \right) h_{ss} \cos h_{ss} \right] \right)^{-1}. \quad (36.54)$$

The normalization condition is expressed by

$$\int_{-t_s}^{t_s} r_t dt = 1. \quad (36.55)$$

### 3. For both CPR and CPRG models

The instantaneous solar beam radiation on a horizontal surface,  $I_{b,h}$ , is given by

$$I_{b,h} = r_t \bar{H}_h - r_d \bar{H}_d. \quad (36.56)$$

The instantaneous solar beam radiation on a tilted surface,  $I_{b,c'}$  is

$$I_{b,c} = I_{b,h} \frac{\cos i}{\sin \alpha}. \quad (36.38)$$

Then the total radiation on a tilted surface,  $I_c$  is

$$I_c = (r_i \bar{H}_h - r_d \bar{H}_d) \frac{\cos i}{\sin \alpha} + r_d \bar{H}_d \cos^2 \left( \frac{\beta}{2} \right) + \rho r_i \bar{H}_h \sin^2 \left( \frac{\beta}{2} \right). \quad (36.57)$$

### 36.5.4 Spectral Models

Many biological, chemical, and physical processes are activated more powerfully at some wavelengths than at others. Therefore, it is important to know the spectral characteristics of the incident radiation. In order to model spectral solar radiation at a location, radiation needs to be modeled as it travels through the atmosphere. These models are complex to begin with and are made more complex since different wavelengths are absorbed, reflected, and scattered differently in the atmosphere. Examples of radiative transfer numerical models include the Santa Barbara DISORT, the atmospheric radiative transfer code SBDART, and the moderate resolution transmission code MODTRAN. SBDART, developed at the University of California at Santa Barbara, is relatively simpler to use than MODTRAN, is freely accessible, and even has a convenient user interface online: <http://arm.mrcsb.com/sbdart/>

MODTRAN, developed by the Air Force Geophysical Laboratory (AFGL), has a much higher resolution and is considered as the standard in atmospheric applications.

These models, however, are not convenient for solar energy or other engineering-type applications.

**FIGURE 36.20**

A sample spectral irradiance prediction compared with measured data for Golden, Colorado.

Bird's simple spectral model (SPCTRAL2), the SMARTS, and REST2 can be used for solar engineering applications. Even though these models are limited to clear sky conditions, they can also be empirically modified to predict spectra under cloudy conditions. SMARTS model offers fast and accurate predictions of spectral irradiance on any tilted surface without the difficulties and limitations associated with the atmospheric models mentioned earlier. Sample outputs produced by SMARTS, compared with actual spectroradiometric measurements from high-performance instruments, are shown in the Figures 36.20 and 36.21.\*

## 36.6 Measurement of Solar Radiation

Solar radiation measurements of importance to most engineering applications, especially thermal applications, include total (integrated over all wavelengths) direct or beam and sky diffuse values of solar radiation on instantaneous, hourly, daily, and monthly bases. Some applications such as photovoltaics, photochemical, and daylighting require knowledge of spectral (wavelength specific) or band (over a wavelength range—e.g., ultraviolet, visible, infrared) values of solar radiation. This section describes some of the instrumentation used to measure solar radiation and sunshine and some sources of long-term measured data for different parts of the world. Also described briefly in this section is the method of satellite-based measurements.

A sample prediction for direct normal, diffuse, and global horizontal spectral irradiance.

### 36.6.1 Instruments for Measuring Solar Radiation and Sunshine

There are two basic types of instruments used to measure solar radiation, *pyranometer* and *pyrheliometer*. A pyranometer has a hemispherical view of the surroundings and therefore is used to measure total, direct and diffuse, solar radiation on a surface. A pyrheliometer, on the other hand, has a restricted view (about 5°) and is, therefore, often used to measure the direct or beam solar radiation by pointing it toward the sun. Pyranometers are also used to measure the sky diffuse radiation by using a shadow band to block the direct sun view. A detailed discussion of the instrumentation and calibration standards is given by Iqbal [15] and Zerlaut [48].

A pyranometer consists of a flat sensor/detector (described later) with an unobstructed hemispherical view, which allows it to convert and correlate the total radiation incident on the sensor to a measurable signal. The pyranometers using thermal detectors for measurements can exhibit serious errors at tilt angles from the horizontal due to free convection. These errors are minimized by enclosing the detector in double hemispherical high-transmission glass domes. The second dome minimizes the error due to infrared radiative exchange between the sensor and the sky. A desiccator is usually provided to eliminate the effect due to condensation on the sensor or the dome. Figure 36.22 shows pictures of typical commercially available precision pyranometer.

**FIGURE 36.22**

Typical commercially available pyranometers with (a) thermal detector and (b) photovoltaic detector.

**FIGURE 36.23**

A pyranometer with a shade ring to measure sky diffuse radiation.

A pyranometer can be used to measure the sky diffuse radiation by fitting a shade ring to it, as shown in Figure 36.23, in order to block the beam radiation throughout the day. The position of the shade ring is adjusted periodically as the declination changes. Since the shade ring obstructs some diffuse radiation from the pyranometer, correction factors must be applied.

Geometric correction factors (GCFs) that account for the part of the sky obstructed by the shade ring can be easily calculated. However, a GCF assumes isotropic sky, which results in errors because of the circumsolar anisotropy. Eppley Corp. recommends additional correction factors to account for anisotropy as +7% for clear sky, +4% for partly cloudy condition, and +3% for cloudy sky. Mujahid and Turner [30] determined that these correction factors gave less than 3% errors on partly cloudy days but gave errors of -11% for clear sky conditions and +6% on overcast days. They suggested correction factors due

**TABLE 36.7**

Shading Band Correction Factors due to Anisotropy

to anisotropy as tabulated in Table 36.7, which reduce the errors to less than  $\pm 3\%$ . It must be remembered that these correction factors are in addition to the GCFs. Recently, a sun occulting disk has been employed for shading the direct sun.

Beam or direct solar radiation is usually measured with an instrument called a pyr-heliometer. Basically a pyr-heliometer places the detector at the base of a long tube. This geometry restricts the sky view of the detector to a small angle of about  $5^\circ$ . When the tube points toward the sun, the detector measures the beam solar radiation and a small part of the diffuse solar radiation within the view angle. Figure 36.24 shows the geometry of a pyr-heliometer sky occulting tube.

**FIGURE 36.24**

Geometry of a pyr-heliometer sky occulting tube.

In this figure, the opening half angle

$$\theta_o = \tan^{-1} \frac{R}{L}. \quad (36.58)$$

The slope angle

$$\theta_p = \tan^{-1} \left[ \frac{(R-r)}{L} \right]. \quad (36.59)$$

The limit half angle

$$\theta = \tan^{-1} \left[ \frac{(R+r)}{L} \right]. \quad (36.60)$$

The field of view is  $2\theta_o$ . The World Meteorological Organization (WMO) recommends the opening half angle  $\theta_o$  to be  $2.5^\circ$  [48] and the slope angle  $\theta_p$  to be  $1^\circ$ .

Continuous tracking of the sun is required for the accuracy of the measurements. This is obtained by employing a tracking mechanism with two motors, one for altitude and the other for azimuthal tracking. Another problem is that the view angle of a pyrheliometer is significantly greater than the angle subtended by the solar disk (about  $0.5^\circ$ ). Therefore, the measurements using a pyrheliometer include the beam and the circumsolar radiation. These measurements may present a problem in using the data for central receiver systems that use only direct beam radiation. However, this is not a significant problem for parabolic trough concentrators that in most cases have a field of view of the order of  $5^\circ$ .

### 36.6.2 Detectors for Solar Radiation Instrumentation

Solar radiation detectors are of four basic types [15,48]: thermomechanical, calorimetric, thermoelectric, and photoelectric. Of these, thermoelectric and photoelectric are the most common detectors in use today.

A *thermoelectric detector* uses a thermopile that consists of a series of thermocouple junctions. The thermopile generates a voltage proportional to the temperature difference between the hot and cold junctions that, in turn, is proportional to the incident solar radiation. Figure 36.25 shows different types of thermopile configurations. The Eppley black and white pyranometer uses a radial differential thermopile with the hot junction coated with 3M Velvet Black™ and the cold junction coated with a white barium sulfate paint.

*Photovoltaic detectors* normally use silicon solar cells measuring the short circuit current. Such detectors have the advantage of being simple in construction. Because heat transfer is not a consideration, they do not require clear domes or other convection suppressing devices. They are also insensitive to tilt as the output is not affected by natural convection. One of the principal problems with photovoltaic detectors is their spectral selectivity. Radiation with wavelengths greater than the bandgap of the photovoltaic detector cannot be measured. Silicon has a bandgap of 1.07 eV corresponding to a wavelength of  $1.1 \mu\text{m}$ . A significant portion of the infrared part of solar radiation has wavelengths greater than  $1.1 \mu\text{m}$ . Therefore, photovoltaic detectors are insensitive to changes in the infrared part of solar radiation.

**FIGURE 36.25**

Various thermopile configurations. (From Zerlaut, G., *Solar radiation instrumentation*, in *Solar Resources*, Roland L. Hulstrom, ed., MIT Press, Cambridge, MA, 1989.)

### 36.6.3 Measurement of Sunshine Duration

The time duration of bright sunshine data is available at many more locations in the world than the solar radiation. That is why a number of researchers have used these data to estimate the available solar radiation. Two instruments are widely used to measure the sunshine duration. The device used by the U.S. National Weather Service is called a *sunshine switch*. It is composed of two photovoltaic cells—one shaded, the other not. During daylight a potential difference is created between the two cells, which in turn operates the recorder. The intensity level required to activate the device is that just sufficient to cast a shadow. The other device commonly used to measure the sunshine duration is called the *Campbell–Stokes sunshine recorder*. It uses a solid, clear glass sphere as a lens to concentrate the solar beam on the opposite side of the sphere. A strip of standard treated paper marked with time graduations is mounted on the opposite side of the sphere where the solar beam is concentrated. Whenever the solar radiation is above a threshold, the concentrated beam burns the paper. The length of the burned part of the strip gives the duration of bright sunshine. The problems associated with the Campbell–Stokes sunshine recorder include the uncertainties of the interpretation of burned portions of the paper, especially on partly cloudy days, and the dependence on the ambient humidity. [Figure 36.26](#) shows a Campbell–Stokes sunshine recorder.

### 36.6.4 Measurement of Spectral Solar Radiation

Spectral solar radiation measurements are made with spectroradiometers. Full-spectrum scanning is difficult, requires constant attention during operation, and is therefore expensive. Zerlaut [48] has described a number of solar spectroradiometers. These instruments consist basically of a monochromator, a detector–chopper assembly, an integrating sphere, and a signal conditioning/computer package. They have the capability of measuring solar radiation in the wavelength spectrum of 280–2500 nm.

**FIGURE 36.26**

Campbell–Stokes sunshine recorder.

### 36.6.5 Wideband Spectral Measurements

Some applications of solar energy require solar radiation data in wideband wavelength ranges such as visible, ultraviolet, and infrared rather than complete spectral data. For example, solar photocatalytic detoxification using  $\text{TiO}_2$  as the catalyst needs data in the UV wavelength range, while passive solar applications need data in the infrared wavelength range. Instruments such as pyranometers and pyrhemimeters can be adapted for wideband spectral measurements by using cut-on and cutoff filters. Eppley instruments provide standard cut-off filters at wavelengths 530 nm (orange), 630 nm (red), and 695 nm (dark red). They are provided as plain filters at the aperture of a pyrhemimeter tube and as outer glass domes for pyranometers. Instrument manufacturers provide various interference filters peaking at different wavelengths in the solar spectrum.

Solar UV measurements are important in general since prolonged exposure to solar UV can cause skin cancer, fading of colors, and degradation of plastic materials. Such measurements have become even more important because the photocatalytic effect based on  $\text{TiO}_2$  as a catalyst depends only on the solar UV wavelength range. [Figure 36.27](#) shows an Eppley model total ultraviolet radiometer (TUVR) that measures the total hemispherical UV radiation from 295 to 385 nm. This radiometer uses a selenium photoelectric cell detector, a pair of band pass filters to allow wavelengths from 295 to 385 nm to pass through, and a beveled Teflon diffuser.

### 36.6.6 Solar Radiation Data

Measured solar radiation data are available at a number of locations throughout the world. Data for many other locations have been estimated based on measurements at similar climatic locations.

**FIGURE 36.27**

Eppley TUV-R®. (Courtesy of Eppley Lab, Newport, RI.)

Solar radiation data for the United States are available from the National Climatic Data Center (NCDC) of the National Oceanic and Atmospheric Administration (NOAA) and the NREL. In the mid-1970s, NOAA compiled a database of measured hourly global horizontal solar radiation for 28 locations for the period 1952–1975 (called SOLMET) and of data for 222 additional sites (called ERSATZ) estimated from SOLMET data and some climatic parameters such as sunshine duration and cloudiness. NOAA also has two data sets of particular interest to engineers and designers: the TMY and the Weather Year for Energy Calculations (WYEC) data sets. TMY data set represents typical values from 1952 to 1975 for hourly distribution of direct beam and global horizontal solar radiation. The WYEC data set contains monthly values of temperature, direct beam and diffuse solar radiation, and estimates of *illuminance* (for daylighting applications). Illuminance is solar radiation in the visible range to which the human eye responds. Recently, NREL compiled an NSRDB for 239 stations in the United States [28,32]. NSRDB is a collection of hourly values of global horizontal, direct normal, and diffuse solar radiation based on measured and estimated values for a period of 1961–1990. Since long-term measurements were available for only about 50 stations, measured data make up only about 7% of the total data in the NSRDB. A TMY data set from NSRDB is available as TMY2.

The data for other locations in the world are available from national government agencies of most countries of the world. Worldwide solar radiation data are also available from the World Radiation Data Center (WRDC) in St. Petersburg, Russia, based on worldwide measurements made through local weather service operations [47]. WRDC, operating under the auspices of the World Meteorological Organization (WMO), has been archiving data from over 500 stations and operates a website in collaboration with NREL with an

address of <http://wrdc.mgo.nrel.gov>. An International Solar Radiation Data Base was also developed by the University of Lowell [46].

### 36.7 Solar Radiation Mapping Using Satellite Data

Remote sensing satellite data have been used since the early 1960s to extract quantitative and qualitative cloud data. The most important application of cloud cover mapping has been the observation of storms and hurricanes, etc. Recently, however, considerable interest has been developed in using the cloud mapping data to estimate terrestrial solar radiation. Since meteorological satellites from a number of countries can now cover most of the earth, the data can be used to estimate solar radiation where no measured data exist or none is being measured.

Weather satellites are available in three main orbiting configurations—equatorial, polar, and geostationary. The equatorial satellites are low-level orbiting satellites (~600 km altitude) that generally orbit the earth in a west to east direction in a sinusoidal path that crosses the equator at least twice per orbit. Polar satellites are also low-orbit satellites that orbit the earth from the north to the south pole while the earth rotates underneath. Sun synchronous polar orbits have their orbits synchronized with the sun such that the same point on the earth is viewed at the same time each day. Low-orbit satellites are capable of gathering high-resolution spatial data. A geostationary satellite orbits in such a way that it is always over the same point on the earth's surface. Geostationary satellites have very high altitudes (approximately 36,000 km) and can provide high-temporal-resolution images over a large portion of the earth's surface. A number of countries maintain geostationary satellites including the United States (GOES, longitudes 70° W and 140° W), Europe (METEOSAT, longitude 0°), India (INSAT, longitude 70° E), and Japan (GMS, longitude 140° E).

Various types of high-resolution radiometers collect radiative data images of the earth's atmosphere below. These radiometers scan spectral measurements in the wavelength ranges of shortwave (0.2–3.0  $\mu\text{m}$ ), longwave (6.5–25  $\mu\text{m}$ ), and total irradiance (0.2–100  $\mu\text{m}$ ). The spatial resolution of images from the satellite is given by a *pixel* that represents the smallest area of data, generally of the order of 2 km  $\times$  2 km. However, several pixels of data

**FIGURE 36.28**

GOES-8 intermediate-resolution image close-up around Albany. (From Perez, R., The strengths of satellite based resource assessment, *Proceedings of the 1997 ASER Annual Conference*, Washington, DC, pp. 303–308, 1997.)

are required to derive a surface value giving a surface resolution of the order of 10 km × 10 km. Figure 36.28 shows an example of an intermediate-resolution GOES-8 image around Albany, New York, overlaid on a local map.

### 36.7.1 Estimation of Solar Resource from Satellite Data

The signal recorded by a radiometer on a satellite measures the solar radiation flux reflected back from the earth's atmosphere. The basic method behind estimation of ground solar radiation from these data is to apply the principle of energy conservation in the earth-atmosphere system [31], as shown in Figure 36.29. From this figure we can write

$$I_{in} = I_{out} + I_a + I_g, \quad (36.61)$$

where

$I_{in}$  represents the solar radiation incident on the atmosphere

$I_{out}$  represents the outward radiation from the atmosphere

$I_a$  is the radiation absorbed by the atmosphere

$I_g$  is the radiation absorbed by the ground

$I_g$  can be expressed in terms of the surface albedo\*  $\rho$  (reflectivity) and the solar radiation  $I_s$  incident on the earth's surface:

$$I_g = I_s(1 - \rho). \quad (36.62)$$

**FIGURE 36.29**

Solar radiation in the earth-atmosphere model.

From Equations 36.61 and 36.62 we can obtain

$$I_s = \frac{(I_{in} - I_{out} - I_a)}{(1 - \rho)}. \quad (36.63)$$

$I_{out}$  is measured by the satellite radiometers.  $I_{in}$  depends on the sun–earth distance and the solar zenith angle and can be calculated using Equation 36.11 as

$$I_{in} = I_o \left( \frac{D_o}{D} \right)^2 \cdot \cos(z). \quad (36.64)$$

If we could estimate  $I_a$ , and  $A$  were known a priori,  $I_s$  could be estimated using Equation 36.63 from the value of  $I_{out}$  measured by a satellite. However,  $I_a$  cannot be estimated easily since it depends on the atmospheric conditions such as cloud cover, dust particles, and air mass, and surface albedo (reflectance)  $\rho$  varies for every point of the region under consideration. In order to deal with these factors, two types of empirical methods are under development. These are known as statistical and physical methods. These methods have been reviewed in detail by Schmetz [40], Hay [12], Noia et al. [31], Islam [17], and Pinker et al. [36].

*Statistical Methods:* Statistical methods are based on finding a relationship between the radiative flux measured by a satellite radiometer and the simultaneous solar radiation value measured at the earth's surface in the area under consideration. Some of the models developed on statistical approach include Hay and Hanson [13], Tarpley [44], Justus et al. [18], Cano and Sorapipatana et al. [41].

*Physical Methods:* Physical methods are based on the analysis of radiative processes in the atmosphere as the solar radiation passes through it. Some of the models developed with this approach include Gautier [9], Moser and Raschke [29], Dedieu et al. [6], and Marullo et al. [27].

The simplest of the previously mentioned models is by Hay and Hanson [13], which gives the atmospheric transmittance  $T$  as

$$T = \frac{I_s}{I_{in}} = a - b \frac{I_{out}}{I_{in}},$$

or  $I_s = aI_{in} - bI_{out}.$  (36.65)

The values of regression coefficients given by Hay and Hanson [13] are  $a = 0.79$ ,  $b = 0.71$ . This method is simple; however, the coefficients, particularly  $b$ , vary considerably with parameters such as cloud reflectivity. More recent investigations suggest that it is necessary to determine the coefficients  $a$  and  $b$  for different locations.

It is beyond the scope of this book to discuss all the models. It suffices, however, to point out that all the models, including the Hay and Hanson model, more or less give values within 10% of the ground measured values [31]. The methods usually break down under partly cloudy conditions and under snow-covered ground conditions.

### 37.1 Wind Origins

The primary causes of horizontal atmospheric air motion, or wind, are the uneven heating of the earth and its atmosphere by solar radiation and the earth's rotation. The earth's atmosphere reflects about 43% of the incident solar radiation back into space, absorbs about 17% of it in the lower portions of atmosphere, and transmits the remaining 40% to the surface of the earth, where much of it is then reradiated into the atmosphere. The radiation from the hot sun is at short wavelengths (0.15–4  $\mu\text{m}$ ) and passes readily through the atmosphere, while the radiation from the cooler earth is at longer wavelengths (5–20  $\mu\text{m}$ ) and is readily absorbed by the water vapor in the atmosphere. Thus, the radiation from the earth is primarily responsible for the warmth of the atmosphere near the earth's surface. Heat is also transferred from the earth's surface to the atmosphere by conduction and convection.

On average, the total amount of energy radiated to space from the earth and its atmosphere must be equivalent to the total amount of solar radiation absorbed, or the temperature of the earth and its atmosphere would steadily increase or decrease. The more nearly perpendicular the sun's rays strike the earth, the more solar radiation is transferred through the atmosphere. Thus, during the year, tropical regions receive much more solar energy than do polar regions. Winds and ocean currents level out this imbalance in thermal energy, preventing the tropical regions from getting progressively hotter and the polar regions from getting progressively colder. In addition, the lack of homogeneity of the earth's surface—the land, water, desert, forest, rock, sand, black loam soil, etc.—leads to differences in solar radiation absorption and reflection back to the atmosphere, creating differences in atmospheric temperature, density, and pressure. These differences, in turn, create forces that contribute to wind. For example, the difference in radiation absorption and emission by land and water along a coastline is the dominant cause of the light shore winds or breezes; the difference in radiation absorption and emission by mountains and valleys is a significant contribution to the light upslope and downslope breezes often found in mountainous terrain. The earth's rotation results in Coriolis forces, which accelerate each moving particle of air. This acceleration moves an air particle to the right of its direction of motion in the Northern Hemisphere and to the left in the Southern Hemisphere. The geostrophic winds in the upper atmosphere (above 600 m or so) are due to the balance of these Coriolis forces and the pressure gradient forces due to the uneven heating of the atmosphere.

The earth's rotation also imparts an angular momentum to each particle of air in a west-to-east direction. Conservation of angular momentum results in an increase in its west-to-east velocity as the particle moves from the equator toward the poles. In the temperate zones, this causes the westerlies, winds opposite to the general flow, in both hemispheres.

The other long-term, large-scale global wind patterns such as equatorial doldrums, trade winds, easterlies, and subtropical and polar jets, illustrated in [Figure 37.1](#), are also caused by the combination of differential solar heating and the rotation of the earth. These wind patterns are often referred to as the general circulation patterns. In actuality, these patterns are complicated by seasonal effects due to changes in the earth's position relative to the sun during the course of a year and geographical effects due to the uneven distribution of, and physical properties of, water and land surfaces. Centers of high or low pressure, caused by heating or cooling of the lower atmosphere, include hurricanes, monsoons, and extratropical cyclones. Small-scale phenomena characterized by local wind include land and sea breezes, valley and mountain winds, monsoon-like flow, Foehn winds (dry, high-temperature winds on the downwind side of mountain ranges, commonly referred to in the western United States as "chinooks"), thunderstorms, and tornadoes.

Variations of wind speed in time can be divided into the categories of interannual, annual, diurnal, and short-term. Interannual variations in wind speed occur over timescales greater than 1 year. They can have a large effect on long-term wind turbine production. Meteorologists generally conclude that it takes 30 years of data to accurately determine long-term values of weather or climate and that it takes at least 5 years of data to arrive at a reliable average annual wind speed at a given location. However, that doesn't mean that data spanning shorter periods of time are useless.

Annual variations refer to significant variations in seasonal or monthly averaged wind speeds that are common over most of the world. For example, for the eastern one-third of the United States, maximum average wind speeds occur during the winter and early spring. Spring maximums occur over the Great Plains, the North Central States, the Texas Coast, in the basins and valleys of the West, and the coastal areas of Central and Southern California.

**FIGURE 37.1**

Semipermanent global wind patterns. (From Spera, D. (ed.), *Wind Turbine Technology: Fundamental Concepts of Wind Turbine Engineering*, ASME Press, New York, 1994. Reproduced by permission of ASME.)

Winter maximums occur over all U.S. mountainous regions, except for some areas in the lower southwest, where spring maximums occur. Spring and summer maximums occur in the wind corridors of Oregon, Washington, and California. [Figure 37.2](#) illustrates how the monthly average wind speed at a location can vary significantly from year to year.

Large diurnal or time-of-day variations in wind occur in both tropical and temperate latitudes. This type of wind speed variation is mainly due to differential heating of the earth's surface during the daily radiation cycle; this is especially true in temperate latitudes over relatively flat areas. A typical diurnal variation is an increase in wind speed during the day, with the wind speeds lowest during the hours from midnight to sunrise. The largest diurnal changes generally occur in spring and summer, and the smallest in winter. However, the diurnal variation may vary with location and altitude above sea level. For example, at altitudes high above surrounding terrain, for example, mountains or ridges above a plain, the diurnal pattern may be very different from the pattern for the surrounding terrain. This variation is due to mixing or transfer of momentum from the upper air to the lower air. There may be significant year-to-year differences in diurnal behavior, even at fairly windy locations. Although gross features of the diurnal cycle can be established with a single year of data, a good characterization of more detailed features, such as the amplitude of the diurnal oscillation and the time of day that the maximum winds occur, requires multiple years of data.

Variations in wind speed with periods of less than 10 min and that have a stochastic or random character are generally considered to represent turbulence or fluctuations

**FIGURE 37.2**

Seasonal changes of monthly average wind speeds for Billings, MT. (From Hiester, T.R. and Pennell, W.T., *The meteorological aspects of siting large wind turbines*, PNL-2522, Pacific Northwest Laboratory, Richland, WA, 1981.)

imposed on the mean wind speed. A gust is a short-term discrete event within a turbulent wind field. The common method of characterizing a gust is to measure or specify the amplitude, the rise time, the maximum gust variation, and the lapse time associated with it. Wind speed is very dependent on local topographical and ground cover variations. Figure 37.3 illustrates differences between two sites that are located in nominally flat terrain only 21 km apart. In spite of the close proximity and the flat terrain, the 5-year average mean wind speeds differ by about 12%.

**FIGURE 37.3**

## 37.2 Energy Available from the Wind

Given the fact that the wind blows everywhere, the idea of harnessing it to provide power is very appealing. Mankind has harnessed the power of the wind to produce mechanical power for well over 1000 years; the use of the wind to mill grain in Persia in the tenth century is well documented, and many experts speculate that the Chinese may have invented the windmill as much as 2000 years ago. How much power is available in the wind? Is it enough to be a viable source of energy in the modern world? Answers to these questions require knowledge of several wind energy basics.

### 37.2.1 Wind Power

Consider the air with an average velocity  $U$  and density  $\rho$  in a cylinder of cross section  $A$  and length  $L$  as shown in Figure 37.4. The mass of the air in that cylinder is  $\rho AL$ , and the kinetic energy (KE) of that air is  $\frac{1}{2}\rho ALU^2$  (Watt-hours or Wh). Now assume that there is a wind turbine rotor at the downwind end of that cylinder of air. The cylinder of air will pass through that rotor in a period of time,  $T$ , where  $T = L/U$ . The power, or time rate of change of the KE, available at the rotor then is  $\frac{1}{2}\rho ALU^2/T$ , which becomes

$$\text{Power} = \frac{1}{2}\rho AU^3 \text{ (W)} \quad (37.1)$$

This is often rearranged and expressed as power per unit area:

$$\text{WPD (wind power density)} = \frac{\text{Power}}{A} = \frac{1}{2}\rho U^3 \text{ (W/m}^2\text{)} \quad (37.2)$$

From Equation 37.1, it is obvious that the most important factor in the available wind power is the velocity of the wind. Increasing the wind velocity by only 20%, say from 5 to 6 m/s, increases the available wind power by 73%. Figure 37.5 illustrates the impact of normal annual wind speed variations at a location on the available wind power at that location.

The standard value for air density at sea-level reference conditions of 101,325 Pa pressure and 15°C is 1.225 kg/m<sup>3</sup>. The actual density depends on the moisture content or humidity of the air, the temperature, and the atmospheric pressure; however, the influence of

**FIGURE 37.4**  
Steady wind passing through turbine rotor disk.

**FIGURE 37.5**

Seasonal variation of available wind power density for Amarillo, TX. (From Rohatgi, J.S. and Nelson, V., *Wind Characteristics: An Analysis for the Generation of Wind Power*, Alternative Energy Institute, West Texas A&M University, Canyon, TX, 1994. Reproduced by permission of Alternative Energy Institute.)

humidity is very small and is normally neglected. Under this condition, the air density can be calculated from the perfect gas law

$$\rho = \frac{P}{RT} \text{ (kg/m}^3\text{)} \quad (37.3)$$

where

$P$  is the atmospheric pressure in Pa or N/m<sup>2</sup>

$R$  is the specific gas constant for air (287 J/kg K)

$T$  is the absolute air temperature in Kelvin

If site air pressure is not available, air density can be estimated as a function of site elevation,  $z$ , and absolute temperature as [1]

$$\rho = \left( \frac{353.05}{T} \right) e^{-0.034(z/T)} \text{ (kg/m}^3\text{)} \quad (37.4)$$

For example, the air density at Denver, Colorado (elevation 1600 m or 5300 ft above sea level), is approximately 15% lower than that at sea level, so wind of a given velocity at Denver contains 15% less power than wind of the same velocity at sea level (assuming the temperature is the same).

### 37.2.2 Wind Shear

Wind moving across the earth's surface is slowed by trees, buildings, grass, rocks, and other obstructions in its path, resulting in a wind velocity that varies with height above the earth's surface—a phenomena known as the *vertical wind profile* or *vertical wind shear*.

In most locations, wind shear is positive (wind speed increases with height), but situations in which the wind shear is negative or inverse are not unusual. In the absence of actual data for a specific site, a commonly used approximation for wind shear in an open area is

$$\frac{U}{U_o} = \left( \frac{h}{h_o} \right)^\alpha \quad (37.5)$$

where

$U$  is the velocity at a height  $h$

$U_o$  is the measured velocity at height  $h_o$

$\alpha$  is the wind shear exponent

The instantaneous wind shear exponent varies widely with elevation, time of day, season of the year, wind speed, temperature, and nature of the terrain. It could be, say, 0.1 during the day and then reach 0.5 at night [2]. The time-averaged shear exponent is the value that is normally used (averaged over several weeks); this varies with terrain characteristics, but usually falls between 0.10 and 0.25. Wind over a body of open water is normally well modeled by a value of  $\alpha$  of about 0.10; wind over a smooth, level, grass-covered terrain such as the U.S. Great Plains by a value of  $\alpha$  of about 0.14; wind over row crops or low bushes with a few scattered trees by a value of  $\alpha$  of 0.20; and wind over a heavy stand of trees, several buildings, or hilly or mountainous terrain by a value of  $\alpha$  of about 0.25. Short-term time-averaged shear factors as large as 1.25 have been documented in rare, isolated cases.

As a result of wind shear, the available wind power at a site may vary dramatically with height. For example, for  $\alpha = 0.20$ , Equations 37.1 and 37.5 reveal that the available wind power density (WPD) at a height of 50 m is approximately  $\{(50/10)^{0.2}\}^3 = 2.63$  times the available WPD at a height of 10 m. Keep in mind that Equation 37.5 is only an estimate; a specific site may display much different wind shear behavior, and that will dramatically affect site WPD, so it is very important to measure the wind resource at the specific site and height where the wind turbine will be located.

National Renewable Energy Laboratory (NREL) scientists recently analyzed wind data obtained from several tall towers at heights of up to 110 m and found that the annual average wind shear exponent at Great Plains sites for heights between 50 and 100 m ranges from 0.15 to 0.25, with a daytime shear between 0.05 and 0.1 and a nighttime shear between 0.25 and 0.40 [3]. They also found that surface roughness effects on wind shear can be significant at heights up to 100 m, wind shear exponents at heights of 100–150 m can exceed those at heights of 50–100 m, and large differences in shear exponents at elevated heights can exist among sites, even in local areas of similar wind climate [4]. Their recommendation from these studies is that direct measurement data at elevated heights are needed to validate model-derived wind resource estimates.

### 37.2.3 Available Resource

The amount of energy available in the wind (the wind energy resource [WER]) at a site is the average amount of power available in the wind over a specified period of time, commonly 1 year. If the wind speed is 20 m/s, the available power is very large at that instant, but if it blows at that speed for only 10 h/year and the rest of the time the wind speed is near zero, the resource for the year is small. Therefore, the relative frequency of occurrence for each wind speed (the wind speed distribution) is very important in determining the resource at the site. This distribution is determined experimentally as the relative

frequency of occurrence of uniform width wind speed ranges extending over the entire range of possible wind speeds (i.e., 0.5 m/s increments from 0 to 30 m/s). The wind speed associated with each range is that at the center of the range. This distribution may be approximated by a continuous curve, the probability density function or pdf, which corresponds to wind speed ranges of infinitesimal width.

If the actual wind speed probability density distribution is not available, it is commonly approximated with the generalized two-parameter Weibull distribution given by

$$f(U) = \frac{k}{C} \left( \frac{U}{C} \right)^{k-1} \exp \left[ - \left( \frac{U}{C} \right)^k \right] \quad (37.6)$$

where

$f(U)$  is the frequency of occurrence of wind speed  $U$

$k$  is the Weibull shape factor

$C$  is the Weibull scale factor

For the special case with parameter  $k$  equal to 2, this reduces to the commonly used Rayleigh distribution:

$$f(U) = \frac{\pi}{2} \frac{U}{\bar{U}^2} \exp \left[ - \frac{\pi}{4} \frac{U^2}{\bar{U}^2} \right] \quad (37.7)$$

where  $\bar{U}$  is the yearly average wind speed.

It is readily apparent that the average wind speed at a site yields a unique Rayleigh distribution for that site. Experimental data from a site also determine the best Weibull distribution for that site, but the process of determining  $k$  and  $C$  from the experimental data is not straightforward.

The measured wind speed distribution at the Amarillo, Texas, airport (yearly average wind speed of 6.6 m/s) is plotted in [Figure 37.6](#), together with the Weibull and Rayleigh distributions for that wind speed. It is obvious that the Rayleigh distribution is not a good representation for these data; the data have a higher peak, have a lower probability of lower wind speeds, and have a significantly higher probability of winds in the 4–12 m/s range. The Weibull distribution (the shape factor  $k$  was picked as 2.6, yielding an estimate for the scale factor  $C$  of 7.4) is a much better approximation of the data. It shows a good match to the peak probability, but it still is not a good match; the data consistently have a somewhat lower probability for wind speeds below about 10 m/s and a somewhat higher probability for wind speeds above 10 m/s.

With a discrete wind speed distribution and the local air density, the WER, or average wind power availability, for a specific site can be estimated as

$$\text{WER} = \frac{1}{2} A \sum_{i=1}^n \rho f(U_i) \Delta U_i U_i^3 (W) \quad (37.8)$$

where

$n$  is the number of wind speeds included in the distribution

$f(U_i) \Delta U_i$  is the probability of the wind speed occurring in the wind speed range  $\Delta U_i$  centered on wind speed  $U_i$

**FIGURE 37.6**  
Measured and analytical wind speed distributions for Amarillo, TX, airport.

If an analytical pdf (such as the Rayleigh or Weibull) is used, this becomes

$$\text{WER} = \frac{1}{2} A \int \rho f(U) U^3 dU(W) \quad (37.9)$$

The wind energy potential (WEP) or potential gross annual wind energy production for a specific site and a specific wind turbine can be calculated with a wind speed distribution and the turbine power curve (the electrical power generated by the turbine at each wind speed), properly adjusted for the local air density. For a discrete wind speed distribution,

$$\text{WEP} = 8760 \sum_{i=1}^n f(U_i) \Delta U_i P(U_i) (\text{Wh}) \quad (37.10)$$

where

8760 is the number of hours in a year

$P(U_i)$  is the electrical power produced by the turbine at wind speed  $U_i$ , the center of the range  $\Delta U_i$

With an analytical pdf (the Rayleigh or Weibull), this becomes

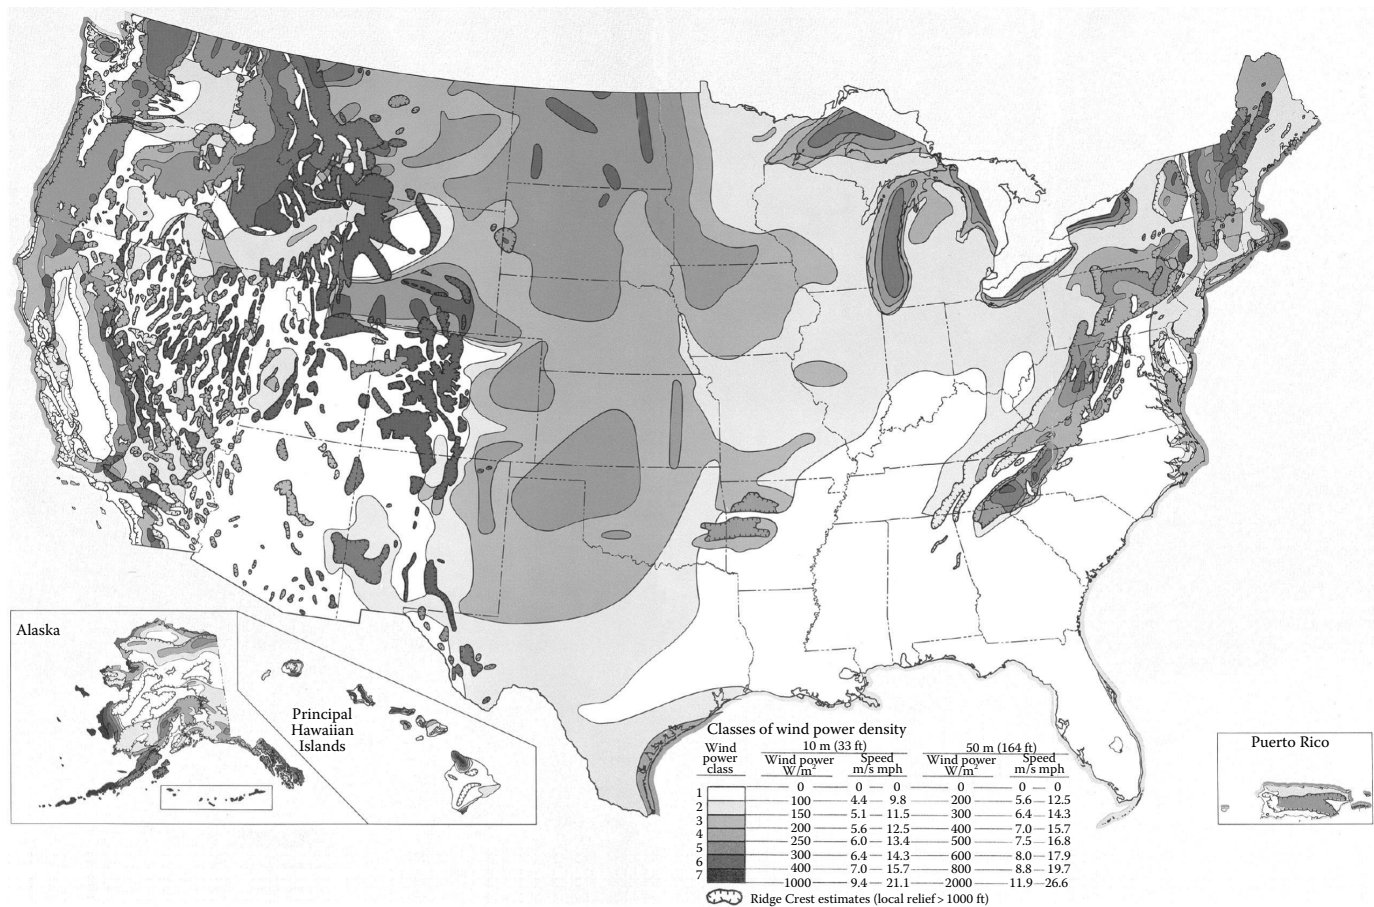

$$\text{WEP} = 8760 \int f(U) P(U) dU (\text{Wh}) \quad (37.11)$$

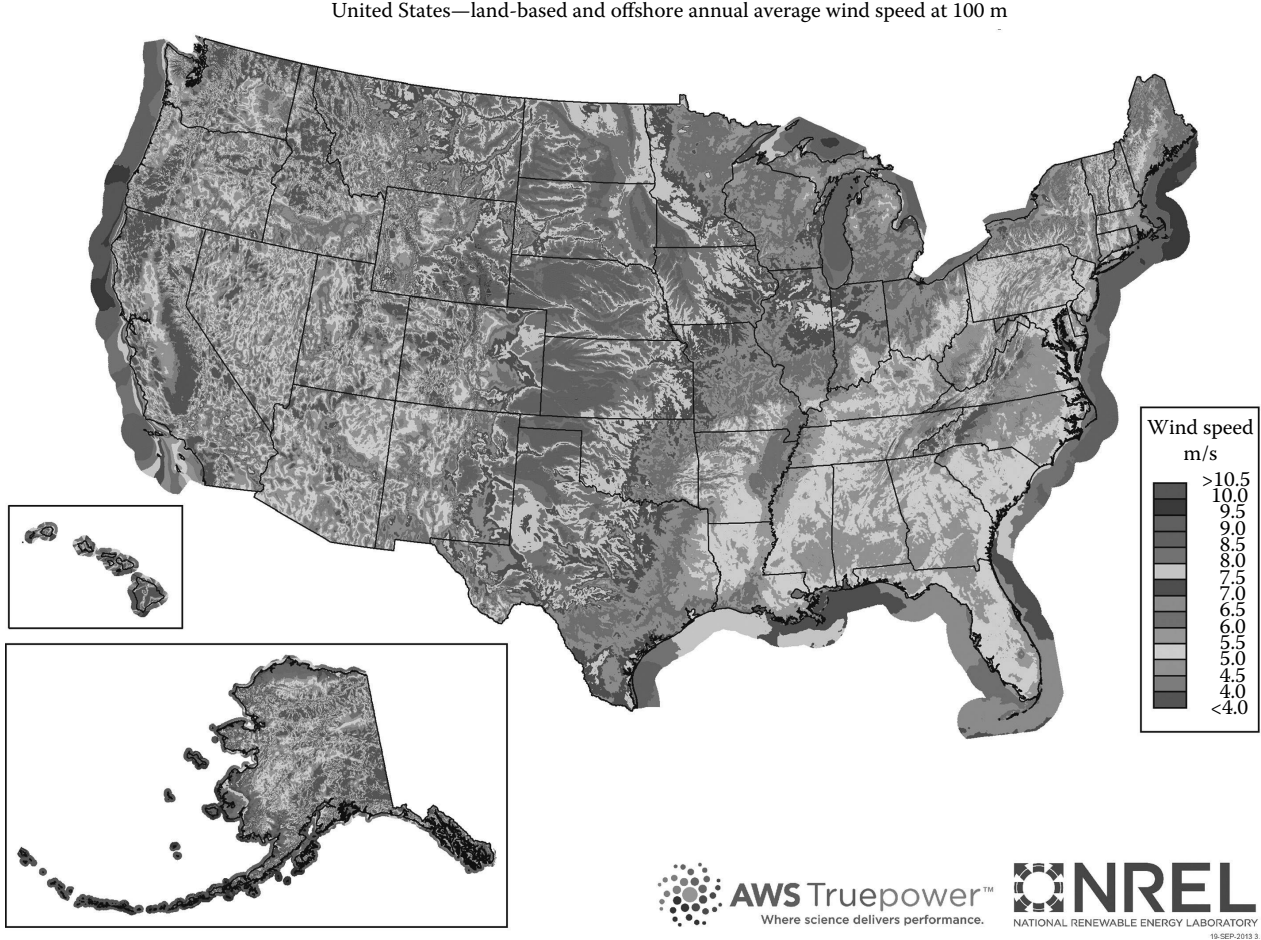

It is quite obvious that using an analytical pdf that is not a good match to the actual distribution at a site (such as the Weibull and Rayleigh distributions shown in Figure 37.6) will yield values for WER and WEP that are not good estimates of the actual values for that site. In order to get good estimates for these quantities, the actual wind speed distribution must be used.

In 1987, Elliott, Holladay, Barchet, Foote, and Sandusky at Battelle Pacific Northwest Laboratory in the United States carefully analyzed and interpreted the available long-term wind data for the United States and summarized their estimate of the WERs in the *Wind Energy Resource Atlas of the United States* [5]. Their summary for the entire United States is reproduced in Figure 37.7. The results are presented in terms of wind power classes based on the annual average power available per square meter of intercepted area (see the legend on Figure 37.7). Sites of wind power class 3 or higher (at least  $150 \text{ W/m}^2$  at 10 m height or  $300 \text{ W/m}^2$  at 50 m height) are usually considered economic for utility-scale wind power development with available wind technology. Sites of wind power class 2 or lower (less than  $150 \text{ W/m}^2$  at 10 m height or  $300 \text{ W/m}^2$  at 50 m height) are usually considered economic only for remote or hybrid wind power systems. Troen and Petersen at Denmark's Risø National Laboratory produced a European Wind Atlas [6] in 1989 that used somewhat different techniques to estimate the wind resources of the European Community countries. Their work summarizes the resource available at a 50 m height for five different topographic conditions.

The estimates shown in Figure 37.7 and those presented in [6] are quite crude and have been superseded in recent years by much higher-resolution maps at higher elevations, made possible by improvements in wind resource computer modeling programs, increases in computer speed, and development of high-altitude wind speed-measuring capabilities. In particular, NREL, in collaboration with AWS Truepower, has recently released new maps of the U.S. wind resource at 50, 80, and 100 m elevations [7]. The new 100 m resource map, displayed in Figure 37.8, reveals that many areas in the U.S. Midwest and Southeast thought to lack an adequate wind resource (see Figure 37.7) actually have commercially viable wind resources at turbine tower heights of 100 m or greater. Many countries around the world have embarked on similar high-resolution mapping efforts to accurately quantify their wind resources and identify those areas of highest resource. The resultant resource maps are frequently available to the public, but in some cases, a payment is required to obtain them. High-resolution wind resource maps of the individual states in the United States may be found on the web at [www.windpoweringamerica.gov/wind\\_maps.asp](http://www.windpoweringamerica.gov/wind_maps.asp). Some states have developed even more detailed maps in recent years, and these may be found on websites for the individual states. Similar maps for some other countries may be found at [www.nrel.gov/wind/international\\_wind\\_resources.html](http://www.nrel.gov/wind/international_wind_resources.html), and information on where to find maps and/or data for other countries may be found at [www.windatlas.dk/index.htm](http://www.windatlas.dk/index.htm). These newer wind resource evaluations frequently reveal far greater wind resource than earlier evaluations. In some cases, this is due to the higher resolution now available, but in some cases, this is because the early evaluations sometimes used unverified long-term data from existing weather stations where the anemometers had not been properly maintained—the bearings had deteriorated over time, and the anemometers registered lower winds than what actually existed. The verification procedures used in the newer evaluations are designed to help identify and eliminate this type of biased data. But even the highest resolution resource estimates are just that—estimates. The actual wind resources in any specific area can vary dramatically from those estimates and must be determined with long-term, site-specific, and elevation-specific measurements.

The U.S. wind energy resources. (From Elliott, D.L. et al., Wind energy resource atlas of the United States, DOE/CH10094-4, Solar Energy Research Institute, Golden, CO, 1987. Reproduced by permission of National Renewable Energy Laboratory, Golden, CO.)

**FIGURE 37.8**  
The U.S. high-altitude wind energy resources. (From Office of Energy Efficiency and Renewable Energy, U.S. Department of Energy, [http://energy.gov/sites/prod/files/styles/media\\_energy\\_gov\\_wysiwyg\\_fullwidth/public/wind\\_speed\\_map\\_lg.jpg?itok=ITLo1T1G](http://energy.gov/sites/prod/files/styles/media_energy_gov_wysiwyg_fullwidth/public/wind_speed_map_lg.jpg?itok=ITLo1T1G), accessed March 2015.)

Archer and Jacobson from Stanford University [8] have estimated the average global wind power potential for all land-based locations with wind class 3 or better (mean annual wind speeds in excess of 6.9 m/s at 80 m height) to be on the order of 72 TW (1 TW =  $10^{12}$  W) for the year 2000, yielding an average WEP of 627,000 TW h/year. In reality, the use of approximately 90% of the land mass is restricted, leaving only about 10% available for wind power generation. Thus, a realistic WEP from the Stanford study is on the order of 62,700 TW h/year. This figure is consistent with the published European Wind Energy Association [9] figure of 53,000 TW h/year of WEP and corresponds to over three times the world's total electricity needs in 2001 of 14,000–16,000 TW h/year. Many of the countries around the world have adequate wind resources to supply their entire energy consumption. Of course, this resource is not necessarily available at the right time or the right place, and actually capturing wind energy on this vast a scale is not apt to happen.

The wind resource over the water-covered portion of the earth's surface is many, many times greater than that over the land, but current wind energy technology is restricted to shallow water (water depths on the order of 30 m or less). The available wind resource over water restricted to these depths is still significant—recent NREL work has shown that the U.S. offshore gross wind resource at these depths is estimated at over 1000 GW, or roughly the generating capacity currently carried on the U.S. electric grid [10]. Keep in mind that this resource value will likely shrink by 60% or more after all environmental and socioeconomic constraints have been taken into account. Development of the technology required to enable utilization of the much larger WERs at greater water depths is the focus of much current research.

### **37.2.4 Environmental/Societal Restrictions**

The fact that a site has great wind resources and access to transmission lines with excess capacity does not mean that it is suitable for wind power development. Potential environmental and social issues must be considered and resolved before a wind facility can be built. In the best possible scenario, such issues will add expense and development time to a project. In the worst scenario, such issues could cause cancellation of a project. Some of the issues that could affect the suitability of a proposed site include the presence of endangered or protected species, nearby residences or airports (which might require significant setbacks of the nearest wind turbines), nearby scenic areas, recreational use or other specific use restrictions of the candidate site, or religious significance of the site. The following sections discuss two issues that are topics of research today.

#### **37.2.4.1 Impacts of Wind Facilities on Birds and Bats**

The greatest environmental issues that the wind industry has had to face are the possible impacts of wind facilities on birds and bats and their habitats. Concerns about the bird fatality issue were, in large part, the result of relatively high numbers of raptor deaths in the Altamont Pass wind farms east of San Francisco, CA, in the 1980–1985 time frame. Dozens of studies of this issue have been conducted during the past 30 years. Sinclair and Morrison [11] and Sinclair [12] give overviews of some of the early U.S. studies, and the National Wind Coordinating Committee has recently published a fact sheet summarizing the research performed prior to 2010 [13]. One conclusion of these studies is that the Altamont Pass situation appears to be a worst-case scenario, due in large part to bad turbine siting and to the presence of overhead power lines that led to a large number of bird electrocutions. Colson [14] and Wolfe [15] report that the numerous

recommendations for minimizing the impact of new wind farms on birds resulting from these studies include the following:

- Conduct site-specific mitigation studies.
- Avoid bird migration corridors and areas of high bird population such as micro-habitats or fly zones.
- Use fewer, larger turbines.
- Minimize the number of perching sites on turbine towers by using tubular, rather than lattice, towers.
- Bury electrical lines.

The subsequent development of industry siting guidelines for wind farms has proven to be quite effective; recent studies have shown that relatively low raptor fatality rates exist at most wind energy developments, with the possible exception of those wind farms in California that were developed prior to the establishment of these siting guidelines.

If large numbers of raptors are present, additional restrictions on turbine placement, style, height, etc., may be required by local authorities to minimize the potential for collisions with turbines. In reality, far more songbirds than raptors are killed by turbines; in spite of this, the estimated cumulative impact of songbird collisions with wind turbines is several orders of magnitude lower than the estimated impacts from the leading human-related causes of songbird mortality (vehicles, buildings and windows, power transmission lines, communication towers, toxic chemicals, and feral and domestic cats), according to the NWCC [13,16]. Bird collisions with wind turbines caused the deaths of only 0.01%–0.02% of all the birds killed by collisions with man-made structures across the United States in 2001. In contrast, bird collisions with buildings and windows accounted for about 55% of structure-related bird deaths, while collisions with vehicles, high-tension power lines, and communication towers accounted for about 17%.

Relatively small numbers of bat fatalities were reported at wind energy facilities in the United States before 2001, largely because most monitoring studies were designed to assess bird fatalities, according to Kunz et al. [17]. Bat carcasses are much more difficult to find than are bird carcasses, and they are quickly removed by predators, so it is quite likely that these studies underestimated bat fatalities. However, once more careful studies revealed that some wind farms were causing a large number of bat fatalities, the wind industry joined with Bat Conservation International, the U.S. Fish & Wildlife Service, and NREL to identify and quantify the problem and to explore ways to mitigate these deaths. Several wind energy companies are providing a portion of the funding for cooperative efforts to resolve this issue.

Although bat fatalities at wind energy facilities appear to be highest along forested ridgetops in the eastern United States, studies have revealed that bat fatalities are a widespread problem—turbine-related bat deaths have been reported at every wind facility studied to date, both in the United States and in Europe [13].

This problem has been actively studied for over a decade at this point, but it is still poorly understood. A few of the findings to date are as follows:

- Some migratory tree-roosting bat species appear particularly vulnerable to wind power fatalities.
- Bat fatalities peak at wind facilities during the late summer and early fall bat migration seasons.
- Most bat fatalities occur during periods of low wind, when flying insects, which are their primary source of food, are most common, and bats are most active.

Why are bats being killed by turbines? As documented by Baerwald et al. [18], given that echolocating bats detect moving objects better than stationary ones, their relatively high fatality rate at wind farms is perplexing. According to the NWCC [13], bats may be attracted to the turbines; possibly because the towers appear to be potential roosting trees, there is a high concentration of insects around the turbines (due to the favorable conditions created during turbine installation); or the sounds produced by turbines are attractive. On the other hand, the bats may become disoriented by the turbine sounds or by the electromagnetic fields in the vicinity of the turbine nacelles. This remains a research topic at this time.

In contrast to turbine-related bird deaths, which appear to be caused entirely by collisions with the turbines, the manner in which bats are killed by turbines is not well understood. While direct collisions with the turbines certainly account for many of the deaths, some researchers hypothesize that a large portion of the bat fatalities are caused by barotrauma; Baerwald et al. [18] have found that the internal organs of a sizable portion of the dead bats they found in the vicinity of wind turbines have been damaged by the low-pressure areas present near the blade tips and in the blade wake.

Preliminary studies reported by Baerwald et al. [19] and Arnett et al. [20] have demonstrated that bat fatalities have been reduced by 50%–87% by increasing the cut-in wind speed of the turbine, but much work remains to be done before this issue is resolved. Until this problem is better understood, the prudent course of action would be to postpone the development of promising sites that have significant numbers of bats nearby. At the very least, the latest information from the appropriate national wind energy association regarding bat collisions with wind turbines should be obtained and carefully studied.

### 37.2.5 Impact of Wind Facilities on Radar

While fixed objects in the vicinity do not generally create a problem for radar installations, the rotating blades of wind turbines do; wind turbine blades have a very large radar signature, especially when turbines are grouped together in a wind farm. As a result, wind farms located in the near vicinity of government radar installations used for national defense, national security, aviation safety, and weather forecasting interfere with those radars by creating clutter, reducing detection sensitivity, obscuring potential targets, and scattering target returns. These effects tend to decrease radar sensitivity, generate false targets, interfere with target tracking, and impede critical weather forecasts. Many hundreds of MW of proposed U.S. wind developments in the vicinity of radar installations are on hold because of this issue—developers cannot get approval from one or more government agencies due to concerns that these developments will interfere with the existing radar installations.

In an effort to resolve this problem in order to accommodate future wind energy growth, the U.S. Departments of Energy, Defense, and Homeland Security and the Federal Aviation Administration are currently funding a field test and evaluation of commercial off-the-shelf wind–radar interference mitigation technologies. Results of this effort should be available in the 2014 time frame, but widespread implementation of any successful mitigation technology is apt to take several years. In the meantime, the prudent course of action would be to postpone the development of promising sites that might create a radar interference issue.

---

### **37.3 Wind Resource Assessment**

Three things must be present before a commercial wind energy generation plant can be successfully developed: a site with a good wind resource, access to a transmission line with the capacity to accept the plant output, and a buyer to purchase the energy generated. Only the identification of sites with adequate wind resource will be considered here. In addition, this discussion will be limited to the evaluation of onshore wind resources. Evaluation of offshore resources requires significantly more effort and a much larger financial investment.

Many different approaches are available when investigating the wind resource in a given land area. The preferred approach will depend on your wind energy program objectives and on previous experience with wind resource assessment. In any case, the process normally consists of three basic scales or stages of assessment:

1. Prospecting or identifying general areas of high wind resource. In this stage, wind developers typically rely on existing wind resource information to narrow the search region to the most promising areas.
2. Area wind resource evaluation to determine the actual wind resource. Wind measurement programs are normally undertaken in areas under serious consideration for wind power development. Wind developers use these measurements to determine the actual quality of the resource, compare different candidate sites, estimate the performance of specific turbines, analyze the economic potential of wind development, and make preliminary determinations of turbine placements.
3. Micrositing, in which the siting of the individual wind turbines is optimized. By carefully studying the small-scale variability of the wind resource at a particular location, the developer can position the wind turbines to get maximum wind exposure with minimal interference from other turbines or obstructions, and thus maximize the overall energy output. There are many computer codes available to perform this function. The level of sophistication of these codes varies widely. The better ones use computational fluid dynamics to model the wind farm, utilizing digital elevation data to define the terrain of the wind farm and site measurement data to provide calibration and wind input information. In some cases, professional wind energy development companies may be willing to perform this service gratis, in hopes of getting the rights to develop the site. Advertisements for these programs can be found in most wind energy trade magazines. Further discussion of micrositing is beyond the scope of this contribution.

#### **37.3.1 Prospecting**

The goal of prospecting for wind energy development sites is to identify areas within a fairly large region such as a utility service area, a county, or even a multistate region that are likely to have good wind resources and that are located near existing power transmission lines with the capacity to handle the power generated by the new development. A good initial step in this process is to obtain the highest resolution available wind resource maps of the entire area of interest (see Section 37.2.3 for links to some map sources) and use those to identify areas of high winds. Keep in mind that values on the wind resource maps are just estimates—some areas of good resource may not be identified, and some areas identified as

having good resource may actually have very poor resources. Use these maps in conjunction with topographic maps that show the location of major transmission lines, roads, etc., to narrow the general search area. Use of geographic information system (GIS) will permit the overlaying of the resource information with topographic information and road and transmission line information, greatly facilitating the identification of promising sites. Even with all the information that can be gleaned from GIS systems and hard copy and online maps, field visits to prospective sites are very worthwhile, as observation of biological indicators and topographic features often help identify the best wind resource areas.

### **37.3.1.1 Biological Indicators**

Persistent winds can cause plant deformation; careful observation of these plant deformations can be used to compare candidate sites and, in at least some cases, to estimate the average wind speed. [Figure 37.9](#) illustrates various levels of tree deformity, corresponding to increasing levels of wind from one prevailing direction. The Griggs–Putnam index, explained in Hewson et al. [21], correlates these degrees of deformation to specific wind speeds for one particular type of tree. While the vegetation in an area of interest may not permit the estimation of actual wind speeds based upon the sketches in this figure, the relative wind speeds in the area might well be established by observing the amount of flagging or throwing that is present. It should be noted that, although wind-flagged trees (i.e., trees with branches bent away from a prevailing wind) may indicate that the annual average wind speed is quite strong, trees that are not flagged do not necessarily indicate that the winds are light; those trees may be exposed to strong winds from several directions, with insufficient persistence in any one direction to cause flagging.

### **37.3.1.2 Effects of Topography**

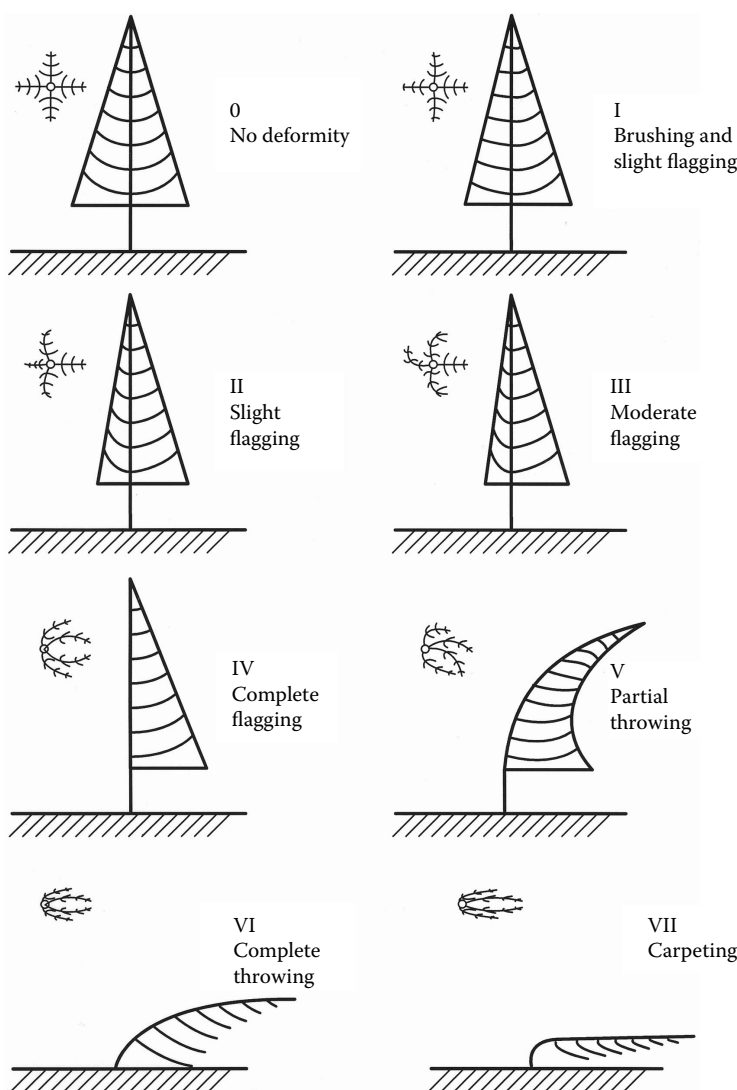

The effects of surrounding terrain on the wind speed at a specific site are discussed in various wind turbine siting handbooks including Troen and Petersen [6], Hiester and Pennell [22], Wegley et al. [23], and Rohatgi and Nelson [24]; the following discussion borrows heavily from these sources. Numerous researchers emphasize that the influence of terrain features on the energy output from a turbine may be so great that the economics of the whole project may depend on the proper selection of the site. The ready availability of detailed GIS maps and mapping technology today has greatly simplified this aspect of prospecting.

#### **37.3.1.2.1 Terrain Classification**

The most basic classification divides terrain into flat and non-flat categories. In a strict sense, the earth's surface is never truly flat; there are always some irregularities such as forest and shelterbelts (or wind breaks), and/or gentle slopes. However, according to Frost and Nowak [25], the terrain can be considered flat (for the purpose of wind turbine siting) if it meets the following conditions:

- Elevation differences between the wind turbine site and the surrounding terrain are not greater than about 60 m anywhere in an 11.5 km diameter circle around the turbine site.
- No hill has an aspect ratio (height to width) greater than 1/50 within 4 km upwind and downwind of the site.
- The elevation difference within 4 km upwind is small compared to the rotor ground clearance.

**FIGURE 37.9**

Griggs-Putnam index of tree deformation. (From Hewson, E.W. et al., *Vegetation as an indicator of high wind velocity*, RLO/2227-T24-78-2, Oregon State University, Corvallis, OR, 1978.)

Flat terrain is obviously the simplest type of terrain for siting a turbine—the wind speed at a given height is nearly the same over the entire area. In the absence of any obstructions to speed up wind flow, typically the best way to increase the available wind power is to raise the rotor higher above the ground to take advantage of positive wind shear. In most natural terrain, however, the surface of the earth is not uniform but changes significantly from location to location, affecting the local wind profile. [Figure 37.10](#) illustrates the significant change in a vertical wind profile that results from wind flow going from a smooth to a rough surface—the shape of the profile shifts quite dramatically over a relatively short horizontal distance. In addition, most flat terrain has a variety of man-made (buildings, silos, etc.) and natural obstacles that affect the flow of wind. The effects of these obstacles

**FIGURE 37.10**

Effect of change in surface roughness from smooth to rough. (From Wegley, H.L. et al., *A Siting Handbook for Small Wind Energy Conversion Systems*, PNL-2521, Pacific Northwest Laboratory, Richland, WA, 1980.)

**FIGURE 37.11**

Wind speed, power, and turbulence effects downstream of a building. (From Wegley, H.L. et al., *A Siting Handbook for Small Wind Energy Conversion Systems*, PNL-2521, Pacific Northwest Laboratory, Richland, WA, 1980.)

have been studied extensively; an example of the effect of a building on wind speed, available power, and turbulence is shown in Figure 37.11. Note that the estimates in the figure apply at a height equal to 1 building height above the ground, and that power losses become small (<10%) after a downwind distance equal to 15 building heights.

Ridges are elongated hills with a length-to-height ratio of at least 10 that have little or no flat area on the summit. As illustrated in Figure 37.12, the ideal prevailing wind direction for wind turbine siting should be perpendicular to the ridge axis. When the prevailing wind is not perpendicular to the axis, the ridge will not be as attractive a site. Concavity in the windward direction enhances speedup, and convexity reduces speedup by deflecting the wind flow around the ridge. The slope of a ridge is also an important parameter; steeper slopes give rise to stronger wind flow, but they also give rise to high turbulence in the lee of the ridge.

Depressions are characterized by terrain features lower than the surroundings and include valleys, canyons, basins, and passes. These can cause significant speedup of the wind if they effectively channel the wind. The factors that influence the flow in depressions, in addition to diurnal flow variations, include orientation of the wind in relation to the depression, atmospheric stability, the width, length, slope and roughness of the depression, and the regularity of the section of valley or canyon. Canyons in mountainous terrain, such as those illustrated in Figure 37.13, can be very effective in creating high wind speeds.

**FIGURE 37.12**

Effect of ridge orientation and shape on site suitability. (From Wegley, H.L. et al., *A Siting Handbook for Small Wind Energy Conversion Systems*, PNL-2521, Pacific Northwest Laboratory, Richland, WA, 1980.)

**FIGURE 37.13**

Increased wind speeds due to channeling of prevailing winds by mountains. (From Rohatgi, J.S. and Nelson, V., *Wind Characteristics: An Analysis for the Generation of Wind Power*, Alternative Energy Institute, West Texas A&M University, Canyon, TX, 1994. Reproduced by permission of Alternative Energy Institute.)

Non-flat or complex terrain has large-scale elevations or depressions such as hills, ridges, valleys, and canyons. Keep in mind that information on wind direction should be considered when defining the terrain classification. For example, if an isolated hill (200 m high and 1000 m wide) were situated 1 km south of a proposed site, the site would normally be classified as complex. If, however, the wind blows only 5% of the time from this direction and the average speed from this direction is low, say 2 m/s, then this terrain would be classified as flat. Additional summaries of the effects on wind flow of many types of large-scale features, including mountains, large cliffs and escarpments, valleys and canyons (including

slope winds, prevailing winds in alignment, and prevailing winds in nonalignment), gaps and gorges, passes and saddles, and large basins, are given in Rohatgi and Nelson [24].

### 37.3.2 Wind Resource Evaluation

Once general areas of high wind resources have been identified, the actual resource available at one or more of those sites can be determined by performing a full wind resource evaluation or site assessment. This is a costly, complex, and time-consuming activity. Numerous companies perform this service; a good method for locating some is to access the appropriate national wind energy association membership list and search for “meteorology consultants.” Even if the service is contracted out, a cursory knowledge of the process is important to ensure that the contractor does a good job. Numerous handbooks detailing the steps for conducting successful measurement programs are available. While the following discussion, which borrows heavily from AWS Scientific, Inc. [1], is for land-based resource assessment, many of the important aspects are also applicable to off-shore resource assessment [26].

Long-term wind speed variability at a site is nearly as important as mean wind speed, as far as long-term energy production is concerned. Meteorologists generally agree that a well-done evaluation/assessment project will take a minimum of 1 year to complete [23], but a project duration of 2 or more years will produce more reliable results and is recommended by Schwartz and Elliott [27] and many other experts. One year is usually sufficient to determine the diurnal and seasonal variability of the wind with an accuracy of 10% at a confidence level of 90%, according to Aspliden et al. [28] and Corotis [29]. In some cases, high-quality data may be available from a nearby representative site, and this might be used to shorten the duration of the assessment project and to estimate the interannual variability of the wind. In particular, long-term data from the nearest airport or weather recording station can help determine whether the data obtained at a site is representative of normal winds for the site or whether it is representative of higher- or lower-than-average winds. Wegley et al. [23] and Gipe [30] give suggestions on methods of using available data from nearby sites to estimate site wind speed with minimal on-site data.

A single site assessment with a very basic single monitoring station (cup anemometer and wind vane instrumentation) on a 50 m tilt-up tower operated for 2 years can be expected to run in excess of \$20,000 (2005\$); a 60 m monitoring station will run about \$2500 more. Multiple sites will see some economies of scale, depending on how close the sites are to each other. The total cost to operate a second site can be expected to be 10%–15% less than the cost for the first site. Five sites in fairly close proximity can probably be operated for an average site cost about 25% less than for a single site. Most savings will be realized in the labor and travel categories, although equipment cost savings may be realized as a result of quantity discounts, by sharing installation equipment, and by sharing parts inventories. Conducting an abbreviated resource assessment program to minimize expenses may well turn out to be a case of “penny wise, pound foolish” in that the return on investment of the entire wind farm project will be directly affected by the quality of the actual wind resource at each turbine site. Without a proper site assessment, the resource estimates may not be a good reflection of the actual resource, and the production of the wind project may be much different than projected.

For small wind turbines, the expense of anemometers, data logger, and data analysis may be more than the price of the wind turbine. In this case, historical regional data may be judged to be adequate for estimating the wind resource. Inexpensive digital weather stations, including rudimentary data loggers that work with a personal computer, are

available for under \$1000, and one of these could be used in conjunction with the historical data to improve the accuracy of the resource assessment. While these inexpensive weather stations may be adequate for this particular application, they are not highly accurate and are not designed for long-term durability, so they are not suitable for collecting long-term data for accurate wind resource assessment as is needed for commercial enterprises. Wind speed, direction, distribution, and shear can vary significantly over fairly short distances in either the horizontal or the vertical direction, so in order to get the best possible estimate of the WER at a particular location, it is important to measure the wind resource at the specific site and height of interest. In complex terrain, this probably means the use of several monitoring stations to adequately assess a single site.

The keys to a successful assessment program are the early identification of the objectives of the program and the timely development of a detailed plan of action to ensure that the data needed to meet the objectives are acquired. Such a plan should include, at a minimum, the following:

- Quality control measures, including a quality assurance (QA) program
- Site data to be measured
- The program duration, minimum measurement accuracy, and target data recovery rate (these heavily impact the equipment type and quality)
- Number and tentative location of monitoring towers, together with sensor measurement heights
- Data sampling and recording intervals
- Data storage, handling, and processing procedures

The data recovery rate is defined as the percentage of possible data records that have actually been collected over a reporting period:

$$\text{Data recovery rate} = \frac{\text{Data records collected}}{\text{Data records possible}} \times 100(\%)$$

where

$$\text{Data records collected} = \text{Data records possible} - \text{Number of invalid records}$$

For example, assume that the total possible number of 10 min records in December is 4464. If 264 records were deemed invalid, the number of valid data records collected would be 4200 (4464–264). The data recovery rate for this example would be

$$\text{Data recovery rate} = \frac{4200}{4464} \times (100) = 94.1\%$$

A data recovery rate of at least 90% (95% or better should be possible) for all measured parameters over the duration of the program, with any data gaps kept to a minimum (less than 1 week), should be a major goal of any measurement program.

A QA program for flagging and handling suspect data is imperative to ensure the acquisition of high-quality data and the successful completion of the assessment

program. The specifics of the components of this QA program should be determined and documented early in the assessment program and should include, at a minimum, the following:

- Acquisition of equipment that meets accuracy and reliability specifications
- Equipment calibration methods and frequency of calibration
- Installation and maintenance instructions for equipment
- Data validation methods, including specifics on evaluating, removing and/or replacing suspect data, and reporting all of these actions
- Data analysis instructions, including specific calculations to be performed

QA will also help to minimize the uncertainties that are always inherent in the data. If the assessment process is carefully followed, these uncertainties can be characterized and controlled to maximize the usefulness of the assessment program conclusions.

### 37.3.2.1 Data Measurement

The core of the monitoring program is the collection of wind speed, wind direction, and air temperature data. Keep in mind that it is generally less expensive to provide and monitor extra sensors than to conduct an unscheduled site visit to replace or repair a failed sensor that is the sole source of an essential measurement. Care must be used in mounting the various sensors to minimize any interference of one sensor on another. It is especially important to avoid any interference with the wind measurements.

If the rotor is relatively small, wind speed measurements at the turbine hub height will suffice, but for larger rotors, acquiring wind speed data at multiple measurement heights is necessary for determining the site vertical wind shear characteristics, for conducting turbine performance simulations at several turbine hub heights, and to assist in data validation (multiple anemometers make spotting a bad one fairly easy). Redundant anemometers are sometimes used to minimize the risk of wind speed data loss due to a failed primary anemometer and to provide substitution data when the primary anemometer is shadowed by the tower (when it is directly downwind of the tower). Typical anemometer heights are every 10 m, starting at 20 or 30 m and going up to maximum tower height (50–60 m for a tilt-up tower). The vertical distances between anemometers mounted at different heights are referred to as *height layers*. For example, for anemometers installed at heights of 30, 40, and 50 m, height layers would be 30–50, 30–40, and 40–50 m.

The following sensor types have traditionally been those commonly used for the measurement of near-horizontal wind speed:

- *Cup anemometer*: This instrument consists of a cup assembly (three or four cups) centrally connected to a vertical shaft for rotation. At least one cup always faces the oncoming wind. The cups convert wind pressure force to rotational torque, and the transducer in the anemometer produces an electrical signal that is proportional to wind speed.
- *Propeller anemometer*: This instrument consists of a propeller mounted on a horizontal shaft that is oriented into the wind through the use of a tail vane. The propeller anemometer also generates an electrical signal proportional to wind speed.

The current trend toward taller turbine towers and the large expense of erecting met towers of comparable height has encouraged the development of ground-based remote sensing technology, capable of monitoring wind conditions at heights well above 100 m. The two major types of remote sensing are light detection and ranging (LIDAR) and sonic detection and ranging (SODAR). Detailed information on these technologies and their use is available in [26,31–32]. These are also commonly used to characterize off-shore wind resources. Further discussion of these technologies is beyond the scope of this contribution; the remainder of this discussion will focus on data systems that utilize traditional anemometers.

Although the two anemometer types differ somewhat in their responsiveness to wind speed fluctuations, there is no clear advantage of one type over the other. In practice, the cup type is most commonly used for resource assessment. When selecting an anemometer model, the following should be considered:

- *Intended application:* Anemometers intended for low-wind-speed applications, such as air pollution studies, are usually made from lightweight materials. These are probably not suitable for very windy or icy environments.
- *Survival wind speed:* Be sure the anemometer is capable of withstanding the maximum wind speed that it is likely to see. An anemometer with a survival wind speed of 25 m/s is not apt to survive in most windy sites. A survival speed of 50 m/s should be adequate for most sites.
- *Starting threshold:* This is the minimum wind speed at which the anemometer starts and maintains rotation. For wind resource assessment purposes, it is more important for the anemometer to survive a 25 m/s wind gust than to be responsive to winds under 1 m/s.
- *Distance constant:* This is the distance the air travels past the anemometer during the time it takes the cups or propeller to reach 63% of the equilibrium speed after a step change in wind speed (the *response time* of the anemometer to a change in wind speed). Longer-distance constants are usually associated with heavier anemometers; inertia causes them to take longer to slow down when the wind decreases. These instruments may overestimate the wind speed.
- *Reliability and maintenance:* Wind sensors are mechanical and eventually wear out, although most have special, long-life bearings that will normally last for at least 2 years. Be sure to get units with bearings that will last for the entire duration of the measurement project.

Anemometers are subject to a variety of errors in the determination of true wind speed, and equations that may be used to estimate the size of these errors are given in Justus [33]. When anemometers are calibrated in steady air flows in a wind tunnel, they may measure the true wind within  $\pm 1\%$ . In gusty winds, however, anemometers generally speed up faster than they slow down, so that accuracies of  $\pm 5\%$  may be more realistic in application. Additional information on anemometers may be found in publications by American Wind Energy Association (AWEA) [34] and ASME [35].

Wind direction vanes should be installed at all significant monitoring levels. Wind direction information is important for identifying preferred terrain shapes and orientations and for optimizing the layout of wind turbines within a wind farm. The most familiar type of vane uses a fin connected to a vertical shaft. The vane constantly seeks a position of force equilibrium by aligning itself into the wind and produces an electrical

signal proportional to the position of the vane relative to some reference direction (usually selected as true—not magnetic—north). Some wind vanes have a *dead band*, a narrow section of the rotation where the sensor transitions from the full rotation reading of nearly 360° to the initial reading of 0°. The output of the sensor in this section is usually unpredictable. The position of this dead band should be carefully noted for reference when the vane is mounted to the tower. Newer direction vanes have eliminated this dead band.

Air temperature is used to calculate air density, a quantity required to estimate the WPD and the power that a wind turbine will generate. It is normally measured either near ground level (2–3 m) or near hub height. In most locations, the average near-ground-level air temperature will be within 1°C of the average temperature at hub height. Ambient air temperature sensors are readily available. The temperature sensor must be protected from direct solar radiation by mounting it within a radiation shield.

Once the basic measurement system is installed, additional resource-related parameters can be acquired at minimal cost. The most common additional parameters are vertical wind speed, change in temperature with height (commonly referred to as  $\Delta T$ ), barometric pressure, and solar radiation.

The vertical wind speed provides more detail about site turbulence and can be a good predictor of wind turbine loads. Historically, this parameter has only been a research measurement, but as wind energy development spreads into new regions of the country, regional information on vertical wind velocity may become important. The propeller anemometer is especially well suited for measuring the vertical wind component. For this application, the rotation axis would be mounted vertically. The polarity of the DC output signal indicates rotational direction, and the signal magnitude indicates actual vertical speed. The vertical wind speed anemometer should be located near the upper basic wind speed monitoring level.

$\Delta T$  provides information about turbulence and atmospheric stability. This is measured with a matched set of temperature sensors located near the lower and upper measurement levels; the existing air temperature sensor may be matched with an identical sensor and used to measure  $\Delta T$ , or a separate pair of matched sensors may be used. Sensors for this application are usually tested over a specified range and matched by the manufacturer. Be sure to use identical equipment (e.g., radiation shield and mounting hardware) with both sensors so the inherent errors in the signals will cancel out when the difference between the two values is taken. Radiation shields that use either forced (mechanical) or natural (passive) aspiration are normally used on both sensors to reduce the radiation-induced errors.

Barometric pressure is used with air temperature to determine air density. Since it does not vary much over relatively short distances, many resource assessment programs do not measure barometric pressure; they use elevation-adjusted data taken at a nearby regional National Weather Service station. Several atmospheric (barometric) pressure sensors that are suitable for this application are commercially available. Be sure to select one that will give accurate readings in a windy environment.

Solar radiation, when used in conjunction with wind speed and time of day, can be an indicator of atmospheric stability and is often used in numerical wind-flow modeling. These measurements may also be useful for later solar energy evaluation studies. A *pyranometer* is used to measure global (or total) solar radiation, the combination of direct sunlight and diffuse sky radiation. Remember that the pyranometer must be in a position where it will never be shaded in order to measure accurately. The recommended measurement height is 3–4 m above ground.

Table 37.1 lists nominal specifications for the most common types of sensors. Some sensors require the use of separate signal conditioners, electronic packages that supply power

**TABLE 37.1**

Typical Specifications for Sensors

Specification	Wind Speed	Wind Direction	Air Temperature	Vertical Wind Speed	$\Delta T$	Atmospheric Pressure	Solar Radiation
Measurement range	0–50 m/s	0°–360°	–40° to 60°C	0–50 m/s	–40° to 60°C	94–106 kPa (sea level equivalent)	0–1500 W/m <sup>2</sup>
Starting threshold	≤1.0 m/s	≤1.0 m/s	N/A	≤1.0 m/s	N/A	N/A	N/A
Distance constant	≤4.0 m/s	N/A	N/A	≤4.0 m/s	N/A	N/A	N/A
Allowable sensor error	≤3%	≤5°	≤1°C	≤3%	≤1°C	≤1 kPa	≤5%
Sensor resolution	≤0.1 m/s	≤1°	≤0.1°C	≤0.1 m/s	≤0.1°C	≤0.2 kPa	≤1 W/m <sup>2</sup>

Note: All sensors should have an operating temperature range of –40°C to 60°C and an operating humidity range of 0%–100%.

to the sensor, and process the signal received from the sensor to convert it into a form that can be used by the data logger, the device that actually acquires the raw data and calculates and saves the average statistics. Data loggers (or data recorders) come in a variety of types, sizes, and capabilities; most include peripheral storage and data transfer devices. Be sure the data logger is compatible with the sensor types, number of sensors, and desired sampling and recording intervals. The data logger should also

- Be capable of recording the time and date corresponding to each data record with that data record
- Contribute negligible errors to the signals received from the sensors
- Operate over the temperature range of –40°C to 60°C and over a relative humidity range of 0%–100%
- Offer retrievable data storage media
- Operate on battery power (with an AC adaptor to permit the use of AC power when it is available)

The amount of data logger storage capacity that is needed depends on the averaging interval, the number of active data channels, the need for calculating derived quantities such as wind shear exponent and turbulence intensity, and the maximum time span between data retrievals, including potential delays. Manufacturers usually provide tables or methods to calculate the approximate available storage capacity in days for various memory configurations. To be safe, get enough storage capacity to store an additional week of data, in case a data retrieval or site access problem develops.

While all data loggers allow manual retrieval of stored data, many either come equipped with or can easily be equipped with communications equipment to enable remote retrieval of data, typically via cell phone or satellite phone link. The manual method promotes frequent visual on-site inspection of the equipment during the site visits required to retrieve the data, which may be beneficial. However, this method also requires frequent expensive site visits and additional data-handling steps (thus increasing potential data loss).

Remote data retrieval permits more frequent data retrieval and inspection than that is feasible with manual data retrieval. This allows for prompt identification and resolution of site problems and enhances the data recovery rate. The disadvantages include the up-front cost of the required additional equipment, the cost of monthly service, and the risk of communication system problems. The additional costs are usually quickly offset by the savings from not having to make site visits, and choosing good quality equipment helps minimize the communication problem risk.

Data loggers with cell phone capability are extremely popular due to their ease of use and reasonable cost. A major concern with these units is whether the signal strength at the measurement site will be sufficient to establish a solid communication link. Keep in mind that the data logger cell phone is much more powerful than a typical cell phone—it will normally be equipped with a high gain antenna to permit communication at a much greater range. A general rule of thumb is that a good connection is usually possible as long as there is a cell phone tower in line of sight within about 120 km. Replacement of the standard antenna with one with higher gain may be an option if the nearest cell tower is further away. Additional information regarding cell phone links and accounts should be available from the data logger supplier or manufacturer.

Satellite telephone service may be all that is available in really remote locations, but that service is usually quite expensive—the transceiver is much more costly, and the monthly fees are usually much higher than is the case for cell phone service. In addition, utilizing a satellite communication link may require the development of specialized data transfer software for the specific application. Again, additional information should be available from the data logger supplier or manufacturer.

If phone service (either cellular or satellite) is either unavailable at the site or is prohibitively expensive, try to arrange for manual data retrieval by someone who lives near the monitoring site. That individual may then be able to send the data media by mail or transmit the data via e-mail or landline phone transmission. If this means of data retrieval is utilized, be sure to incorporate additional procedures to protect against data loss in the event that the data media gets damaged or lost in the mail or the transmitted data become corrupted.

The overall accuracy of any system is determined by its weakest link or least accurate component. It is also influenced by its complexity, the total number of components or links. The measurement of any parameter (wind speed, wind direction, etc.) requires that several components (sensor, signal conditioner, cabling, and data logger), each potentially contributing an error to the measured parameter, be interconnected. The combination of these errors will determine the system error (the difference between the measurement result and the actual value sensed) for that parameter. Errors contributed by the sensors represent the main concern, because those associated with the electronic subsystem (data logger, signal conditioner, and associated wiring and connectors) are typically negligible (less than 0.1%). Using wind speed as an example, the allowable system error in the measured wind speed might be specified as less than or equal to 3% of the true wind speed value, allowing for a 6% error window ( $\pm 3\%$ ) centered about the true wind speed. This means that the wind speed sensor must have a system error of 3% or less.

The resolution of a data measurement is the smallest change in a measured quantity that can be detected by the measuring system. Again, this is primarily a function of the sensor, as most data loggers have far more resolution than is normally required. For example, an anemometer system with an 8-bit data logger analog-to-digital converter or digitizer (a very low resolution for a data logger) that is set up to measure a maximum wind speed of 50 m/s has a data logger resolution of  $50/(2^8) = 0.2$  m/s. Most data loggers will have higher-precision digitizers

(10-bit or 12-bit are common) with a resolution of much less than this (0.05 or 0.01 m/s, respectively). Thus, to achieve the resolution of 0.1 m/s specified for anemometers in Table 371, the anemometers themselves must have a resolution of 0.1 m/s or better.

System reliability is the measure of how well an instrumentation system will consistently provide valid data for a measured parameter over its measurement range—how well it performs in the long run. In selecting instrumentation, it is important to identify and select components that are designed to reliably measure the selected parameters at the prescribed heights for the full monitoring duration and at the required levels of data recovery and accuracy. The instrumentation must also be capable of withstanding the environment of the specific location (e.g., weather extremes, dust, and salt) and be tailored to the selected mode of data retrieval (manually or via cell phone or satellite phone communication link). Although vendors often provide reliability information in terms of a mean time between failures under certain conditions, the best indication of a product's reliability is its performance history. Ask the vendor for a few references and check with those references to determine their satisfaction or lack of satisfaction with the product of interest. Comprehensive QA procedures and the use of redundant sensors are two of the best ways that the user can maximize system reliability. However, there is little that can be done to improve the reliability of sensors or data loggers that are prone to failure.

The equipment should also be proven, affordable, and user-friendly. Complete monitoring systems can be purchased from a single vendor, or components from different vendors can be combined. If components from different vendors are used, be sure the individual components are compatible with each other.

Lists of wind resource assessment equipment vendors may be found in the member lists of the various national wind associations. At the AWEA site ([www.awea.org](http://www.awea.org)), for instance, they may be found by accessing the member directory, selecting "search," "consultants," and then "meteorology."

### 37.3.2.2 Sampling Rates and Statistical Quantities

All data sensors should be sampled once every 1 or 2 s. The resultant data are not typically recorded, but stored into data logger accumulators for the specified averaging period (10 min is the default international averaging period for wind measurements). At the end of the averaging period, the statistics are calculated and stored, the accumulators are cleared, and the storage of data into the accumulators begins anew. The data logger should contain built-in programming to calculate and store, as a minimum, the following statistics:

- The average, standard deviation, and maximum and minimum values for the wind speed at each anemometer level, together with the wind directions associated with each maximum and minimum value
- The average and standard deviation for the wind direction at each level
- The average, standard deviation and maximum and minimum wind speed difference for each height layer, together with the wind direction associated with each maximum and minimum difference
- The air temperature
- The vertical wind speed (if measured)

- The  $\Delta T$  (if measured)
- The barometric pressure (if measured)
- The solar radiation (if measured)

These statistics, together with a corresponding time and date stamp, constitute the data to be recorded; as mentioned earlier, the individual data samples are not normally saved.

Except for wind direction, the average is defined as the numeric mean of all samples. For wind direction, the average is defined as the mean direction on a  $0^\circ$ – $360^\circ$  scale. The standard deviation is defined as the true population standard deviation for all samples within the averaging interval.

### **37.3.2.3 Lightning Protection Devices**

Keep in mind that a single lightning strike can destroy the entire site monitoring system and all associated electronics, and repairing lightning damage will require a large investment in both time and replacement parts. While no amount of protection can ensure that lightning will not strike the system, appropriate protection can minimize that risk. Consult with the data logger and instrumentation suppliers to ensure that adequate lightning protection is incorporated in the data logger and in all sensors, signal conditioners, and power supplies that will be used. If the supplied lightning protection is not adequate for application, determine what additional protection is needed and add it before installing the monitoring system.

### **37.3.2.4 Towers and Sensor Mounting**

Towers for mounting sensors are available in either tubular or lattice types. Both types are available in tilt-up, telescoping, and fixed versions. For new sites, the tubular, tilt-up, guyed tower, which makes possible the assembly of the tower and the mounting of the sensors on the ground, is an excellent and convenient choice. It also requires very little ground preparation and is relatively low cost. The current maximum height of available tilt-up towers is about 60 m; if the tower is to be used in icing conditions, the maximum height is reduced to about 50 m. Keep in mind that raising a tower of this size is not a simple task, and neither is replacing tower-mounted sensors; they both require experienced personnel and proper equipment. Taller towers can certainly be constructed, but they are far less portable and much more expensive. If you need measurements above 60 m and you intend to evaluate multiple sites, you may want to consider the remote sensing systems mentioned earlier [26].

The sensor support hardware includes the masts (vertical extensions) and mounting booms (horizontal extensions). Tubing, not solid stock, masts, and booms should be used. These are used to position the sensors away from the support tower so as to minimize any influence of the tower, mounting hardware, and other equipment and sensors on each of the measured parameters. This can be achieved by consulting specific manufacturers' instructions and referring to the sample installation configuration shown in [Figure 37.14](#). Detailed information may be found in [34] and virtually any other wind measurement handbook.

Refer to the manufacturer's instructions for the proper sensor and data logger wiring configurations. Wiring to connect the sensors, signal conditioners, and data logger should be shielded and/or twisted pair cable, whenever possible, to prevent ambient electrical noise from affecting the accuracy of the measurements. Be sure to use insulation and conductor types that are flexible over the full temperature range expected at the site and use

**FIGURE 37.14**

Typical instrumentation placement on meteorological tower.

wire with UV-resistant insulation. Rodents and raptors, in particular, seem to have an affinity for wire insulation, so consider using armored cable or protective conduit in areas that are accessible by them. Try to mount the data logger and communications equipment in a substantial locked container. Mount the communications antenna high enough to discourage vandalism but where it can still be easily accessed by service personnel. Vandals are a concern, even in very remote locations.

Seal all sensor terminal connections with silicone caulking and protect them from direct exposure to sunlight and water with rubber boots or electrical tape. Wrap the sensor cabling along the length of the support arm and tower and secure it with UV-resistant wire ties or electrical tape. Wrap tape around the sensor wire and leave sufficient slack in the wire wherever chafing can occur between the sensor wire(s) and the support structure (e.g., tilt-up tower anchor collars).

### 37.3.2.5 Data Collection and Handling

All of these efforts devoted to selecting and mounting sensors and ensuring that acquired data are free of interference are for naught if the resultant data are subsequently lost or contaminated. The data collection and handling elements of the monitoring system must incorporate procedures that offer a high level of data protection. In general, the procedures should comply with those specified by the data logger manufacturer and reflect good common sense. A few pertinent comments are listed here.

#### 37.3.2.5.1 Data Retrieval Frequency

A key factor in achieving a high level of data recovery is the ability to identify potential data acquisition problems and to quickly determine if a problem exists (a failed sensor, icing, possible loss of ground, etc.) and, if necessary, initiate the steps required to fix the problem. Data transfer and review are the first-order means of achieving this end. A schedule of regular site data transfers or downloads should be developed and maintained. The maximum recommended manual download interval is every 2 weeks. For remote data transfer systems, a weekly retrieval rate may suffice, but a shorter interval, such as every other day, may be preferable to minimize potential loss of data if a problem arises and to efficiently transfer the large amount of data resulting from 10-min data averaging. Situations may arise that warrant additional data transfers. For example, sensor data irregularities may become apparent during the review of site data, or the site may experience severe weather, such as icing or thunderstorms. Either of these situations merits a prompt follow-up data transfer (either manual or remote) and review.

Any time a site visit is made, the first order of business should be retrieval of the raw data from the data logger, either by manually downloading it to an in-field laptop computer or by transferring it over a telephone link to a central site computer. This will minimize the risk of potential data loss from operator error, static discharges, or electrical surges during handling and/or checking of system components. The last order of business before leaving the site should be a verification that the monitoring system is functioning properly.

#### 37.3.2.5.2 Data Protection and Storage

Sensor data that have not been subjected to a validation or verification process are commonly referred to as raw data. There is a constant risk of raw data loss or alteration during any measurement program. Aside from the data logger programming requirements, the actual data collection process requires minimal human intervention, and data are adequately protected by following recommended installation and operation procedures, including grounding all equipment. These field data will eventually be transferred to a personal computer for analysis; while this may be the primary location of the working database, it should not be the storage area for the archived or raw database, as frequent usage of a computer increases the likelihood of electrical surges, static discharges, and other events that may damage hard drives and destroy any databases. Preserve the original raw data; make at least two copies of that data set on removable media and store the original and all but one of the copies in separate locations (not in the same building). Then, apply the validation and processing steps to the remaining copy. Back up this active database on a regular schedule during the validation process. Once the database is fully validated, create multiple copies of it and again store each copy in a separate location (not in the same building).

Improper data-handling procedures represent a high risk for data loss. The data reduction and analysis staff will be handling the data medium and be in constant contact with significant numbers of raw and processed databases. Ensure that all personnel are fully trained and understand the data retrieval software and computer operating system, that they are well aware of all instances in which data can be accidentally overwritten or erased, and that they employ good handling practices for all data storage media.

#### 37.3.2.5.3 Data Validation

After the field data are collected, transferred to an office computing environment, and appropriate copies are made, the next steps are to validate and process that data. Again, these steps should be performed on a copy of the database, not on the original data. Data validation consists of the inspection of all the collected data for completeness and reasonableness, and the elimination of erroneous values. This step transforms raw data into validated data and is

crucial to maintaining high rates of data recovery during the course of the monitoring program. There are many possible causes of erroneous data: faulty or damaged sensors, loose wire connections, broken wires, damaged mounting hardware, data logger malfunctions, static discharges, sensor calibration drift, and icing conditions are some of the contributors. The goal of data validation is to detect as many significant errors from as many causes as possible; catching all the subtle ones is impossible. For example, a disconnected wire can be easily detected by a long string of zero (or random) values, but a loose wire that becomes disconnected intermittently may only partly reduce the recorded value, yet produce data that appear reasonable. Therefore, slight deviations in the data can escape detection (although the use of redundant sensors can reduce this possibility). Properly exercising the other QA components of the monitoring program will also reduce the chances of data problems.

Data should be validated as soon as possible after they are transferred from the site to the office; the sooner a potential measurement problem is spotted, the quicker it can be addressed, and the lower the risk of losing large amounts of data. Data can be validated either manually or automatically, with computer processing. Obviously, manual verification can be extremely tedious and time consuming, but it is a good practice to validate the initial data from a site in this manner, in order to learn the characteristics of the data and become familiar with the types of suspect data that can be expected. This knowledge then makes possible the tailoring of the computer routines to optimize the automated validation process. Validation software is available from several sources, including from data logger vendors, but it is still commonly homegrown and tailored for particular applications.

Data validation can be split into two distinct operations: data screening and data verification.

**37.3.2.5.3.1 Data Screening** This operation uses a series of validation routines or algorithms to screen all the data to identify suspect or questionable values—values that deserve scrutiny but are not necessarily erroneous. For example, an unusually high hourly wind speed caused by a locally severe thunderstorm may appear on an otherwise average windy day. The result of this data screening is a report that lists the suspect values and which validation routine each of those suspect values failed.

General system checks ensure that each data record contains the appropriate number of data fields and that records are contiguous in time (i.e., time and date stamps are in order, and none are missing). Measured data checks, on the other hand, ensure that the actual data are reasonable. These normally include range tests, relational tests, and trend tests.

- Range tests are the simplest and most commonly used validation tests. The measured data are compared to upper and lower limiting values that include nearly (but not absolutely) all of the expected values for the site for each data parameter. For example, a reasonable range for average wind speeds for most sites is 0–25 m/s. Negative values clearly indicate a problem; speeds above 25 m/s are possible, but should be verified with other information. Data reduction and analysis personnel can fine-tune these limiting values as they gain experience. In addition, the limits for appropriate data parameters should be adjusted seasonally. For instance, the limits for air temperature and solar radiation should be lower in winter than in summer. In general, a single item of data should be subjected to more than one range check before it is judged to be valid, because a single check is unlikely to detect all problems. For example, if a frozen wind vane reports an average direction of exactly 180° for six consecutive 10 min intervals, the values would pass the 0°–360° range test, but a check on the standard deviation would reveal a value of zero and should be flagged as suspect.

- Relational tests are based on expected physical relationships between various parameters. These ensure that physically improbable situations are flagged as suspect. For example, a significantly higher wind speed at the 25 m level than at the 40 m level should be flagged as suspect.
- Trend tests are based on the rate of change in a parameter over time. An example of a trend that indicates an unusual circumstance and a potential problem is a change in air temperature greater than 5°C in 1 h.

Some data loggers include the capability to record the system battery voltage for each averaging interval. Range and relational tests for a reduction in battery voltage may be used to give early warning of site hardware problems and ensure that data are not lost due to a bad battery or a blown fuse.

With experience, the data analysis personnel directly involved in the validation process will become very familiar with the local wind climatology and will learn which criteria are most often triggered and under which conditions. The behavior of the wind under various weather conditions will become apparent, as will the relationship between various parameters. This is an invaluable experience that cannot be gained solely by scanning monthly summary tables, and it may prove to be important for evaluating the impact of the local meteorology on wind turbine operation and maintenance. For example, some validation tests may almost always be failed under light wind conditions, yet the data are valid. This occurrence may argue for one set of test criteria under light wind conditions (below 4 m/s perhaps) and another set for stronger winds. The data analysis personnel should be authorized and encouraged to modify validation test criteria and create new ones as needed, based on their experience with the site data. However, be sure to establish operating procedures to ensure appropriate documentation and reporting of any such changes that are made.

**37.3.2.5.3.2 Data Verification** Once suspect data are identified, case-by-case decisions must be made on what to do with the suspect values—retain them as valid, reject them as invalid, or replace them with redundant valid values (if available). This operation requires the application of judgment of a qualified person familiar with the monitoring equipment and local meteorology. The disposition of each suspect value should be noted in a data verification report. This report should include, for each suspect value, the sensor from which the value was obtained, the date and time that the value was obtained, and the disposition of the suspect value, including the source for the replacement value or the validation code for the rejected value.

If a suspect data value is judged to be valid, leave the value as is. If a suspect value is judged to be invalid, but valid data from a redundant sensor is available, replace the invalid value with that from the redundant sensor. If a suspect value is judged to be invalid, and no data from a redundant sensor are available, replace the value with a unique error code that will serve as both a flag for later data processing programs and an indication of the specific problem with the original value. Selection of the specific error code may require review of the site log or other site data. The data processing and reporting software must incorporate means for handling these error codes. The results of this process are a validated database and a data verification report itemizing the disposition of each suspect data value.

#### **37.3.2.5.4 Data Processing and Reporting**

Once the data validation step is complete, the validated data set is ready to be processed to quantify the wind resource. This typically involves performing calculations on the data set, as well as binning or sorting the recorded 10-min average data values into

useful subsets based on other chosen averaging intervals, such as hourly or weekly. Hourly averages are normally used for reporting purposes. The processed data are then summarized into weekly or monthly informative reports of summary tables and performance graphs. Items included in these reports typically include mean wind speed, wind direction frequency distribution, maximum gust, mean turbulence intensity, mean power density, and diurnal wind speed and power density (by time of day) for each anemometer and wind direction level, mean shear for each height layer, daily and monthly wind speed distribution for the primary height anemometer, and hourly temperature. Data processing and reporting software is available from several sources, including many data logger manufacturers and vendors of spreadsheet, database, and statistical software. Whatever method is used, procedures must be developed to ensure that flagged data points or invalid data codes are excluded from the computations of hourly averages and other quantities. These procedures should be developed and implemented before the first data are recorded.

The wind shear exponent, turbulence intensity, and WPD are items that are usually included in wind resource reports, but may not be routinely produced by some data loggers. These parameters can be easily calculated using a spreadsheet software application to obtain hourly and monthly averages. A description of each parameter and calculation method is presented in detail as follows:

- Vertical wind shear exponent

Wind shear is defined as the change in horizontal wind speed with a change in height. The wind shear exponent ( $\alpha$ ) must be determined for a set of anemometry levels at each site, because the magnitude of  $\alpha$  is influenced by site-specific characteristics. Solving the power law equation (Equation 37.5) for  $\alpha$  gives

$$\alpha = \frac{\ln(U/U_0)}{\ln(h/h_0)} \quad (37.12)$$

where

$U$  is the wind speed at height  $h$

$U_0$  is the wind speed at height  $h_0$

- Turbulence intensity

Wind turbulence is the rapid disturbances or irregularities in the wind speed, direction, and vertical component. It is an important site characteristic, because high turbulence levels may decrease power output and cause extreme loading on wind turbine components. The most common indicator of turbulence for siting purposes is the standard deviation ( $\sigma$ ) of wind speed. Normalizing this value with the mean wind speed gives the turbulence intensity (TI), defined as

$$TI = \frac{\sigma}{\bar{U}} \quad (37.13)$$

where

$\sigma$  is the standard deviation of wind speed

$\bar{U}$  is the mean wind speed (m/s)

- WPD

WPD is defined in Equation 37.14 as the wind power available per unit area swept by the turbine blades. It combines the effects of the wind speed distribution and its dependence on air density and wind speed. For experimental data, WPD may be calculated as

$$\text{WPD} = \frac{1}{2n} \sum_{i=1}^n \rho U_i^3 \text{ (W/m}^2\text{)} \quad (37.14)$$

where

$n$  is the number of records in the averaging interval

$\rho$  is the air density (kg/m<sup>3</sup>)

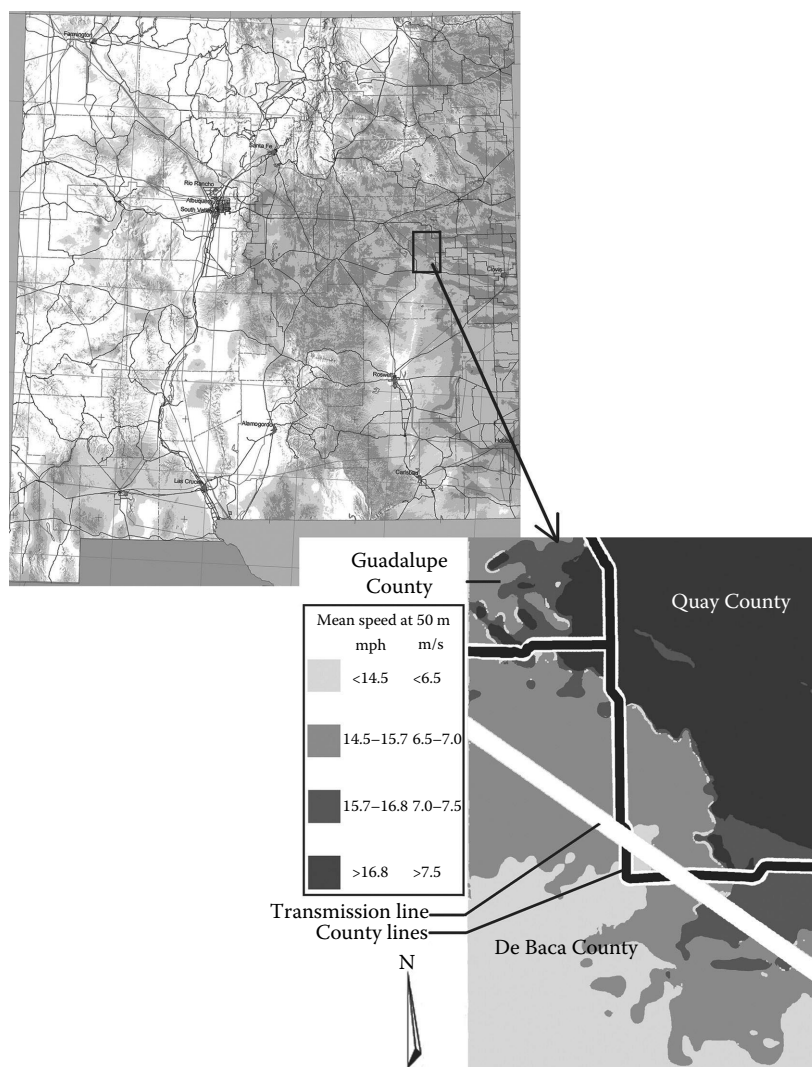

$U_i^3$  is the cube of the  $i$ th wind speed value (m/s)

### 37.4 Example: Initial Wind Farm Development in New Mexico

By 2001, the New Mexico Public Utility Commission (PUC) had, for some time, been looking at the idea of implementing a Renewable Portfolio Standard (RPS) requiring the Public Service Company of New Mexico (PNM), the state electrical utility, to obtain some of its electricity from renewable sources. The state legislature was also seriously considering enacting an RPS, but it had not yet done that in 2002. PNM had been investigating wind energy and monitoring the wind resource at some promising wind sites for several years, but had not yet been seriously considering adding wind to its generation mix. With the RPS under consideration in both the PUC and the legislature, PNM saw the handwriting on the wall and started seriously considering renewable energy, in general, and wind energy, in particular.

PNM decided to encourage the development of the first large wind farm in the state of New Mexico—they would purchase all of the electricity produced by the facility. New Mexico has fairly good wind resources to the east of the north/south central mountain range and in the eastern part of the state, so those are logical areas in which to start prospecting. The state has worked with NREL and True Solutions (now AWS Truepower) to develop a high-resolution wind map (available at [www.emnrd.state.nm.us/ECMD/RenewableEnergy/images/WindMapForWeb.jpg](http://www.emnrd.state.nm.us/ECMD/RenewableEnergy/images/WindMapForWeb.jpg)). This map also shows the route of high-power transmission lines across the state. A map with transmission line details reveals a 345 kV PNM transmission line running from Clovis, in eastern New Mexico, to Albuquerque in the north-central part of the state. That line directly feeds the 1 GW Albuquerque load, and 2002, it had significant excess capacity.

This line passes through or near several areas with reasonable winds (annual average of 7 m/s or greater), mostly just east of Albuquerque. In the eastern part of the state, one of the areas near the line with reasonable winds appears to be near the intersection of Guadalupe, De Baca, and Quay counties. The statewide map in [Figure 37.15](#) locates this area of interest, and the expanded scale map shows the estimated resource from the wind map. The wind map indicates average wind speeds of 7 m/s right in the area of the transmission line, with somewhat higher winds just a little to the north.

**FIGURE 37.15**

Wind resource map of the western edge of Tiabán Mesa in eastern New Mexico. (Reproduced by permission of AWS Truewind and the New Mexico Energy, Minerals, and Natural Resources Department. [www.emnrd.state.nm.us/ECMD/RenewableEnergy/images/WindMapForWeb.jpg](http://www.emnrd.state.nm.us/ECMD/RenewableEnergy/images/WindMapForWeb.jpg), accessed August 2005.)

Closer inspection of the topography in the area shows that the western edge of this high resource corresponds to the western edge of Tiabán Mesa. The mesa edge runs generally north/south in this area, and the top of the mesa is 60–90 m above the plains just to the west. This topography can certainly be expected to enhance the wind speed near the mesa edge. A site visit reveals heavy flagging of the vegetation from the southwest, indicative of a predominant wind direction. The land is privately owned, with no use restrictions, no large bird populations, and no environmental concerns. A measurement program quickly confirmed that the winds are predominantly southwest and that the annual average wind speeds along the mesa edge, from just south of the transmission line crossing to several miles north, are 7 m/s or better. Prospective developers thus had the

**FIGURE 37.16**

Perspective view of western edge of Tiabán Mesa. Every second wind turbine and transmission line tower indicated.

three essential components for a wind farm development—access to a transmission line with excess capacity, a customer for the power (PNM), and a good wind resource.

In August 2002, FPL Energy and PNM announced their agreement to develop the first large wind energy project in the state of New Mexico. FPL Energy built the 204 MW New Mexico Wind Energy Center on the western edge of Tiabán mesa in 2003. A perspective view of the mesa edge, with the turbine locations and transmission line indicated, is given in Figure 37.16. The PNM-built substation lies right under the existing transmission line and immediately adjacent to the line of turbines on the mesa edge; this ready access to the transmission line was a key driver in the decision to locate the wind farm in this spot. PNM purchases the entire output of the wind farm and sells it at a premium to residential and small business customers through their “Sky Blue” renewable energy program. Two years of operation have confirmed that the site resource is a good one: the yearly average wind speed at the 65 m turbine hub height has been 8 m/s. At the wind farm elevation of 1460 m, this wind speed yields a power density of 460 W/m<sup>2</sup>, which corresponds to an NREL wind class 4 site.

### CONTENTS

38.1 Materials and Products in MSW .....	1085
38.2 Management of MSW .....	1088
38.3 Summary .....	1090
References.....	1091

This chapter has been extracted from the most recent in a series of reports released by the U.S. Environmental Protection Agency (EPA) to characterize municipal solid waste (MSW) in the United States. This report characterizes the national municipal waste stream based on data through 2011. As characterized in the EPA report, MSW includes wastes from residences and commercial establishments. No construction and demolition debris or industrial wastes are included. (Some wastes from industrial establishments, such as packaging and office wastes, are, however, included.)

Identifying the components of the MSW stream is an important step toward addressing the issues associated with using it for energy generation. MSW characterizations, which analyze the quantity and composition of the waste stream, involve estimating how much MSW is generated, recycled, combusted, and disposed of in landfills. This chapter characterizes the MSW stream *of the nation as a whole*. Local and regional variations are not addressed.

The methodology used for the characterization of MSW for this chapter estimates the waste stream on a nationwide basis by a “material flows methodology.” EPA’s Office of Solid Waste and its predecessors in the Public Health Service sponsored work in the 1960s and early 1970s to develop this methodology, which is based on production data (by weight) for the materials and products in the waste stream, with adjustments for imports, exports, and product lifetimes.

### 38.1 Materials and Products in MSW

In 2011, generation of MSW totaled 250.4 million tons. A breakdown by percentage of the materials generated in MSW in 2011 is shown in [Figure 38.1](#). Paper and paperboard products are the largest component of MSW by weight (28% of generation), and food waste and yard trimmings are the second and third largest components (14.5% and 13.5% of generation). Plastics come next, at 23.7% of MSW generation. Inorganic portions of the waste stream—metals and glass—total 13.4% of generation. (The “other” category also

**FIGURE 38.1**

Materials generated in MSW by weight and percentage, 2011.

contains some inorganic materials such as broken pottery and kitty litter.) Rubber, leather, textiles, and wood make up about 14.6% of MSW generation.

Most of the materials in MSW have some level of recovery for recycling or composting. This is illustrated in [Table 38.1](#). Since each materials category (except for yard trimmings and food waste) is made up of many different products, some of which may not be recovered at all, the overall recovery rate for any particular material will be lower than recovery rates for some products within the materials category.

The highest recovery rate shown in [Table 38.1](#) is that for nonferrous metals other than aluminum (68.4% of generation). This is because the lead in lead-acid batteries is recovered at very high rates. Paper and paperboard were recovered at 65.6% of generation in 2011, and they had by far the highest recovered tonnage. Within that category, newspapers were recovered at 72.5% and corrugated boxes at 91% of generation. Yard trimmings were recovered for composting at a rate of 57.3% in 2011. Recovery rates for other materials are shown in the table.

The many products in MSW are grouped into three main categories: durable goods (e.g., appliances), nondurable goods (e.g., newspapers), and containers and packaging (e.g., beverage cans and corrugated boxes) (see [Figure 38.2](#)). The materials in MSW are generally made up of products from each category. There are, however, exceptions. The durable goods category contains no paper and paperboard. The nondurable goods category includes only small amounts of metals and essentially no glass or wood. The containers and packaging category includes only very small amounts of rubber, leather, and textiles.

Generation and recovery of MSW by product category are shown in [Table 38.2](#). Overall, the materials in durable goods were recovered at a rate of 18.4% in 2011. Recovery of materials (lead and plastic) from lead-acid batteries was at 96.2% in 2011. Major appliances were recovered at an overall rate of 64.2% because of the high rate of recovery of steel in appliances. Recovery of tires at 44.6% is due to recovery of rubber and some steel.

The overall recovery rate for nondurable goods was estimated at 36.5% in 2011. Recovery of paper products such as newspapers and other paper products accounts for most of this. Recovery of containers and packaging is at the highest rate—50.7% in 2011. Large tonnages

**TABLE 38.1**

Generation and Recovery of Materials in MSW, 2011

Material	Weight Generated	Weight Recovered	Percentage of Generation (%)
Paper and paperboard	70.02	45.90	65.6

Note: In millions of tons and percentage of generation of each product category. Negligible = less than 5000 tons or 0.05%.

of corrugated boxes were recovered, at a rate of 91.0%. Steel cans were recovered at a rate of 70.6%, and aluminum cans at 54.5%. Other packaging made of glass, plastics, and wood was also recovered.

### 38.2 Management of MSW

The breakdown of how much MSW went to recycling and composting, combustion, and land disposal\* in 2011 is shown in Figure 38.3. Recovery of materials for recycling and composting was estimated to have been 86.9 million tons, or 34.7% of generation, in 2011.

**FIGURE 38.3**

Management of MSW in the United States, 2011.

\* Land disposal is calculated as the remainder after recycling, composting, and combustion are deducted from generation. This disposal is overwhelmingly landfilled; however, small amounts are littered, self-disposed (e.g., by on-site burning), or otherwise not taken to landfills.

**FIGURE 38.4**

The trend of municipal solid waste generation, 1960–2011.

Combustion of MSW (with energy recovery) was estimated to have been 29.3 million tons, or 11.7% of generation. The remainder—134.2 million tons, or 53.6% of generation—was land disposed.

Generation of MSW grew steadily from 1960 to 2011, from 88.1 million tons to 250.4 million tons per year (Figure 38.4). As illustrated by the graph, the growth of generation is not continuous, but fluctuates with the economy and, of course, with population growth. It has been demonstrated that there is a high degree of correlation between MSW generation and gross domestic product, and recession years can be identified on the graph. Another way to look at generation is in pounds per capita (pcd) (Figure 38.5). After years of steady growth, pcd peaked at 4.74 pounds per capita per day in 2000, decreasing slightly between 2001 and 2003, rising again to 4.74 pcd in 2004 followed by a steady decline to 4.36 pcd in 2009. The per capita rate rose to 4.44 in 2010 followed by a decline to 4.40 in 2011. Decreasing per capita rates follow periods of economic turn downs.

**FIGURE 38.5**

Generation of municipal solid waste in pounds per capita per day, 1960–2011.

**FIGURE 38.6**

Recovery of MSW for recycling and composting, in percentage of generation, 1960–2011.

Recovery for recycling and composting has increased dramatically since the late 1980s (Figure 38.6). Recovery of MSW was minimal in the 1960s and early 1970s. The percentage recovered crept up to 9.6% by 1980. Interest in recovery grew rapidly in the late 1980s as concerns were raised about diminishing landfill space in parts of the United States, especially the northeast. Recovery reached 16% in 1990, 28.5% in 2000, and 34.7% in 2011. While most recovered material is made up of products in MSW, there also has been an increase in composting of yard trimmings and, to a much lesser extent, food waste.

Combustion handled an estimated 30% of MSW generated in 1960, mostly through incinerators with no energy recovery and no air pollution controls. In the 1960s and 1970s, combustion dropped steadily as the old incinerators were closed, reaching a low of less than 10% of MSW generated by 1980. The percentage of MSW managed by combustion reached about 14.2% in 1990 and 13.9% in 2000; it has been declining slowly since 2000 to 11.7% in 2011.

Land disposal has been declining since the 1980s. Land disposal was 81.4% (U.S. Environmental Protection Agency 2005) of generation in 1980, 69.8% in 1990, and 53.6% in 2011 (U.S. Environmental Protection Agency 2013).

### 38.3 Summary

The history of MSW generation and management is shown in Figure 38.7. The top line of the area graph is MSW generation, while management methods are shown as area plots. Major findings from the referenced EPA report are as follows:

- MSW generation in the United States has grown from 88 million tons in 1960 to 250.4 million tons in 2011. On a per capita basis, generation of MSW during the 1990s was around 4.5 pounds per capita per day, increasing to 4.74 pounds per capita per day in 2000. In 2011, the per capita generation rate had declined to 4.40 pounds per person per day.

**FIGURE 38.7**  
Generation and management of municipal solid waste, 1960–2011.

- In the 1960s and early 1970s, a large percentage of MSW was burned, with little recovery for recycling. Landfill disposal typically consisted of open dumping, often accompanied with open burning of the waste for volume reduction.
- Through the mid-1980s, incineration declined considerably, and landfills became difficult to site, and waste generation continued to increase. Materials recovery rates increased very slowly in this time period, and the burden on the nation's landfills grew dramatically. As Figure 38.7 shows, discards of MSW to landfill or other disposal apparently peaked in 1990 and then began to decline as materials recovery and combustion with energy recovery increased.
- Over time, recycling rates have increased from just over 6% of MSW generated in 1960 to about 10% in 1980, to 16% in 1990, to about 29% in 2000, and to over 34% in 2011.
- Combustion of MSW reached a low point of about 10% of generation around 1980. Since 2004, combustion with energy recovery has held steady at about 12% of generation.
- MSW discards to landfills rose to about 142.3 million tons in 2005 and then declined to 134.3 million tons in 2011. As a percentage of total MSW generation, discards to landfills has consistently decreased—from 69.8% of generation in 1990 to 53.6% in 2011.

### 39.1 Introduction

The term “biomass” encompasses a wide range of materials of recent origin classified as either waste or dedicated energy crops. Waste biomass includes any organic material that has negligible apparent value, represents a nuisance, or is a pollutant to the local environment. Dedicated energy crops are biomass grown specifically for the production of biobased products and fuels. This term excludes crops grown for food or feed even though they can also be used to produce energy. It also includes organic material with maturation times of hundreds to millions of years such as fossil fuels and some forest trees with long maturity terms. Biomass is primarily a form of solar energy stored as chemical energy within organic compounds. The solar-to-biomass conversion process involves interactions among numerous factors, leading to different types of biomass.

In the following sections, we describe the principles of solar energy conversion, biomass types and their properties, and the role of land use for crop production. These concepts help to understand the quantity and quality of global biomass resources.

### 39.2 Solar Energy Conversion to Biomass

Solar energy is the most abundant source of renewable energy on planet earth. Every year, the planet receives 5.6 million exajoules (EJ— $10^{18}$  J) upon its atmosphere. Given that the world consumes about 570 EJ per year, this is enough energy to supply for several thousand

**TABLE 39.1**

Photosynthesis Steps and Efficiencies

Photosynthesis Step	Total Energy (%)	
Incident solar energy (on leaf surface)	100	
Energy in photosynthetically active spectrum	48.7	
Absorbed energy	43.8	
Photochemically converted energy	37.2	
Carbon fixation pathway	C3	C4
Energy in synthesized carbohydrates	12.6	8.5
Energy available after photorespiration	6.5	8.5
Energy available after respiration	4.6	6.0

Source: Zhu, X.G. et al., *Curr. Opin. Biotechnol.*, 19(2), 153, 2008.

years. Unfortunately, solar energy is very diffuse and difficult to convert efficiently. Most of the atmosphere's solar energy never reaches land surfaces, and only a minuscule amount is converted to biomass.

The planet's atmosphere absorbs, reradiates, and reflects 30% of the incident solar radiation and allows 70% to reach the planet's surface. Earth's surface area consists of 29.2% land, of which about 21% is covered by biomass. Overall, only 6.1% of the atmosphere's solar radiation remains available for biomass production. Plants have developed photosynthetic means of storing solar energy that are suitable for their needs but inefficient in their ability to convert solar to chemical energy.

Table 39.1 compares the percent of total energy captured by C3 and C4 plants after several photosynthesis steps. Starting from 100% of the solar energy available at the plant's surface, only 48.7% is in the photosynthetically active spectrum. The absorbed energy represents 43.8%, and 37.2% of the incident solar energy on the leaf's surface is photochemically converted to biomass energy via carbon fixation. C3 and C4 are carbon fixation pathways labeled after the carbon chain length of the first carbohydrate formed during photosynthesis. The vast majority of plants employ three carbon-chain length molecules to fixate carbon, whereas about 3% of known species employ four carbon-chain carbohydrates. Corn, sugarcane, and sorghum are common C4 plants. The process of photosynthetically converting solar energy into chemical compounds can be generalized by the formula 39.1. This formula describes the conversion of CO<sub>2</sub>, H<sub>2</sub>O, and sunlight into sugar (glucose) and oxygen.

C3 and C4 plants can theoretically store up to 4.6% and 6.0% of the solar energy on their leaf surfaces into biomass. This is the amount leftover after the energy spent during carbohydrate synthesis, photorespiration, and respiration. C3 plants are more efficient at carbohydrate synthesis and respiration, but C4 plants have an overall higher efficiency, because they avoid photorespiration penalties. In practice, the most efficient conversion measured in C3 and C4 plants is 2.4% and 3.7%, respectively. There are many environmental factors that lower the efficiency of crops in the field including nutrient availability, weather patterns, and pest activity.

The efficiency of solar energy conversion to biomass can be estimated based on the incident energy and biomass available in a given area. Data for solar incident energy measurements are publicly available from sources such as the National Renewable Energy Laboratory [9]. The U.S. Department of Agriculture (USDA) publishes biomass

productivity data (<http://quickstats.nass.usda.gov/>). USDA data are based on above-ground biomass. However, the biomass efficiency calculations should include the amount of belowground biomass that can exceed a quarter of the total biomass material. The ratio of below- to aboveground biomass is commonly known as the root-to-shoot ratio, and values for different crops are available in the literature [3].

### 39.3 Biomass Properties

#### 39.3.1 Plant Composition

Plant composition and physical properties have a significant impact on biomass energy content. Biomass is commonly characterized by its organic composition, elemental analysis, proximate analysis, and bulk properties such as heating value and bulk density. Table 39.2 shows physical and thermochemical data of representative grain, herbaceous, and woody biomass. Organic composition includes cellulose, hemicellulose, and lignin mass content. Elemental analysis typically reports carbon, hydrogen, oxygen, nitrogen, and ash. Other elements are often reported if they are found in high quantities or important for the target application (such as sulfur for combustion). Proximate analysis is a measure of the moisture content, volatile matter, fixed carbon, and ash content. Heating value is the amount of energy released during complete biomass combustion.

Biomass is mostly composed of lignocellulosic material. Lignocellulose is a term that describes the three-dimensional polymeric composites formed by plants as structural material [1]. Plants contain varying quantities of lignin, cellulose, and hemicellulose.

Lignin is a polymer whose primary function is to provide structural support and protect the plant from microbial activity. Therefore, lignin is a common by-product of biochemical processes, since microbes are unable to easily utilize it as a substrate. On the other hand,

**TABLE 39.2**

Physical and Thermochemical Properties of Selected Biomass

	Feedstock	Corn Stover	Herbaceous Crop	Woody Crop
Organic composition (wt.%)	Cellulose	53	45	50
	Hemicellulose	15	30	23
	Lignin	16	15	22
	Others	16	10	5
Elemental analysis (dry wt.%)	C	44	47	48
	H	5.6	5.8	5.9
	O	43	42	44
	N	0.6	0.7	0.5
	Ash	6.8	4.5	1.6
Proximate analysis (dry wt.%)	Volatile matter	75	81	82
	Fixed C	19	15	16
	Ash	6	4	1.3
HHV (MJ/kg)		17.7	18.7	19.4
Bulk density (kg/m <sup>3</sup> )		160–300	160–300	280–480
Yield (Mg/ha)		8400	14,000	14,000

Source: Brown, R.C., *Biorenewable Resources: Engineering New Products from Agriculture*, Iowa State Press, A Blackwell Publishing Company, Ames, IA, 2003, pp. 59–75.

thermochemical processes can decompose lignin although the products are still hard to predict. Instead of breaking apart into its monomers, lignin decomposition tends to form oligomers from the repolymerization of smaller hydrocarbons. These oligomers can be gasified or catalytically upgraded to desired fuels and chemicals.

Cellulose is a polysaccharide made of glucose chains. Its basic building block is the cellobiose, which consists of two linked glucose units. The typical cellulose chain has a degree of polymerization of 10,000 units. Cellulose tends to agglomerate and with high packing densities can form crystalline cellulose. Crystalline cellulose is inert to chemical treatment and insoluble in most solvents. Cellulose with low packing densities is known as amorphous cellulose. Microbes consume cellulose efficiently, and they can convert it into a variety of chemicals most notably ethanol.

Hemicellulose consists of a large number of heteropolysaccharides built from hexoses, pentoses, and deoxyhexoses. Its degree of polymerization is much lower than cellulose and in the order of 100–200. Hemicellulose requires acid or enzymatic treatment before its sugars become available to microbial activity.

The organic composition of biomass feedstock has a significant impact on the types of processes that can convert it to fuels and chemicals. The proportions of all three organic compounds impact the types and quantities of degradation compounds formed during thermochemical biomass conversion. Furthermore, there are interaction effects among these compounds that are not well understood. Therefore, increasingly powerful analysis techniques are under development to measure not just the quantity but also the physical properties of organic compounds.

### 39.3.2 Biomass Analysis

Proximate analysis is primarily important in thermochemical applications, because it describes the general evolution of biomass combustion products. Proximate analysis is measured by heating biomass under controlled temperature and heating rate conditions. The total weight loss from holding the biomass temperature at 100°C represents its moisture content. Volatile matter is the fraction of biomass that decomposes into gases at moderate temperatures of about 400°C in an inert environment. The remaining fraction is a mixture of solid carbon (fixed carbon) and mineral matter (ash). The ash content can be determined by introducing oxygen and burning the remaining carbon material.

Ultimate analysis is often reported on a dry, ash-free (daf) basis and often used to estimate thermal biomass properties. One correlation of the higher heating value (HHV) of biomass is the formula 39.2 that is based solely on the feedstock carbon content. Although carbon is the primary factor in determining heating value, oxygen is important because of its detrimental effect to heating value and recalcitrance to removal. Researchers have published alternative HHV correlations that incorporate a greater number of factors.

$$\text{HHV(dry)} \left[ \frac{\text{MJ}}{\text{kg}} \right] = 0.4571(\% \text{ C on dry basis}) - 2.70 \quad (39.2)$$

The thermal performance of biomass fuel depends heavily on its heating value. Heating value is the net enthalpy released upon reacting fuel with oxygen at stoichiometric conditions. It is reported on either a lower heating value (LHV) or higher heating value (HHV) basis. The difference between LHV and HHV depends on whether the combustion gases are released above or below the water condensation temperature. Below the

**FIGURE 39.1**

Ternary plot of average elemental carbon, hydrogen, oxygen in fossil and biomass materials and their higher heating values. (Adapted from Anon. Phyllis2 database by ECN (July 2013) available at <http://www.ecn.nl/phyllis2/Browse/Standard/ECN-Phyllis>, accessed March 2015.)

water condensation temperature, the moisture in the fuel contributes a latent enthalpy heat release, resulting in a higher heat output. Biomass heating value is typically about 18 MJ/kg, but it varies by biomass type as shown in Table 39.2.

There are several comprehensive sources of biomass composition available in textbooks and online databases. The U.S. Department of Energy (DOE) *Biomass Feedstock Composition and Property Database*, and the ECN Phyllis database for example are freely available online. These databases contain composition and material property data for a wide range of organic and nonorganic materials. Figure 39.1 compares the HHV of fossil and biomass materials based on their carbon, hydrogen, and oxygen content [10]. As shown, higher carbon content and lower oxygen generally correspond with increasing HHV. However, the greater hydrogen content in natural gas compensates for a slightly higher oxygen content than crude oil.

Combustion calculations require knowledge of the fuel's enthalpy (heat) of formation. This information is difficult to determine from biomass composition information. It can however be estimated after measuring the combustion reaction heating value. Consider the reaction in the following equation:

The heating value ( $\Delta H_R$ ) can be calculated using Equation 39.4, thermodynamic property data, and feedstock composition (such as Table 39.2):

$$\Delta H_R = h_{f,\text{CO}_2}^\circ + dh_{f,\text{H}_2\text{O}}^\circ - (h_{f,\text{CH}_a\text{O}_b}^\circ + ch_{f,\text{O}_2}^\circ). \quad (39.4)$$

## 39.4 Biomass Resources

Biomass is a term that encompasses a wide range of materials. Scientists generally classify biorenewable resources as either wastes or dedicated energy crops. A waste is a material that has been traditionally discarded, because it has no apparent value or represents a nuisance or even a pollutant to the local environment. Dedicated energy crops are plants grown specifically for production of biobased products, that is, for purposes other than food or feed. This section describes estimates for U.S. biorenewable resources.

### 39.4.1 Waste Materials

Categories of waste materials that qualify as biorenewable resources include municipal solid wastes (MSWs), agricultural and forest residues and their by-products, and manure. MSWs refer to anything thrown out in the garbage, and clearly include materials that do not qualify as biorenewable resources, such as glass, metal, and plastics. MSW includes food processing waste that is the effluent from a wide variety of industries ranging from breakfast cereal manufacturers to alcohol breweries. Another category of waste product is agricultural residues. Agricultural residues are simply the part of a crop discarded by farmers after harvest such as corn stover (husks and stalks), rice hulls, wheat straw, and bagasse (fibrous material remaining after the milling of sugarcane). Modern agriculture continues to heavily employ animals. The recent concentration of animals into giant livestock facilities has led to calls to treat animal wastes in a manner similar to that for human wastes. Table 39.3 shows the potential quantities of agricultural and forest residue available in the United States.

Waste materials share few common traits other than the difficulty of characterizing them because of their variable and complex composition. Thus, waste biomass presents special problems to engineers who are tasked with converting this sometimes unpredictable feedstock into reliable power or high-quality fuels and chemicals. The major virtue of waste materials is their low cost. By definition, waste materials have little apparent economic value and can often be acquired for little more than the cost of transporting the material from its point of origin to a processing plant. In fact, it is possible to acquire wastes at a negative cost because of the rising costs for solid waste disposal and sewer

**TABLE 39.3**

Potential Agricultural, Forest, and Process Waste Supply in the United States

	Annual Biomass Supply (Million Dry Mg/Year)
Logging and other residue	58
Fuel treatments	54
Urban wood residues	43
Wood processing residues	64
Pulping liquor	67
Fuelwood	47

discharges and restrictions on landfilling certain kinds of wastes; that is, a biorenewable resource processing plant is paid by a company seeking to dispose of a waste stream. For this reason, many of the most economically attractive opportunities in biorenewable resources involve waste feedstocks.

Clearly, a waste material that can be used as feedstock for an energy conversion process is no longer a waste material. As demand for these new-found feedstocks increases, those that generate it come to view themselves as suppliers and may demand payment for the one-time waste: a negative feedstock cost becomes a positive cost. Such a situation developed in the California biomass power industry during the 1980s [4]. Concerns about air pollution in California led to restrictions on open-field burning of agricultural residues, a practice designed to control infestations of pests. With no means for getting rid of these residues, an enormous reserve of biomass feedstocks materialized. These feedstocks were so inexpensive that independent power producers recognized that even small, inefficient power plants using these materials as fuel would be profitable. A number of plants were constructed and operated on agricultural residues. Eventually, the feedstock producers had plant operators bidding up the cost of their once nuisance waste material. In the end, many of these plants were closed because of the escalating cost of fuel.

### 39.4.2 Energy Crops

Energy crops are defined as plants grown specifically as an energy resource. We should note that firewood obtained from cutting down an old-growth forest does not constitute an energy crop. An energy crop is planted and harvested periodically. Harvesting may occur on an annual basis, as with sugar beets or switchgrass, or on a 5–7 year cycle, as with certain strains of fast-growing trees such as hybrid poplar or willow. The cycle of planting and harvesting over a relatively short time period assures that the resource is used in a sustainable fashion; that is, the resource will be available for future generations.

Energy crops contain significant quantities of one or more of four important energy-rich components: oils, sugars, starches, and lignocellulose (fiber). Farmers historically cultivated crops rich in the first three components for food and feed: oils from soybeans and nuts; sugars from sugar beets, sorghum, and sugarcane; and starches from corn and cereal crops. Oil, sugars, and starches are easily metabolized. On the other hand, humans find it hard to digest lignocellulose. Certain domesticated animals with specialized digestive tracts are able to break down the polymeric structure of lignocellulose, and use it as an energy source. From this discussion, it might appear that the best strategy for developing biomass resources is to grow crops rich in oils, sugars, and starches. However, even for *oil crops* or *starch crops*, the largest single constituent is invariably lignocellulose (Table 39.4), which is the structural (fibrous) material of the plant: stems, leaves, and roots. If we harvest oils, sugars, and starches and leave the lignocellulose behind as an agricultural residue rather than use as fuel, we will waste the greatest portion of the biomass crop.

**TABLE 39.4**  
Typical Woody Biomass Compositions

Component	Weight (%)
Cellulose	44 ± 6
Hemicellulose	28 ± 4
Lignin	20 ± 5

Research has shown that energy yields (Joules per km<sup>2</sup> per year) are usually greatest for plants that are mostly *roots and stems*; in other words, plant resources are directed toward the manufacture of lignocellulose rather than oils, sugars, and starches. As a result, there has been a bias toward development of energy crops that focus on lignocellulosic biomass, which is reflected in the discussion that follows.

Dedicated energy crops are typically high fiber crops grown specifically for their high productivity of holocellulose (cellulose and hemicellulose). Harvesting may occur on an annual basis, as with switchgrass, or on a 5–7 year cycle, as with certain strains of fast-growing trees such as hybrid poplar. Lignocellulosic crops are conveniently divided into herbaceous energy crops (HECs) and short rotation woody crops (SRWCs) [7].

Herbaceous crops are plants that have little or no woody tissue. The aboveground growth of these plants usually lives for only a single growing season. However, herbaceous crops include both annuals and perennials. Annuals die at the end of a growing season and must be replanted in the spring. Perennials die back each year in temperate climates but reestablish themselves each spring from rootstock. Both annual and perennial HECs are harvested on at least an annual basis, if not more frequently, with yields averaging 550–1100 Mg/km<sup>2</sup>/year, with maximum yields between 2000 and 2500 Mg/km<sup>2</sup>/year in temperate regions [7]. As with trees, yields can be much higher in tropical and subtropical regions.

Herbaceous crops more closely resemble hardwoods in their chemical properties than they do softwoods. Their low lignin content makes them relatively easy to delignify, which improves accessibility of the carbohydrate in the lignocellulose. The hemicellulose contains mostly xylan, which is highly susceptible to acid hydrolysis, compared to the cellulose. As a result, microbes can easily degrade agricultural residues, destroying their processing potential in a matter of days if exposed to the elements. Herbaceous crops have relatively high silica content compared to woody crops, which can present problems during processing.

SRWC is used to describe woody biomass that is fast growing and suitable for use in dedicated feedstock supply systems. Desirable SRWC candidates display rapid juvenile growth, wide site adaptability, and pest and disease resistance. Woody crops grown on a sustainable basis are harvested on a rotation of 3–10 years. Annual SRWC yields range between 500 and 2400 Mg/km<sup>2</sup>/year.

Woody crops include hardwoods and softwoods. Hardwoods are trees classified as angiosperms, which are also known as flowering plants. Examples include willow, oak, and poplar. Hardwoods can be regrown from stumps, a process known as coppicing, which reduces their production costs compared to softwoods. Advantages of hardwoods in processing include: high density for many species; relative ease of delignification and accessibility of wood carbohydrates; the presence of hemicellulose high in xylan, which can be removed relatively easily; low content of ash, particularly silica, compared to softwoods and herbaceous crops; and high acetyl content compared to most softwoods and herbaceous crops, which is an advantage in the recovery of acetic acid.

Softwoods are trees classified as gymnosperms, which encompass most trees known as evergreens. Examples include pine, spruce, and cedar. Softwoods are generally fast growing, but their carbohydrate is not as accessible for chemical processing as the carbohydrates in hardwood. Since softwoods have considerable value as construction lumber and pulpwood, they are more readily available as waste material in the form of logging and manufacturing residues compared to hardwoods. Logging residues, consisting of a high proportion of branches and tops, contain considerable high-density compression wood, which is not easily delignified. Therefore, logging residues are more suitable as boiler fuel or other thermochemical treatments than as feedstock for chemical or enzymatic processing.

### 39.4.3 Algae

*Algae* is a broad term that encompasses several eukaryotic organisms. Eukaryotic organisms are characterized by complex structures enclosed within their cell membranes. Although algae do not share many of the structures that define terrestrial biomass, they are capable of photosynthesis and capturing carbon. Algae's affinity to convert CO<sub>2</sub> into lipids has drawn academic and industrial attention as a means to simultaneously lower carbon emissions and produce biofuels.

Algal biomass uses CO<sub>2</sub> as its carbon source and sunlight as its energy source. About 1.8 kg of CO<sub>2</sub> is fixed for every kg of algal biomass, which contains up to 50% carbon by dry weight. Controlled production of renewable fuels from algae has been proposed in either raceway ponds or photobioreactors. Raceway ponds consist of open, shallow recirculation channels with mechanical flow control and surfaces that enhance light retention. Raceway ponds are inexpensive, but relatively inefficient when compared to photobioreactors. There are various photobioreactor designs with the common goal of maintaining a monoculture of algae that is efficiently exposed to sunlight and carbon dioxide. A common design employs arrays of tubes arranged vertically to minimize land use and oriented north–south to maximize light exposure.

Given that algae do not require fresh water or fertile soils, waste lands have been suggested as potential locations to grow algae. One suggestion is to build algae ponds in the desert Southwest United States where inexpensive flat land, abundant sunlight, water from alkaline aquifers, and CO<sub>2</sub> from power plants could be combined to generate renewable fuels. Algae's potential for yields of 1.12–9.40 million liters of oil/km<sup>2</sup>/year promises significant reductions in the land footprint required to produce biofuels.

---

## 39.5 Land Use for Biomass Production

Global land use is broadly defined by five categories: pasture, crop, forest, urban, and abandoned. Pasture is land devoted primarily to animal grazing; crop lands are areas actively cultivated for food production; forest land contains primarily large trees; urban areas are heavily populated regions; and abandoned lands are territories that formerly fit one of the previous categories but are no longer employed for human activities. Humans, because of population migrations or land use change, alter the portions of land devoted to each of these categories over time.

Researchers estimate that 14.5 and 33.2 million km<sup>2</sup> of global land area were devoted to crops and pasture respectively in 2000 [2]. These land use groups can coexist within the same region. For example, the U.S. Midwest and parts of the Southeast include regions with more than 70% of the land devoted to crops, and the western sides of the Midwest and Southern U.S. states have a high concentration of land for pasture.

Modern day farmers devote their production to a small selection of crops depending on socioeconomic factors. [Table 39.5](#) shows a sample of biomass crops grown in various geographical regions and their annual yields. Crops such as corn and sugarcane can serve both food and energy needs due to their high yields of sugar-rich biomass and biomass residue (stover and bagasse respectively).

**TABLE 39.5**

Nominal Annual Yields of Biomass Crops

Biomass Crop	Geographical Location	Annual Yield (Mg/km <sup>2</sup> )
Corn: grain	North America	700
Corn: cobs	North America	130
Corn: stover	North America	840
Jerusalem artichoke: tuber	North America	4500
Jerusalem artichoke: sugar	North America	640
Sugarcane: crop	Hawaii	5500
Sugarcane: sugar	Hawaii	720
Sugarcane: bagasse (dry)	Hawaii	720
Sweet sorghum: crop	Midwest United States	3800
Sweet sorghum: sugar	Midwest United States	530
Sweet sorghum: fiber (dry)	Midwest United States	490
Switchgrass	North America	1400
Hybrid poplar	North America	1400
Wheat: grain	Canada	220
Wheat: straw	Canada	600

Source: Wayman, M. and Parekh, S., *Biotechnology of Biomass Conversion: Fuels and Chemicals from Renewable Resources*, Open University Press, Philadelphia, PA, 1990.

We can estimate the amount of biomass available in a given region by assuming nominal values for crop productivity and available land use data using the equation:

$$\text{Total biomass} \left[ \frac{\text{kg}}{\text{year}} \right] = f \times \text{crop}_{\text{yield}} \left[ \frac{\text{kg}}{\text{km}^2 \times \text{year}} \right] \times \text{land}_{\text{area}} [\text{km}^2] \quad (39.5)$$

In Equation 39.5,  $f$  is a factor that accounts for crop rotations, farmer participation, and land conservation among other considerations that restrict the land use. As an example, Iowa has a total land area of 144,700 km<sup>2</sup> that is predominantly covered by corn and soybeans. In 2010, farmers planted 37.5% of Iowa land with corn, netting an average yield of 165 bushels per acre (1035 Mg/km<sup>2</sup>). Thus, the total amount of corn grown in Iowa that year was 56.2 million Mg.

Farmers and seed companies have managed to increase crop yields every year for the past couple of decades. Crop yield increases follow the exponential growth formula:

$$\text{Crop}_{\text{yield}}(t) \left[ \frac{\text{kg}}{\text{km}^2} \right] = \text{crop}_{\text{yield},0} e^{kt}, \quad (39.6)$$

where

$k$  is the growth rate

$t$  is the period of time since the initial value  $\text{Crop}_{\text{yield},0}$

The USDA maintains a comprehensive database of agricultural statistics (available online at <http://quickstats.nass.usda.gov/>). The data span several years, and include county-level data for crops, demographics, economics, animals and products, and environmental impacts.

The United States benefits from large biomass resources. Based on crop historical data and growth projections, we can expect traditional biomass resources to continue as a significant potential energy resource. The development of fast-growing dedicated energy crops and algae could help address concerns over land use. Much work remains to continue the production and conversion of biomass in economic and environmentally friendly ways.

## **40.1 Introduction**

This section defines the scope of the entire chapter and presents a brief overview of the types of applications that solar thermal energy can potentially satisfy.

### **40.1.1 Motivation and Scope**

Successful solar system design is an iterative process involving consideration of many technical, practical, reliability, cost, code, and environmental considerations (Mueller Associates 1985). The success of a project involves identification of and intelligent selection among trade-offs, for which a proper understanding of goals, objectives, and constraints is essential. Given the limited experience available in the solar field, it is advisable to keep solar systems as simple as possible and not be lured by the promise of higher efficiency offered by more complex systems. Because of the location-specific variability of the solar resource, solar systems offer certain design complexities and concerns not encountered in traditional energy systems.

The objective of this chapter is to provide energy professionals which a fundamental working knowledge of the scientific and engineering principles of solar collectors and solar systems relevant to both the prefeasibility study and the feasibility study of a solar project. Conventional equipment such as heat exchangers, pumps, and piping layout are but briefly described. Because of space limitations, certain equations/correlations had to be omitted, and proper justice could not be given to several concepts and design approaches. Effort has been made to provide the reader with pertinent references to textbooks, manuals, and research papers.

A detailed design of solar systems requires in-depth knowledge and experience in (1) the use of specially developed computer programs for detailed simulation of solar system performance, (2) designing conventional equipment, controls, and hydronic systems,

(3) practical aspects of equipment installation, and (4) economic analysis. These aspects are not addressed here, given the limited scope of this chapter. Readers interested in acquiring such details can consult manuals such as Mueller Associates (1985) or SERI (1989).

The lengthy process outlined above pertains to large solar installations. The process is much less involved when a small domestic hot-water system, or unitary solar equipment or single solar appliances such as solar stills, solar cookers, or solar dryers are to be installed. Not only do such appliances differ in engineering construction from region to region, there are also standardized commercially available units whose designs are already more or less optimized by the manufacturers, normally as a result of previous experimentation, both technical or otherwise. Such equipment is not described in this chapter for want of space.

The design concepts described in this chapter are applicable to domestic water heating, swimming pool heating, active space heating, industrial process heat, convective drying systems, and solar cooling systems.

---

## 40.2 Solar Collectors

### 40.2.1 Collector Types

A solar thermal collector is a heat exchanger that converts radiant solar energy into heat. In essence this consists of a receiver that absorbs the solar radiation and then transfers the thermal energy to a working fluid. Because of the nature of the radiant energy (its spectral characteristics, its diurnal and seasonal variability, changes in diffuse to global fraction, etc.), as well as the different types of applications for which solar thermal energy can be used, the analysis and design of solar collectors present unique and unconventional problems in heat transfer, optics, and material science. The classification of solar collectors can be made according to the type of working fluid (water, air, or oils) or the type of solar receiver used (nontracking or tracking).

Most commonly used working fluids are water (glycol being added for freeze protection) and air. [Table 40.1](#) identifies the relative advantages and potential disadvantages of air and liquid collectors and associated systems. Because of the poorer heat transfer characteristics of air with the solar absorber, the air collector may operate at a higher temperature than a liquid-filled collector, resulting in greater thermal losses and, consequently, a lower efficiency. The choice of the working fluid is usually dictated by the application. For example, air collectors are suitable for space heating and convective drying applications, while liquid collectors are the obvious choice for domestic and industrial hot-water applications. In certain high-temperature applications, special types of oils are used that provide better heat transfer characteristics.

The second criterion of collector classification is according to the presence of a mechanism to track the sun throughout the day and year in either a continuous or discreet fashion (see [Table 40.2](#)). The stationary flat-plate collectors are rigidly mounted, facing toward the equator with a tilt angle from the horizontal roughly equal to the latitude of the location for optimal year-round operation. The compound parabolic concentrators (CPCs) can be designed either as completely stationary devices or as devices that need seasonal adjustments only. On the other hand, Fresnel reflectors, paraboloids, and heliostats need two-axis tracking. Parabolic troughs have one axis tracking either along

**TABLE 40.1**

Advantages and Disadvantages of Liquid and Air Systems

Characteristics	Liquid	Air
Efficiency	Collectors generally more efficient for a given temperature difference	Collectors generally operate at slightly lower efficiency
System configuration	Can be readily combined with service hot-water and cooling systems	Space heat can be supplied directly but does not adapt easily to cooling. Can preheat hot-water
Freeze protection	May require antifreeze and heat exchangers that add cost and reduce efficiency	None needed
Maintenance	Precautions must be taken against leakage, corrosion and boiling	Low maintenance requirements. Leaks repaired readily with duct tape, but leaks may be difficult to find
Space requirements	Insulated pipes take up nominal space and are more convenient to install in existing buildings	Duct work and rock storage units are bulky, but ducting is a standard HVAC installation technique
Operation	Less energy required to pump liquids	More energy required by blowers to move air; noisier operation
Cost	Collectors cost more	Storage costs more
State of the art	Has received considerable attention from solar industry	Has received less attention from solar industry

Tubular collectors	Paraboloids
Compound parabolic concentrators (CPCs)	Heliostats with central receivers

the east-west direction or the north-south direction. These collector types are described by Kreider (1979) and Rabl (1985).

A third classification criterion is to distinguish between nonconcentrating and concentrating collectors. The main reason for using concentrating collectors is not that *more energy* can be collected but that the thermal energy is obtained at higher temperatures. This is done by decreasing the area from which heat losses occur (called the receiver area) with respect to the aperture area (i.e., the area that intercepts the solar radiation). The ratio of the aperture to receiver area is called the *concentration ratio*.

## 40.2.2 Flat-Plate Collectors

### 40.2.2.1 Description

The flat-plate collector is the most common conversion device in operation today, since it is most economical and appropriate for delivering energy at temperatures up to about 100°C. The construction of flat-plate collectors is relatively simple, and many commercial models are available.

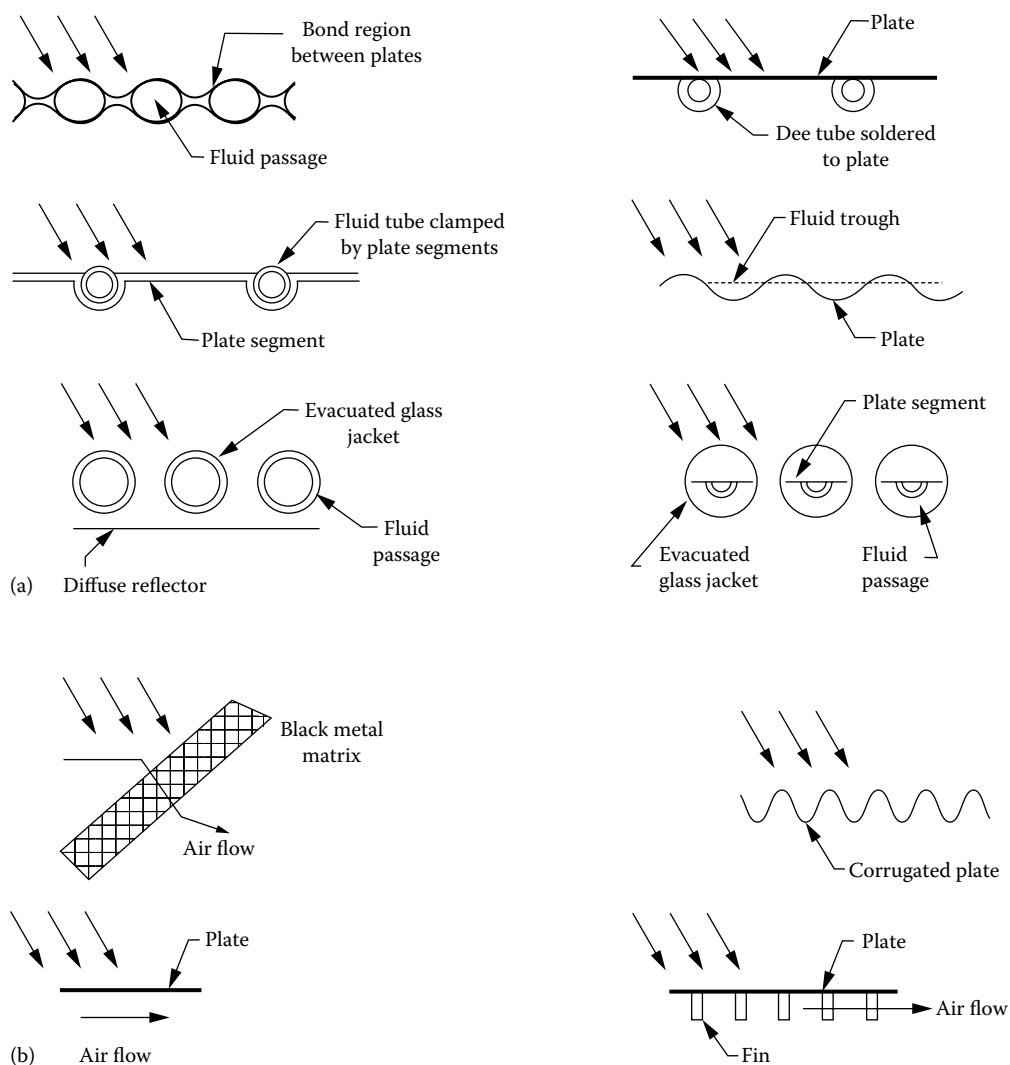

**FIGURE 40.1**  
Cross-section (a) and isometric (b) view of a flat-plate collector.

Figure 40.1 shows the physical arrangements of the major components of a conventional flat-plate collector with a liquid working fluid. The blackened absorber is heated by radiation admitted via the transparent cover. Thermal losses to the surroundings from the absorber are contained by the cover, which acts as a black body to the infrared radiation (this effect is called the *greenhouse effect*), and by insulation provided under the absorber plate. Passages attached to the absorber are filled with a circulating fluid, which extracts energy from the hot absorber. The simplicity of the overall device makes for long service life.

The absorber is the most complex portion of the flat-plate collector, and a great variety of configurations are currently available for liquid and air collectors. Figure 40.2 illustrates some of these concepts in absorber design for both liquid and air absorbers. Conventional materials are copper, aluminum, and steel. The absorber is either painted with a dull black paint or can be coated with a *selective surface* to improve performance (see Section 40.2.3 for more details). Bonded plates having internal passageways perform well as absorber plates because the hydraulic passageways can be designed for optimal fluid and thermal performance. Such collectors are called *roll-bond* collectors. Another common absorber consists of tubes soldered or brazed to a single metal sheet, and mechanical attachments of the tubes to the plate have also been employed. This type of collector is called a *tube-and-sheet* collector. Heat pipe collectors have also been developed, though these are not as

**FIGURE 40.2**

Typical flat-plate absorber configurations. (a) Air and (b) liquid collectors.

widespread as the previous two types. The so-called *trickle type* of flat-plate collector, with the fluid flowing directly over the corrugated absorber plate, dispenses entirely with fluid passageways. Tubular collectors have also been used because of the relative ease by which air can be evacuated from such collectors, thereby reducing convective heat losses from the absorber to the ambient air.

The absorber in an air collector normally requires a larger surface than in a liquid collector because of the poorer heat transfer coefficients of the flowing air stream. Roughness elements and producing turbulence by way of devices such as expanded metal foil, wool, and overlapping plates have been used as a means for increasing the heat transfer from the absorber to the working fluid. Another approach to enhance heat transfer is to use packed beds of expanded metal foils or matrices between the glazing and the bottom plate.

### 40.2.2.2 Modeling

A particular modeling approach and the corresponding degree of complexity in the model are dictated by the objective as well as by experience gained from past simulation work. For example, it has been found that transient collector behavior has insignificant influence when one is interested in determining the long-term performance of a solar thermal system. For complex systems or systems meant for nonstandard applications, detailed modeling and careful simulation of system operation are a must initially, and simplifications in component models and system operation can subsequently be made. However, in the case of solar thermal systems, many of the possible applications have been studied to date and a backlog of experience is available not only concerning system configurations but also with reference to the degree of component model complexity.

Because of low collector time constants (about 5–10 min), heat capacity effects are usually small. Then the instantaneous (or hourly, because radiation data are normally available in hourly time increments only) steady-state useful energy  $q_C$  in watts delivered by a solar flat-plate collector of surface area  $A_C$  is given by

$$q_C = A_C F' [I_T \eta_0 - U_L (T_{Cm} - T_a)]^+ \quad (40.1)$$

where

$F'$  is the plate efficiency factor, which is a measure of how good the heat transfer is between the fluid and the absorber plate

$\eta_0$  is the optical efficiency, or the product of the transmittance and absorptance of the cover and absorber of the collector

$U_L$  is the overall heat loss coefficient of the collector, which is dependent on collector design only and is normally expressed in  $W/(m^2 \text{ } ^\circ C)$

$T_{Cm}$  is the *mean* fluid temperature in the collector (in  $^\circ C$ )

$I_T$  is the radiation intensity on the plane of the collector (in  $W/m^2$ )

The + sign denotes that negative values are to be set to zero, which physically implies that the collector should not be operated when  $q_C$  is negative (i.e., when the collector loses more heat than it can collect).

However, because  $T_{Cm}$  is not a convenient quantity to use, it is more appropriate to express collector performance in terms of the fluid *inlet* temperature to the collector ( $T_{Ci}$ ). This equation is known as the classical Hottel–Whillier–Bliss (HWB) equation and is most widely used to predict instantaneous collector performance:

$$q_C = A_C F_R [I_T \eta_0 - U_L (T_{Ci} - T_a)]^+ \quad (40.2)$$

where  $F_R$  is called the heat removal factor and is a measure of the solar collector performance as a heat exchanger, since it can be interpreted as the ratio of actual heat transfer to the maximum possible heat transfer. It is related to  $F'$  by

$$\frac{F_R}{F'} = \frac{(mc_p)_C}{A_C F' U_L} \left\{ 1 - \exp \left[ - \frac{A_C F' U_L}{(mc_p)_C} \right] \right\} \quad (40.3)$$

where  $(mc_p)_C$  is the heat capacity of the total fluid flow rate times the specific heat of fluid flowing through the collector.

**FIGURE 40.3**

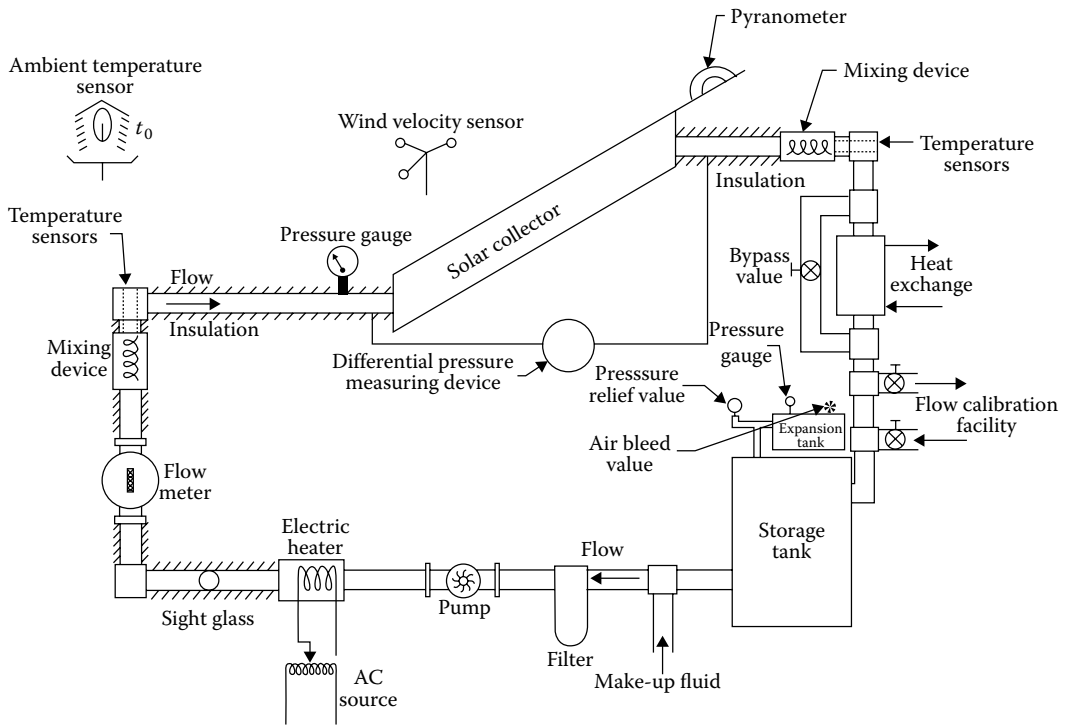

Variation of  $F_R/F'$  as a function of  $[(mc_p)_C/(A_C F' U_L)]$ . (From Duffie, J. A. and Beckman, W. A., *Solar Engineering of Thermal Processes*, Wiley Interscience, New York, 1980.)

The variation of  $(F_R/F')$  with  $[(mc_p)_C/A_C F' U_L]$  is shown graphically in Figure 40.3. Note the asymptotic behavior of the plot, which suggests that increasing the fluid flow rate more than a certain amount results in little improvement in  $F_R$  (and hence in  $q_C$ ) while causing a quadratic increase in the pressure drop.

Factors influencing solar collector performance are of three types: (1) constructional, that is, related to collector design and materials used, (2) climatic, and (3) operational, that is, fluid temperature, flow rate, and so on. The plate efficiency factor  $F'$  is a factor that depends on the physical constructional features and is essentially a constant for a given liquid collector. (This is not true for air collectors, which require more careful analysis.) Operational features involve changes in  $m_C$  and  $T_{Ci}$ . While changes in  $m_C$  affect  $F_R$  as per Equation 40.3, we note from Equation 40.2 that to enhance  $q_C$ ,  $T_{Ci}$  needs to be kept as low as possible. For solar collectors that are operated under more or less constant flow rates, specifying  $F_R \eta_0$  and  $F_R U_L$  is adequate to predict collector performance under varying climatic conditions.

There are a number of procedures by which collectors have been tested. The most common is a *steady-state procedure*, where transient effects due to collector heat capacity are minimized by performing tests only during periods when radiation and ambient temperature are steady. The procedure involves simultaneous and accurate measurements of the mass flow rate, the inlet and outlet temperatures of the collector fluid, and the ambient conditions (incident solar radiation, air temperature, and wind speed). The most widely used test procedure is the ASHRAE Standard 93-77 (1978), whose test setup is shown in Figure 40.4. Though a solar simulator can be used to perform indoor testing, outdoor testing is always more realistic and less expensive. The procedure can be used for nonconcentrating collectors using air or liquid as the working fluid (but not two phase mixtures) that have a single inlet and a single outlet and contain no integral thermal storage.

Steady-state procedures have been in use for a relatively long period and though the basis is very simple the engineering setup is relatively expensive (see Figure 40.4). From an

**FIGURE 40.4**

Set up for testing liquid collectors according to ASHRAE Standard 93-72.

overall heat balance on the collector fluid and from Equation 40.2, the expressions for the instantaneous collector efficiency under normal solar incidence are

$$\eta_c \equiv \frac{q_c}{A_c I_T} = \frac{(mc_p)_{ci}(T_{co} - T_{ci})}{A_c I_T} \quad (40.4)$$

$$= \left[ F_R \eta_n - F_R U_L \left( \frac{T_{ci} - T_a}{I_T} \right) \right] \quad (40.5)$$

where  $\eta_n$  is the optical efficiency at normal solar incidence.

From the test data, points of  $\eta_c$  against reduced temperature  $[(T_{ci} - T_a)/I_T]$  are plotted as shown in Figure 40.5. Then a linear fit is made to these data points by regression, from which the values of  $F_R \eta_n$  and  $F_R U_L$  are easily deduced. It will be noted that if the reduced term were to be taken as  $[(T_{cm} - T_a)/I_T]$ , estimates of  $F' \eta_n$  and  $F' U_L$  would be correspondingly obtained.

#### 40.2.2.3 Incidence Angle Modifier

The optical efficiency  $\eta_0$  depends on the collector configuration and varies with the angle of incidence as well as with the relative values of diffuse and beam radiation. The incidence angle modifier is defined as  $K_\eta = (\eta_0/\eta_n)$ . For flat-plate collectors with 1 or 2 glass covers,  $K_\eta$  is almost unchanged up to incidence angles of  $60^\circ$ , after which it abruptly drops to zero.

**FIGURE 40.5**

Thermal efficiency curve for a double glazed flat-plate liquid collector. Test conducted outdoors on a 1.2 m by 1.25 m panel with 10.2 cm of glass fiber back insulation and a flat copper absorber with black coating of emissivity of 0.97. (From ASHRAE Standard 93-77, *Methods of Testing to Determine the Thermal Performance of Solar Collectors*, American Society of Heating, Refrigeration and Air Conditioning Engineers, New York, 1978.)

A simple way to model the variation of  $K_\eta$  with incidence angle for flat-plate collectors is to specify  $\eta_n$ , the optical efficiency of the collector at normal beam incidence, to assume the entire radiation to be beam, and to use the following expression for the angular dependence (ASHRAE 1978)

$$K_\eta = 1 + b_0 \left( \frac{1}{\cos \theta} - 1 \right) \quad (40.6)$$

where

$\theta$  is the solar angle of incidence on the collector plate (in degrees)

$b_0$  is a constant called the incidence angle modifier coefficient

Plotting  $K_\eta$  against  $[(1/\cos \theta) - 1]$  results in linear plots (see Figure 40.6), thus justifying the use of Equation 40.6.

We note that for one-glass and two-glass covers, approximate values of  $b_0$  are  $-0.10$  and  $-0.17$ , respectively.

In case the diffuse solar fraction is high, one needs to distinguish between beam, diffuse, and ground-reflected components. Diffuse radiation, by its very nature, has no single incidence angle. One simple way is to assume an equivalent incidence angle of  $60^\circ$  for diffuse and ground-reflected components. One would then use Equation 40.6 for the beam component along with its corresponding value of  $\theta$  and account for the contribution of diffuse and ground reflected components by assuming a value of  $\theta = 60^\circ$  in Equation 40.6. For more accurate estimation, one can use the relationship between the effective diffuse solar incidence angle versus collector tilt given in Duffie and Beckman (1980). It should be noted that the preceding equation gives misleading results with incidence angles close to  $90^\circ$ . An alternative functional form for the incidence angle modifier for both flat-plate and concentrating collectors has been proposed by Rabl (1981).

**FIGURE 40.6**

Incidence angle modifiers for two flat-plate collectors with nonselective coating on the absorber. (Adapted from ASHRAE, Methods of testing to determine the thermal performance of solar collectors, Standard 93-77, American Society of Heating, Refrigeration and Air Conditioning Engineers, New York, 1978.)

**Example 40.1**

From the thermal efficiency curve given in Figure 40.5 determine the performance parameters of the corresponding solar collector.

Extrapolating the curve yields  $y$ -intercept = 0.69,  $x$ -intercept = 0.105 ( $\text{m}^2 \text{ } ^\circ\text{C}/\text{W}$ ). Since the reduced temperature in Figure 40.5 is in terms of the inlet fluid temperature to the collector, Equation 40.5 yields  $F_R \eta_n = 0.69$  and  $F_R U_L = 0.69/0.105 = 6.57 \text{ W}/(\text{m}^2 \text{ } ^\circ\text{C})$ . Alternatively, the collector parameters in terms of the plate efficiency factor can be deduced. From Figure 40.5, the collector area =  $1.22 \times 1.25 = 1.525 \text{ m}^2$ , while the flow rate ( $m/A_C$ ) =  $0.0136 \text{ kg}/(\text{s m}^2)$ . From Equation 40.3,

$$F'/F_R = -(0.0136 \times 4190/6.57) \ln[-6.57/(0.0136 \times 4190)] = 1.0625$$

Thus  $F'U_L = 6.57 \times 1.0625 = 6.98 \text{ W}/(\text{m}^2 \text{ } ^\circ\text{C})$  and  $F'\eta_n = 0.69 \times 1.0625 = 0.733$ .

**Example 40.2**

How would the optical efficiency be effected at a solar incidence angle of  $60^\circ$  for a flat-plate collector with two glass covers?

Assume a value of  $b_0 = -0.17$ . From Equation 40.6,  $K_\eta = 0.83$ . Thus

$$F_R\eta_0 = F_R\eta_n K_\eta = 0.69 \times 0.83 = 0.57$$

**40.2.2.4 Other Collector Characteristics**

There are three collector characteristics that a comprehensive collector testing process should also address. The collector *time constant* is a measure that determines how intermittent sunshine affects collector performance and is useful in defining an operating control strategy for the collector array that avoids instability. Collector performance is usually enhanced if collector time constants are kept low. ASHRAE 93-77 also includes a method for determining this value. Commercial collectors usually have time constants of about 5 min or less, and this justifies the use of the HWB model (see Equation 40.2).

Another quantity to be determined from collector tests is the collector *stagnation temperature*. This is the equilibrium temperature reached by the absorber plate when no heat is being extracted from the collector. Determining the maximum stagnation temperature, which occurs under high  $I_T$  and  $T_a$  values, is useful in order to safeguard against reduced collector life due to thermal damage to collectors (namely irreversible thermal expansion, sagging of covers, physical deterioration, optical changes, etc.) in the field when not in use. Though the stagnation temperature could be estimated from Equation 40.2 by setting  $q_C = 0$  and solving for  $T_{Ci}$ , it is better to perform actual tests on collectors before field installation.

The third collector characteristic of interest is the *pressure drop* across the collector for different fluid flow rates. This is an important consideration for liquid collectors, and more so for air collectors, in order to keep parasitic energy consumption (namely electricity to drive pumps and blowers) to a minimum in large collector arrays.

**40.2.3 Improvements to Flat-Plate Collector Performance**

There are a number of ways by which the performance of the basic flat-plate collectors can be improved. One way is to enhance optical efficiency by treatment of the glass cover thereby reducing reflection and enhancing performance. As much as a 4% increase has been reported (Anderson 1977). Low-iron glass can also reduce solar absorption losses by a few percent.

These improvements are modest compared to possible improvements from reducing losses from the absorber plate. Essentially, the infrared upward reradiation losses from the heated absorber plate have to be decreased. One could use a second glass cover to reduce the losses, albeit at the expense of higher cost and lower optical efficiency. Usually for water heating applications, radiation accounts for about two-thirds of the losses from the absorber to the cover with convective losses making up the rest (conduction is less than about 5%). The most widely used manner of reducing these radiation losses is to use selective surfaces whose emissivity varies with wavelength (as against matte-black painted absorbers, which are essentially gray bodies). Note that 98% of the solar spectrum is at wavelengths less than  $3.0\ \mu\text{m}$ , whereas less than 1% of the black body radiation from a  $200^\circ\text{C}$  surface is at wavelengths less than  $3.0\ \mu\text{m}$ . Thus selective

**FIGURE 40.7**

Spectral reflectance of several surfaces. (From Edwards, D. K. et al., Basic studies on the use of solar energy, Report No. 60-93, Department of Engineering, University of California at Los Angeles, Los Angeles, CA, 1960.)

surfaces for solar collectors should have high-solar absorptance (i.e., low reflectance in the solar spectrum) and low long-wave emittance (i.e., high reflectance in the long-wave spectrum). The spectral reflectance of some commonly used selective surfaces is shown in Figure 40.7. Several commercial collectors for water heating or low-pressure steam (for absorption cooling or process heat applications) are available that use selective surfaces.

Another technique to simultaneously reduce both convective and radiative losses between the absorber and the transparent cover is to use honeycomb material (Hollands 1965). The honeycomb material can be reflective or transparent (the latter is more common) and should be sized properly. Glass honeycombs have had some success in reducing losses in high-temperature concentrating receivers, but plastics are usually recommended for use in flat-plate collectors. Because of the poor thermal aging properties, honeycomb flat-plate collectors have had little commercial success. Currently the most promising kind seems to be the simplest (both in terms of analysis and construction), namely collectors using horizontal rectangular slats (Meyer 1978). Convection can be entirely suppressed provided the slats with the proper aspect ratio are used.

Finally, collector output can be enhanced by using side reflectors, for instance a sheet of anodized aluminum. The justification in using these is their low cost and simplicity. For instance, a reflector placed in front of a tilted collector cannot but increase collector performance because losses are unchanged and more solar radiation is intercepted by the collector. Reflectors in other geometries may cast a shadow on the collector and reduce performance. Note also that reflectors would produce rather nonuniform illumination over the day and during the year, which, though not a problem in thermal collectors, may drastically penalize the electric output of photovoltaic modules. Whether reflectors are cost-effective depends on the particular circumstances and practical questions such as aesthetics and space availability. The complexity involved in the analysis of collectors with planar reflectors can be reduced by assuming the reflector to be long compared to its width and treating the problem in two dimensions only. How optical performance of solar

collectors are affected by side planar reflectors is discussed in several papers, for example Larson (1980) and Chiam (1981).

#### 40.2.4 Other Collector Types

##### 40.2.4.1 Evacuated Tubular Collectors

One method of obtaining temperatures between 100°C and 200°C is to use evacuated tubular collectors. The advantage in creating and being able to maintain a vacuum is that convection losses between glazing and absorber can be eliminated. There are different possible arrangements of configuring evacuated tubular collectors. Two designs are shown in Figure 40.8. The first is like a small flat-plate collector with the liquid to be heated making one pass through the collector tube. The second uses an all-glass construction with the glass absorber tube being coated selectively. The fluid being heated passes up the middle of the absorber tube and then back through the annulus. Evacuated tubes can collect both direct and diffuse radiation and do not require tracking. Glass breakage and leaking joints due to thermal expansion are some of the problems which have been experienced with such collector types. Various reflector shapes (like flat-plate, V-groove, circular, cylindrical, involute, etc.) placed behind the tubes are often used to usefully collect some of the solar energy, which may otherwise be lost, thus providing a small amount of concentration.

**FIGURE 40.8**

Two common configurations of tubular vacuum collectors: (a) with absorber plate and fluid single-pass, (b) with concentric tubes and fluid two-pass. (From Charters, W.W.S. and Pryor, T.L., *An Introduction to the Installation of Solar Energy Systems*, Victoria Solar Energy Council, Melbourne, Australia, 1982.)

#### 40.2.4.2 Compound Parabolic Concentrators

The CPC collector, discovered in 1966, consists of parabolic reflectors that funnel radiation from aperture to absorber rather than focusing it. The right and left halves belong to different parabolas (hence the name *compound*) with the edges of the receiver being the foci of the opposite parabola (see Figure 40.9). It has been proven that such collectors are *ideal* in that any solar ray, be it beam or diffuse, incident on the aperture within the acceptance angle will reach the absorber while all others will bounce back to and fro and reemerge through the aperture. CPCs are also called *nonimaging* concentrators because they do not form clearly defined images of the solar disk on the absorber surface as achieved in classical concentrators. CPCs can be designed both as low-concentration devices with large acceptance angles or as high-concentration devices with small acceptance angles. CPCs with low-concentration ratios (of about 2) and with east-west axes can be operated as stationary devices throughout the year or at most with seasonal adjustments only. CPCs, unlike other concentrators, are able to collect all the beam and a large portion of the diffuse radiation. Also they do not require highly specular surfaces and can thus better tolerate dust and degradation. A typical module made up of several CPCs is shown in Figure 40.10. The absorber surface is located at the bottom of the trough, and a glass cover may also be used to encase the entire module. CPCs show considerable promise for water heating close to the boiling point and for low-pressure

**FIGURE 40.9**

Cross-section of a symmetrical nontruncated CPC. (From Duffie, J.A. and Beckman, W.A., *Solar Engineering of Thermal Processes*, Wiley Interscience, New York, 1980.)

steam applications. Further details about the different types of absorber and receiver shapes used, the effect of truncation of the receiver and the optics, can be found in Rabl (1985).

## 40.3 Long-Term Performance of Solar Collectors

### 40.3.1 Effect of Day-to-Day Changes in Solar Insolation

Instantaneous or hourly performance of solar collectors has been discussed in “Flat-Plate Collectors.” For example, one would be tempted to use the HWB Equation 40.2 to predict long-term collector performance at a prespecified and constant fluid inlet temperature  $T_{Ci}$  merely by assuming average hourly values of  $I_T$  and  $T_a$ . Such a procedure would be erroneous and lead to underestimation of collector output because of the presence of the control function, which implies that collectors are turned on only when  $q_C > 0$ , that is, when radiation  $I_T$  exceeds a certain critical value  $I_C$ . This critical radiation value is found by setting  $q_C$  in Equation 40.2 to zero:

$$I_C = U_L (T_{Ci} - T_a) / \eta_0 \quad (40.7a)$$

To be more rigorous, a small increment  $\delta$  to account for pumping power and stability of controls can also be included if needed by modifying the equation to

$$I_C = U_L (T_{Ci} + \delta - T_a) / \eta_0 \quad (40.7b)$$

Then, Equation 40.2 can be rewritten in terms of  $I_C$  as

$$q_C = A_C F_R \eta_0 [I_T - I_C]^+ \quad (40.8)$$

Why one cannot simply assume a mean value of  $I_T$  in order to predict the mean value of  $q_C$  will be illustrated by the following simple concept (Klein 1978). Consider the three identical day sequences shown in sequence A of Figure 40.11. If  $I_{C1}$  is the critical radiation

**FIGURE 40.11**

Effect of radiation distribution on collector long-term performance. (From Klein, S.A., Calculation of flat-plate collector utilizability, *Solar Energy*, 21, 393, 1978.)

intensity and if it is constant over the whole day, the useful energy collected by the collector is represented by the sum of the shaded areas. If a higher critical radiation value shown as  $I_{C2}$  in Figure 40.11 is selected, we note that no useful energy is collected at all. Actual weather sequences would not look like that in sequence A but rather like that in sequence B, which is comprised of an excellent, a poor, and an average day. Even if both sequences have the same average radiation over 3 days, a collector subjected to sequence B will collect useful energy when the critical radiation is  $I_{C2}$ . Thus, neglecting the variation of radiation intensity from day-to-day over the long term and dealing with mean values would result in an underestimation of collector performance.

Loads are to a certain extent repetitive from day-to-day over a season or even the year. Consequently, one can also expect collectors to be subjected to a known diurnal repetitive pattern or mode of operation, that is, the collector inlet temperature  $T_{Ci}$  has a known repetitive pattern.

### 40.3.2 Individual Hourly Utilizability

In this mode,  $T_{Ci}$  is assumed to vary over the day but has the same variation for all the days over a period of  $N$  days (where  $N = 30$  days for monthly and  $N = 365$  for yearly periods). Then from Equation 40.8, total useful energy collected over  $N$  days during individual hour  $i$  of the day is

$$q_{CN}(i) = A_C F_R \bar{\eta}_0 \bar{I}_{Ti} \sum_{i=1}^N \frac{[I_{Ti} - I_C]^+}{\bar{I}_{Ti}} \quad (40.9)$$

Let us define the radiation ratio

$$X_i = \frac{I_{Ti}}{\bar{I}_{Ti}} \quad (40.10)$$

and the critical radiation ratio

$$X_C = \frac{I_C}{\bar{I}_{Ti}}$$

The modified HWB Equation 40.8 can be rewritten as

$$q_{CN}(i) = A_C F_R \bar{\eta}_0 \bar{I}_{Ti} N \phi_i(x_c) \quad (40.11)$$

where the individual hourly utilizability factor  $\phi_i$  is identified as

$$\phi_i(X_C) = \frac{1}{N} \sum^N (X_i - X_C)^+ \quad (40.12)$$

Thus  $\phi_i$  can be considered to be the fraction of the incident solar radiation that can be converted to useful heat by an ideal collector (i.e., whose  $F_R \eta_0 = 1$ ). The utilizability factor is thus a *radiation statistic* in the sense that it depends solely on the radiation values at the specific location. As such, it is in no way dependent on the solar collector itself. Only after the radiation statistics have been applied is a collector dependent significance attached to  $X_C$ .

Hourly utilizability curves on a *monthly* basis that are independent of location were generated by Liu and Jordan (1963) over 30 years ago for flat-plate collectors (see [Figure 40.12](#)). The key climatic parameter which permits generalization is the *monthly clearness index*  $\bar{K}$  of the location defined as

$$\bar{K} = \frac{\bar{H}}{\bar{H}_0} \quad (40.13)$$

where

$\bar{H}$  is the monthly mean daily global radiation on the horizontal surface

$\bar{H}_0$  is the monthly mean daily extraterrestrial radiation on a horizontal surface

Extensive tables giving monthly values of  $\bar{K}$  for several different locations worldwide can be found in several books, for example, Duffie and Beckman (1980) or Reddy (1987). The curves apply to equator-facing tilted collectors with the effect of collector tilt accounted for by the factor  $\bar{R}_{b,T}$  which is the ratio of the monthly mean daily extraterrestrial radiation on the tilted collector to that on a horizontal surface. Monthly mean daily calculations can be made using the 15th of the month, though better accuracy is achieved using slightly different dates (Reddy 1987). Clark et al. (1983), working from measured data from several U.S. cities, have proposed the following correlation for individual hourly utilizability over monthly time scales applicable to flat-plate collectors only:

$$\begin{aligned} \phi_i &= 0 \quad \text{for } X_C \geq X_{\max} \\ &= (1 - X_C/X_{\max})^2 \quad \text{for } X_{\max} = 2 \\ &= \left| a \left| -[a^2 + (1 + 2a)(1 - X_C/X_{\max})^2]^{1/2} \right| \right| \quad \text{otherwise} \end{aligned} \quad (40.14)$$

where

$$a = (X_{\max} - 1)(2 - X_{\max}) \quad (40.15)$$

and

$$X_{\max} = 1.85 + 0.169(\bar{r}_T/\bar{k}^2) - 0.0696 \cos \beta / \bar{k}^2 - 0.981 \bar{k} / (\cos \delta)^2 \quad (40.16)$$

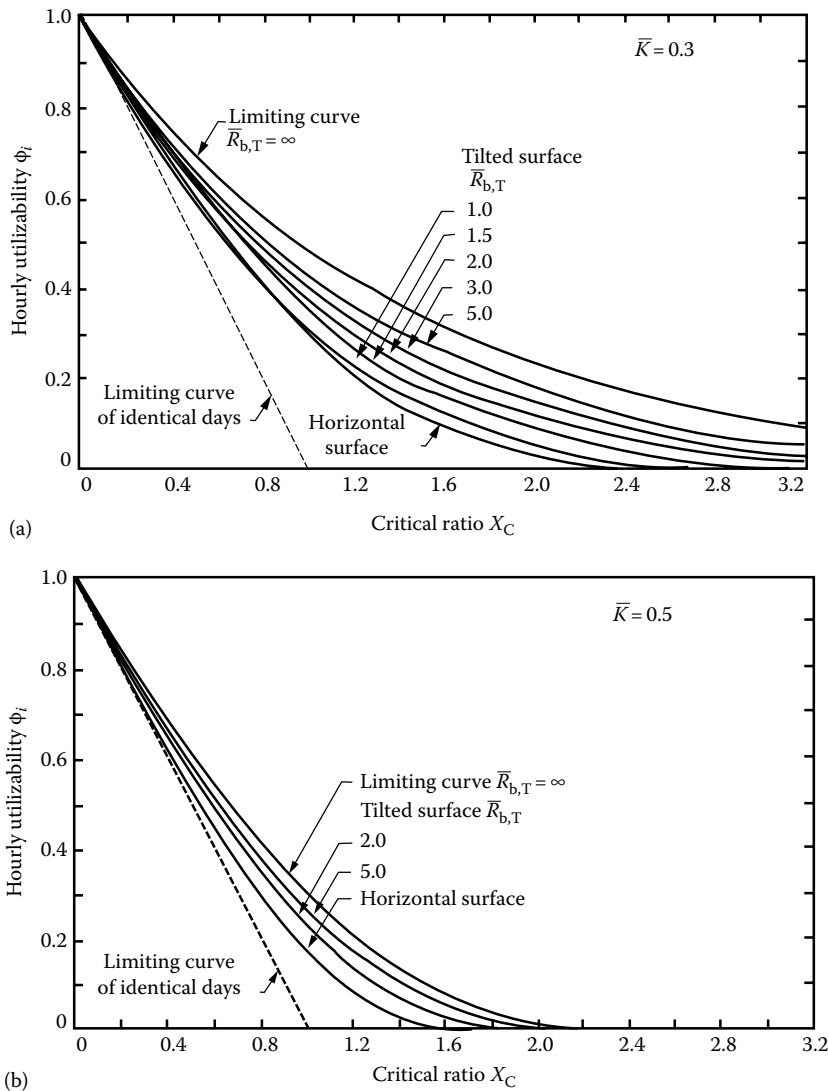

where

$\bar{k}$  is the monthly mean *hourly* clearness index for the particular hour

$\delta$  is the solar declination

$\beta$  is the tilt angle of the collector plane with respect to the horizontal

$\bar{r}_T$  is the ratio of monthly average hourly global radiation on a tilted surface to that on a horizontal surface for that particular hour

**FIGURE 40.12**

Generalized hourly utilizability curves of Liu and Jordan (1963) for three different monthly mean clearness indices  $K$ . (a)  $\bar{K} = 0.3$ , (b)  $\bar{K} = 0.5$ . (Continued)

**FIGURE 40.12 (Continued)**

Generalized hourly utilizability curves of Liu and Jordan (1963) for three different monthly mean clearness indices  $K$ . (c)  $\bar{K} = 0.7$ . (From Liu, B. Y. H. and Jordan, R. C., A rational procedure for predicting the long-term average performance of flat-plate solar energy collectors, *Solar Energy*, 7, 53, 1963.)

For an isotropic sky assumption,  $\bar{r}_T$  is given by

$$\bar{r}_T = (1 - \bar{I}_d \bar{I}) r_{b,T} + \left( \frac{1 + \cos \beta}{2} \right) \bar{I}_d \bar{I} + \left( \frac{1 - \cos \beta}{2} \right) \rho \quad (40.17)$$

where

$\bar{I}_d$  and  $\bar{I}$  are the hourly diffuse and global radiation on the horizontal surface

$r_{b,T}$  is the ratio of hourly beam radiation on the tilted surface to that on a horizontal surface (this is a purely astronomical quantity and can be calculated accurately from geometric considerations)

$\rho$  is the ground albedo

### Example 40.3

Compute the total energy collected during 11:30–12:30 for the month of September in New York, NY (latitude: 40.75°N,  $T_a = 20^\circ\text{C}$ ) by a flat-plate solar collector of 5 m<sup>2</sup> area having zero tilt. The collector performance parameters are  $F_R \eta_0 = 0.54$  and  $F_R U_L = 3.21 \text{ W}/(\text{m}^2 \text{ } ^\circ\text{C})$  and the collector inlet temperature is 80°C. The corresponding hourly mean clearness index  $\bar{k}$  is 0.44, and the monthly mean hourly radiation on a horizontal surface  $I_{Ti}$  (11:30–12:30) is 6.0 MJ/(m<sup>2</sup> h).

From Equation 40.7a, critical radiation  $I_C = 3.21 \times (80 - 20)/0.54 = 356.7 \text{ W/m}^2 = 1.28 \text{ MJ}/(\text{m}^2 \text{ h})$ . For the average day of September, solar declination  $\delta = 2.2^\circ$ . Also, because the collector is horizontal  $\bar{r}_T = 1$  and  $\beta = 0$ . Thus from Equation 40.16

$$X_{\max} = 1.85 + 0.169/0.44^2 - 0.0696/0.44^2 - 0.981 \times 0.44/(\cos 2.2)^\circ = 1.93.$$

Also from Equation 40.15,  $a = (1.93 - 1)/(2 - 1.93) = 13.29$ .

The critical radiation ratio  $X_C = 1.28/1.93 = 0.663$ .

Because  $X_C < X_{\max}$ , from Equation 40.14 we have

$$\phi_i(X_C) = |13.29 - [13.29^2 + (1 + 2 \times 13.29)(1 - 0.663/1.93)^2]^{1/2}| = |13.29 - 13.73| = 0.444.$$

Finally, the total energy collected is given by Equation 40.11

$$q_{\text{CN}}(11:30-12:30) = 5 \times 0.54 \times 60 \times 30 \times 0.44 = 214 \text{ MJ/h}$$

### 40.3.3 Daily Utilizability

#### 40.3.3.1 Basis

In this mode,  $T_{\text{Ci}}$ , and hence the critical radiation level, is assumed constant during all hours of the day. The *total* useful energy over  $N$  days that can be collected by solar collectors operated all day over  $n$  hours is given by

$$Q_{\text{CN}} = A_C F_R \bar{\eta}_0 \bar{H}_T N \bar{\phi} \quad (40.18)$$

where

$\bar{H}_T$  is the average daily global radiation on the collector surface

$\bar{\phi}$  (called Phibar) is the daily utilizability factor, defined as

$$\bar{\phi} = \frac{\sum_{i=1}^N \sum_{n=1}^n (I_T - I_C)^+}{\sum_{i=1}^N \sum_{n=1}^n I_T} = \frac{1}{Nn} \sum_{i=1}^N \sum_{n=1}^n (X_i - X_C)^+ \quad (40.19)$$

Generalized correlations have been developed both at monthly time scales and for annual time scales based on the parameter  $\bar{K}$ . Generalized (i.e., location and month independent) correlations for  $\bar{\phi}$  on a *monthly* time scale have been proposed by Theilacker and Klein (1980). These are strictly applicable for flat-plate collectors only. Collares-Pereira and Rabl (1979) have also proposed generalized correlations for  $\bar{\phi}$  on a monthly time scale which, though a little more tedious to use are applicable to concentrating collectors as well. The reader may refer to Rabl (1985) or Reddy (1987) for complete expressions.

#### 40.3.3.2 Monthly Time Scales

The Phibar method of determining the daily utilizability fraction proposed by Theilacker and Klein (1980) correlates  $\bar{\phi}$  to the following factors:

1. A geometry factor  $\bar{R}_T/\bar{r}_{T,\text{noon}}$  which incorporates the effects of collector orientation, location, and time of year.  $\bar{R}_T$  is the ratio of monthly average global radiation on the tilted surface to that on a horizontal surface.  $\bar{r}_{T,\text{noon}}$  is the ratio of radiation at noon on the tilted surface to that on a horizontal surface for the average day of the month.

Geometrically,  $\bar{r}_{T,\text{noon}}$  is a measure of the maximum height of the radiation curve over the day, whereas  $\bar{R}_T$  is a measure of the enclosed area. Generally the value  $(\bar{R}_T/\bar{r}_{T,\text{noon}})$  is between 0.9 and 1.5.

2. A dimensionless critical radiation level  $\bar{X}_{C,K}$  where

$$\bar{X}_{C,K} = \frac{I_C}{\bar{I}_{T,\text{noon}}} \quad (40.20)$$

with  $\bar{I}_{T,\text{noon}}$  the radiation intensity on the tilted surface at noon, given by

$$\bar{I}_{T,\text{noon}} = \bar{r}_{\text{noon}} \bar{r}_{T,\text{noon}} \bar{H} \quad (40.21)$$

where  $\bar{r}_{\text{noon}}$  is the ratio of radiation at noon to the daily global radiation on a horizontal surface during the mean day of the month which can be calculated from the following correlation proposed by Liu and Jordan (1960):

$$r(W) = \frac{I(W)}{H} = \frac{\pi}{24} (a + b \cos W) \frac{(\cos W - \cos W_s)}{\left( \sin W_s - \frac{\pi}{180} W_s \cos W_s \right)} \quad (40.22)$$

with

$$a = 0.409 + 0.5016 \sin(W_s - 60)$$

$$b = 0.6609 - 0.4767 \sin(W_s - 60)$$

where

$W$  is the hour angle corresponding to the midpoint of the hour (in degrees)

$W_s$  is the sunset hour angle given by

$$\cos W_s = -\tan L \tan \delta \quad (40.23)$$

where  $L$  is the latitude of the location. The fraction  $r$  is the ratio of hourly to daily global radiation on a horizontal surface. The factors  $\bar{r}_{T,\text{noon}}$  and  $\bar{r}_{\text{noon}}$  can be determined from Equations 40.17 and 40.22, respectively, with  $W = 0^\circ$ .

The Theilacker and Klein correlation for the daily utilizability for equator-facing flat-plate collectors is

$$\bar{\phi}(X_{C,K}) = \exp\{[a' + b'(\bar{r}_{T,\text{noon}}/\bar{R}_T)][X_{C,K} + c'X_{C,K}^2]\} \quad (40.24)$$

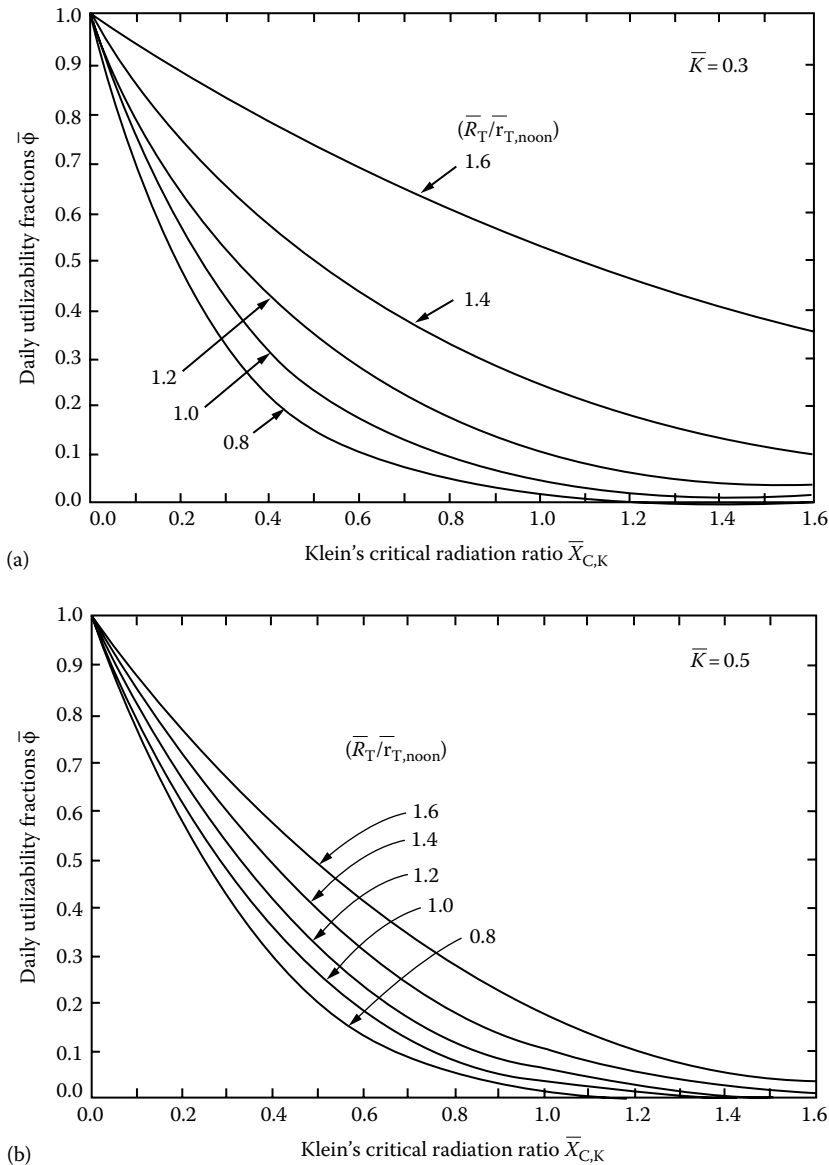

where

$$\begin{aligned} a' &= 7.476 - 20.00\bar{K} + 11.188\bar{K}^2 \\ b' &= -8.562 + 18.679\bar{K} - 9.948\bar{K}^2 \\ c' &= -0.722 + 2.426\bar{K} + 0.439\bar{K}^2 \end{aligned} \quad (40.25)$$

How  $\bar{\phi}$  varies with the critical radiation ratio  $\bar{X}_{C,K}$  for three different values of  $\bar{K}$  is shown in [Figure 40.13](#).

**Example 40.4**

A flat-plate collector operated horizontally at Fort Worth, Texas ( $L = 32.75^\circ\text{N}$ ), has a surface area of  $20\text{ m}^2$ . It is used to heat  $10\text{ kg/min}$  of water entering the collector at a constant temperature of  $80^\circ\text{C}$  each day from 6 a.m. to 6 p.m. The collector performance parameters are  $F_R\eta_0 = 0.70$  and  $F_RU_L = 5.0\text{ W/(m}^2\text{ }^\circ\text{C)}$ . Use Klein's correlation to compute the energy collected by the solar collectors during September. Assume  $\bar{H} = 18.28\text{ MJ/(m}^2\text{-d)}$ ,  $\bar{K} = 0.57$  and  $\bar{T}_a = 25^\circ\text{C}$ . Assume the mean sunset hour angle for September to be  $90^\circ$ .

**FIGURE 40.13**

Generalized daily utilizability curves of Theilacker and Klein (1980) for three different  $K$  values. (a)  $\bar{K} = 0.3$ , (b)  $\bar{K} = 0.5$ . (Continued)

**FIGURE 40.13 (Continued)**

Generalized daily utilizability curves of Theilacker and Klein (1980) for three different  $K$  values. (c)  $\bar{K} = 0.7$ . (From Theilacker, J.C. and Klein, S.A., Improvements in the utilizability relationships, in *American Section of the International Solar Energy Society Meeting Proceedings*, Phoenix, AZ, 1980, 271pp.)

The critical radiation is calculated first:

$$I_C = (5/0.7)(80 - 25) = 393 \text{ W/m}^2 = 1.414 \text{ MJ}/(\text{m}^2\text{h})$$

For a horizontal surface,  $\bar{R}_T = \bar{r}_{T,\text{noon}} = 1$ . From Equation 40.22,  $r(W=0) = \pi/24(a+b) = 0.140$ . Klein's critical radiation ratio (Section 40.10)  $\bar{X}_{C,K} = 1.414/(18.28 \times 0.140) = 0.553$ . From Equation 40.24,  $\bar{\phi} = 0.318$ . Finally, from Equation 40.18, the total monthly energy collected by the solar collectors is  $Q_{CM} = 20 \times 0.7 \times 30 \times 0.318 \times 18.28 = 2.44 \text{ GJ/month}$ .

#### 40.3.3.3 Annual Time Scales

Generalized expressions for the *yearly* average energy delivered by the principal collector types with constant radiation threshold (i.e., when the fluid inlet temperature is constant for all hours during the day over the entire year) have been developed by Rabl (1981) based on data from several U.S. locations. The correlations are basically quadratic of the form

$$\frac{Q_{CY}}{A_C F_R \eta_n} = \tilde{a} + \tilde{b} I_C + \tilde{c} I_C^2 \quad (40.26)$$

where the coefficients  $\tilde{a}$ ,  $\tilde{b}$ , and  $\tilde{c}$  are functions of collector type and/or tracking mode, climate, and in some cases, latitude. The complete expressions as revised by Gordon and Rabl (1982) are given in Reddy (1987). Note that the yearly *daytime* average value of  $T_a$  should be used to determine  $I_C$ . If this is not available, the yearly mean *daily* average value can be used. Plots of  $Q_{CY}$  versus  $I_C$  for flat-plate collectors that face the equator with tilt equal to

**FIGURE 40.14**

Yearly total energy delivered by flat-plate collectors with tilt equal to latitude. (From Gordon, J.M. and Rabl, A., *Solar Energy*, 28, 519, 1982.)

the latitude are shown in Figure 40.14. The solar radiation enters these expressions as  $\tilde{I}_{bn}$ , the annual average beam radiation at normal incidence. This can be estimated from the following correlation

$$\tilde{I}_{bn} = 1.37\tilde{K} - 0.34 \quad (40.27)$$

where

$\tilde{I}_{bn}$  is in kW/m<sup>2</sup>

$\tilde{K}$  is the annual average clearness index of the location

Values of  $\tilde{K}$  for several locations worldwide are given in Reddy (1987).

This correlation is strictly valid for latitudes ranging from 25° to 48°. If used for lower latitudes, the correlation is said to lead to overprediction. Hence, it is recommended that for such lower latitudes a value of 25° be used to compute  $Q_{Cy}$ .

A direct comparison of the yearly performance of different collector types is given in Figure 40.15. A latitude of 35°N is assumed and plots of  $Q_{Cy}$  U.S. ( $T_{Ci} - T_a$ ) have been generated in a sunny climate with  $I_{bn} = 0.6$  kW/m<sup>2</sup>. Relevant collector performance data are given in Figure 40.15. The crossover point between flat-plate and concentrating collectors is approximately 25°C above ambient temperature whether the climate is sunny or cloudy.

**FIGURE 40.15**

Figure illustrating the comparative performance (yearly collectible energy) of different collector types as a function of the difference between collector inlet temperature and ambient collector performance parameters  $F'\eta_0$  and  $F'U_L$  in  $W/(m^2 \text{ } ^\circ C)$  are: flat plate (0.70 and 5.0), CPC (0.60 and 0.75), parabolic trough (0.65 and 0.67), and parabolic dish (0.61 and 0.27). (From Rabl, A., Yearly average performance of the principal solar collector types, *Solar Energy*, 27, 215, 1981.)

## 40.4 Solar Systems

### 40.4.1 Classification

Solar thermal systems can be divided into two categories: standalone or solar supplemented. They can be further classified by means of energy collection as active or passive, by their use as residential or industrial. Further, they can be divided by collector type into liquid or air systems, and by the type of storage they use into seasonal or daily systems.

#### 40.4.1.1 Standalone and Solar Supplemented Systems

*Standalone systems* are systems in which solar energy is the only source of energy input used to meet the required load. Such systems are normally designed for applications where a certain amount of tolerance is permissible concerning the load requirement; in other words, where it is not absolutely imperative that the specified load be met each and every instant. This leniency is generally admissible in the case of certain residential and agricultural applications. The primary reasons for using such systems are their low cost and simplicity of operation.

*Solar-supplemented systems*, widely used for both industrial and residential purposes, are those in which solar energy supplies part of the required heat load, the rest being met by an auxiliary source of heat input. Due to the daily variations in incident solar radiation, the portion of the required heat load supplied by the solar energy system may vary from

day-to-day. However, the auxiliary source is so designed that at any instant it is capable of meeting the remainder of the required heat load. It is normal practice to incorporate an auxiliary heat source large enough to supply the entire heat load required. Thus, the benefit in the solar subsystem is not in its capacity credit (i.e., not that a smaller capacity conventional system can be used), but rather that a part of the conventional fuel consumption is displaced. The solar subsystem thus acts as a fuel economizer.

Solar-supplemented energy systems will be the primary focus of this chapter. Designing such systems has acquired a certain firm scientific rationale, and the underlying methodologies have reached a certain maturity and diversity, which may satisfy professionals from allied fields. On the other hand, unitary solar apparatus are not discussed here, since these are designed and sized based on local requirements, material availability, construction practices, and practical experience. Simple rules of thumb based on prior experimentation are usually resorted to for designing such systems.

#### **40.4.1.2 Active and Passive Systems**

*Active systems* are those systems that need electric pumps or blowers to collect solar energy. It is evident that the amount of solar energy collected should be more than the electrical energy used. Active systems are invariably used for industrial applications and for most domestic and commercial applications as well. *Passive systems* are those systems that collect or use solar energy without direct recourse to any source of conventional power, such as electricity, to aid in the collection. Thus, either such systems operate by natural thermosyphon (for example, domestic water heating systems) between collector, storage, and load or, in the case of space heating, the architecture of the building is such as to favor optimal use of solar energy. Use of a passive system for space heating applications, however, in no way precludes the use of a backup auxiliary system. This chapter deals with active solar systems only.

#### **40.4.1.3 Residential and Industrial Systems**

Basically, the principles and the components used in these two types of systems are alike, the difference being in the load distribution, control strategies, and relative importance of the components with respect to each other. Whereas *residential* loads have sharp peaks in the early morning or in the evening and have significant seasonal variations, industrial loads tend to be fairly uniform over the year. Constant loads favor the use of solar energy because good equipment utilization can be achieved. Because of differences in load distribution, the role played by the storage differs for both applications. Residential loads often occur at times when solar radiation is no longer available. Thus the collector and the storage subsystems interact in a mode without heat withdrawal from the storage. Finally, for economic reasons, many residential systems are designed to operate by natural thermosyphon, in which case no pumps or controls are needed.

On the other hand, for *industrial and commercial* applications, there is no a priori relationship between the time dependence of the load and the period of sunshine. Moreover, a high reliability has to be assured, so the solar system will have to be combined with a conventional system. Very often, a significant portion of the load can be directly supplied by the solar system even without storage. Another option is to use buffer storage for short periods, on the order of a few hours, in case of discontinuous batch process loads. Thus, the proper design of the storage component has to be given adequate consideration. At present, due to economic constraints as well as the fact that proper awareness of the various

installations and operational difficulties associated with larger solar thermal systems is still lacking, solar thermal systems are normally designed either (1) with the no-storage option, or (2) with buffer storage where a small fraction of the total heat demand is only supplied by the solar system.

#### 40.4.1.4 Liquid and Air Collectors

Although air has been the primary fluid for space heating and drying applications, solar air heating systems have until recently been relegated to second place, mainly as a result of the engineering difficulties associated with such systems. Also, applications involving hot air are probably less common than those needing hot water. Air systems for space heating are well described by Löff (1981).

Even with liquid solar collectors, various configurations are possible, and these can be classified basically as *nontracking* (which include flat-plate collectors and CPCs) or *tracking* collectors (which include various types of concentrating collectors). For low-grade thermal heat, for which solar energy is most suited, flat-plate collectors are far more appropriate than concentrating collectors, not only because of their lower cost but also because of their higher thermal efficiencies at low temperature levels. Moreover, their operation and maintenance costs are lower. Finally, for locations having a high fraction of diffuse radiation, as in the tropics, flat-plate collectors are considered to be thermally superior because they can make use of diffuse radiation as well as beam radiation. Although the system design methodologies presented in this chapter explicitly assume flat-plate collector systems, these design approaches can be equally used with concentrating collectors.

#### 40.4.1.5 Daily and Seasonal Storage

By *daily storage* is meant systems having capacities equivalent to at most a few days of demand (i.e., just enough to tide over day-to-day climatic fluctuations). In *seasonal storage*, solar energy is stored during the summer for use in winter. Industrial demand loads, which are more or less uniform over the year, are badly suited for seasonal-storage systems. This is also true of air-conditioning for domestic and commercial applications because the load is maximum when solar radiation is also maximum, and vice versa. The present-day economics of seasonal storage units do not usually make such systems an economical proposition except for community heating in cold climates.

### 40.4.2 Closed-Loop and Open-Loop Systems

The two possible configurations of solar thermal systems with daily storage are classified as closed-loop or open-loop systems. Though different authors define these differently, we shall define these as follows. A *closed-loop system* has been defined as a circuit in which the performance of the solar collector is directly dependent on the storage temperature. [Figure 40.16](#) gives a schematic of a closed-loop system in which the fluid circulating in the collectors does not mix with the fluid supplying thermal energy to the load. Thus, these two subsystems are distinct in the sense that any combination of fluids (water or air) is theoretically feasible (a heat exchanger, as shown in the figure, is of course imperative when the fluids are different). However, in practice, only water–water, water–air, or air–air combinations are used. From the point of system performance, the storage temperature normally varies over the day and, consequently, so does collector performance. Closed-loop system configurations have been widely used to date for domestic hot water

**FIGURE 40.16**  
Schematic of a closed-loop solar system.

and space heating applications. The flow rate per unit collector area is generally around  $50 \text{ kg}/(\text{h m}^2)$  for liquid collectors. The storage volume makes about 5–10 passes through the collector during a typical sunny day, and this is why such systems are called *multipass* systems. The temperature rise for each pass is small, of the order of  $2^\circ\text{C}$ – $5^\circ\text{C}$  for systems with circulating pumps and about  $10^\circ\text{C}$  for thermosyphon systems. An expansion tank and a check valve to prevent reverse thermosyphoning at nights, although not shown in the figure, are essential for such system configurations.

Figure 40.17 illustrates one of the possible configurations of *open-loop systems*. Open-loop systems are defined as systems in which the collector performance is independent of the storage temperature. The working fluid may be rejected (or a heat recuperator can be used) if contaminants are picked up during its passage through the load. Alternatively, the working fluid could be directly recirculated back to the entrance of the solar collector field. In all these open-loop configurations, the collector is subject to a given or known inlet temperature specified by the load requirements.

If the working fluid is water, instead of having a continuous flow rate (in which case the outlet temperature of the water will vary with isolation), a solenoid valve can be placed just at the exit of the collector, set so as to open when the desired temperature level of the fluid in the collector is reached. The water is then discharged into storage, and fresh water

**FIGURE 40.17**  
Schematic of an open-loop solar system.

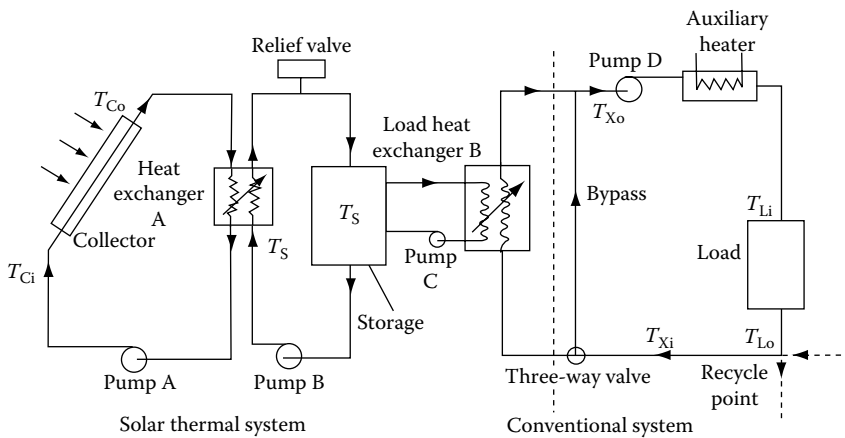

is taken into the collector. The solar collector will thus operate in a discontinuous manner, but this will ensure that the temperature in the storage is always at the desired level. An alternative way of ensuring uniform collector outlet temperature is to vary the flow rate according to the incident radiation. One can collect a couple of percent more energy than with constant rate single-pass designs (Gordon and Zarmi 1985). However, this entails changing the flow rate of the pump more or less continuously, which is injurious to the pump and results in reduced life. Of all the three variants of the open-loop configuration, the first one, namely the single-pass open-loop solar thermal system configuration with constant flow rate and without a solenoid valve, is the most common.

As stated earlier, closed-loop systems are appropriate for domestic applications. Until recently, industrial process heat systems were also designed as large solar domestic hot-water systems with high collector flow rates and with the storage tank volume making several passes per day through the collectors. Consequently, the storage tank tends to be fairly well mixed. Also the tank must be strong enough to withstand the high pressure from the water mains. The open-loop single-pass configuration, wherein the required average daily fluid flow is circulated just once through the collectors with the collector inlet temperature at its lowest value, has been found to be able to deliver as much as 40% more yearly energy for industrial process heat applications than the multipass designs (Collares-Pereira et al. 1984). Finally, in a closed-loop system where an equal amount of fresh water is introduced into storage whenever a certain amount of hot water is drawn off by the load, it is not possible to extract the entire amount of thermal energy contained in storage since the storage temperature is continuously reduced due to mixing. This *partial depletion effect* in the storage tank is not experienced in open-loop systems. The penalty in yearly energy delivery ranges typically from about 10% for daytime-only loads to around 30% for nighttime-only loads compared to a closed-loop multipass system where the storage is depleted every day. Other advantages of open-loop systems are (1) the storage tank need not be pressurized (and hence is less costly), and (2) the pump size and parasitic power can be lowered.

A final note of caution is required. The single-pass design is not recommended for *variable* loads. The tank size is based on yearly daily load volumes, and efficient use of storage requires near-total depletion of the daily collected energy each day. If the load draw is markedly lower than its average value, the storage would get full relatively early the next day and solar collection would cease. It is because industrial loads tend to be more uniform, both during the day and over the year, than domestic applications that the single-pass open-loop configuration is recommended for such applications.

#### 40.4.2.1 Description of a Typical Closed-Loop System

Figure 40.18 illustrates a typical closed-loop solar-supplemented liquid heating system. The useful energy is often (but not always) delivered to the storage tank via a collector-heat exchanger, which separates the collector fluid stream and the storage fluid. Such an arrangement is necessary either for antifreeze protection or to avoid corrosion of the collectors by untreated water containing gases and salts. A safety relief valve is provided because the system piping is normally nonpressurized, and any steam produced in the solar collectors will be let off from this valve. When this happens, energy dumping is said to take place. Fluid from storage is withdrawn and made to flow through the load-heat exchanger when the load calls for heat. Whenever possible, one should withdraw fluid directly from the storage and pass it through the load, and avoid incorporating the load-heat exchanger, since it introduces additional thermal penalties and involves extra equipment and additional parasitic power use. Heat is withdrawn from the storage tank at

**FIGURE 40.18**

Schematic of a typical closed-loop system with auxiliary heater placed in series (also referred to as a topping-up type).

the top and reinjected at the bottom in order to derive maximum benefit from the thermal stratification that occurs in the storage tank. A bypass circuit is incorporated prior to the load heat exchanger and comes into play

1. When there is no heat in the storage tank (i.e., storage temperature  $T_S$  is less than the fluid temperature entering the load heat exchanger  $T_{Xi}$ )
2. When  $T_S$  is such that the temperature of the fluid leaving the load heat exchanger is greater than that required by the load (i.e.,  $T_{Xo} > T_{Li}$ , in which case the three-way valve bypasses part of the flow so that  $T_{Xo} = T_{Li}$ ). The bypass arrangement is thus a differential control device which is said to modulate the flow such that the above condition is met. Another operational strategy for maintaining  $T_{Xo} = T_{Li}$  is to operate the pump in a “bang-bang” fashion (i.e., by short cycling the pump). Such an operation is not advisable, however, since it would lead to premature pump failure.

An auxiliary heater of the *topping-up type* supplies just enough heat to raise  $T_{Xo}$  to  $T_{Li}$ . After passing through the load, the fluid (which can be either water or air) can be recirculated or, in case of liquid contamination through the load, fresh liquid can be introduced. The auxiliary heater can also be placed in parallel with the load (see [Figure 40.19](#)), in which case it is called an *all-or-nothing type*. Although such an arrangement is thermally less efficient than the topping-up type, this type is widely used during the solar retrofit of heating systems because it involves little mechanical modifications or alterations to the auxiliary heater itself.

It is obvious that there could also be solar-supplemented energy systems that do not include a storage element in the system. [Figure 40.20](#) shows such a system configuration with the auxiliary heater installed in series. The operation of such systems is not very different from that of systems with storage, the primary difference being that whenever instantaneous solar energy collection exceeds load requirements (i.e.,  $T_{Co} > T_{Li}$ ), energy dumping takes place. It is obvious that by definition there cannot be a closed-loop, no-storage solar thermal system. Solar thermal systems without storage are easier to construct and operate, and even though they may be effective for 8–10 h a day, they are appropriate for applications such as process heat in industry.

**FIGURE 40.19**

Schematic of a typical closed-loop system with auxiliary heater placed in parallel (also referred to as an all-or-nothing type).

**FIGURE 40.20**

Simple solar thermal system without storage.

Active closed-loop solar systems as described earlier are widely used for service hot-water systems, that is, for domestic hot water and process heat applications as well as for space heat. There are different variants to this generic configuration. A system without the collector-heat exchanger is referred to having collectors *directly coupled* to the storage tank (as against *indirect coupling* as in Figure 40.16). For domestic hot-water systems, the system can be simplified by placing the auxiliary heater (which is simply an electric heater) directly inside the storage tank. One would like to maintain stratification in the tank so that the coolest fluid is at the bottom of the storage tank, thereby enhancing collection efficiency. Consequently, the electric heater is placed at about the upper third portion of the tank so as to assure good collection efficiency while assuring adequate hot water supply to the load. A more efficient but expensive option is widely used in the United States: the *double tank system*, shown in Figure 40.21. Here the functions of solar storage and auxiliary heating are separated, with the solar tank acting as a preheater for the conventional gas or electric unit. Note that a further system simplification can be achieved for domestic applications by placing the load heat exchanger directly inside the storage tank. In certain cases, one can even eliminate the heat exchanger completely.

Another system configuration is the *drain-back* (also called drain-out) system, where the collectors are emptied each time the solar system shuts off. Thus the system invariably

**FIGURE 40.21**

Schematic of a standard domestic hot-water system with double tank arrangement. (From Duffie, J.A. and Beckman, W.A., *Solar Engineering of Thermal Processes*, Wiley Interscience, New York, 1980.)

loses collector fluid at least once, and often several times, each day. No collector-heat exchanger is needed, and freeze protection is inherent in such a configuration. However, careful piping design and installation, as well as a two-speed pump, are needed for the system to work properly (Newton and Gilman 1981). The drain-back configuration may be either open (vented to atmosphere) or closed (for better corrosion protection). Long-term experience in the United States with the drain-back system has shown it to be very reliable if engineered properly. A third type of system configuration is the *drain-down* system, where the fluid from the collector array is removed only when adverse conditions, such as freezing or boiling, occur. This design is used when freezing ambient temperatures are only infrequently encountered.

Active solar systems of the type described above are mostly used in countries such as the United States and Canada. Countries such as Australia, India, and Israel (where freezing is rare) usually prefer thermosyphon systems. No circulating pump is needed, the fluid circulation being driven by density difference between the cooler water in the inlet pipe and the storage tank and the hotter water in the outlet pipe of the collector and the storage tank. The low fluid flow in thermosyphon systems enhances thermal stratification in the storage tank. The system is usually fail-proof, and a study by Liu and Fannery (1980) reported that a thermosyphon system performed better than several pumped service hot-water systems. If operated properly, thermosyphon and active solar systems are comparable in their thermal performance. A major constraint in installing thermosyphon systems in already existing residences is the requirement that the bottom of the storage tank be at least 20 cm or more higher than the top of the solar collector in order to avoid reverse thermosyphoning at night. To overcome this, spring-loaded one-way valves have been used, but with mixed success.

## 40.5 Controls

There are basically five categories to be considered when designing automatic controls (Mueller Associates 1985): (1) collection to storage, (2) storage to load, (3) auxiliary energy to load, (4) miscellaneous (i.e., heat dumping, freeze protection, overheating, etc.), and (5) alarms. The three major control system components are sensors, controllers, and actuating devices. Sensors are used to detect conditions (such as temperatures, pressures, etc.).

Controllers receive output from the sensors, select a course of action, and signal a system component to adjust the condition. Actuated devices are components such as pumps, valves, and alarms that execute controller commands and regulate the system.

The sensors for the controls must be set, operated, and located correctly if the solar system is to collect solar energy effectively, reduce operating time, wear and tear of active components, and minimize auxiliary and parasitic energy use. Moreover, sensors also need to be calibrated frequently. For diagnostic purposes, it may be advisable to add extra sensors and data acquisition equipment in order to verify system operation and keep track of long-term system operation. Potential problems can be then rectified in time. The reader may refer to manuals by Mueller Associates (1985) or by SERI (1989) for more details on controls pertaining to solar energy systems.

Though single-point temperature controllers or solar-cell-activated controls have been used for activated solar collectors, the best way to do so is by differential temperature controllers. Temperature sensors are used to measure the fluid temperature at collector outlet and at the bottom of the storage tank. When the difference is greater than a set amount, say  $5^{\circ}\text{C}$ , then the controller turns the pump on. If the pump is running and the temperature difference falls below another preset value, say  $1^{\circ}\text{C}$ , the controller stops the pump. The temperature deadband between switching-off and reactivating levels should be set with care, since too high a deadband would adversely affect collection efficiency and too low a value would result in short cycling of the collector pump. Figure 40.22 taken from CSU (1980), shows typical diurnal temperature variations of the liquids at collector exit  $T_1$  and in the storage bottom  $T_3$  as a result of heat withdrawal and/or heat losses from the storage. At about 8:30 a.m.,  $T_1 > T_3$  and, since there is no flow in the collector,  $T_1$  increases rapidly until the difference  $(T_1 - T_3)$  reaches the preset activation level (shown as point 1). The collector pump A comes on, and liquid circulation through the collector begins. Because of this cold water surge,  $T_1$  decreases, resulting in a drop of  $(T_1 - T_3)$  to the preset deactivating level (shown as point 2). The pump switches off, and liquid flow through the collectors stops. Gradually  $T_1$  increases again, and so on. The number of on-off cycles at system start-up depends on solar intensity, fluid flow rate, volume of water in the collector loop, and the differential controller setting. A similar phenomenon of cycling also occurs in the afternoon. However, the error introduced in solar collector long-term performance predictions by neglecting this cycling effect in the modeling equations is usually small.

**FIGURE 40.22**

Typical diurnal variation of collector and storage temperatures. Points 1–3 represent the start-up, shut-down, and re-start cycling operation of the circulating pump at the beginning of the day; points 4–6 represent the shut-down cycling behavior at the end of the day. (From CSU, Solar heating and cooling of residential buildings—Design of systems, Manual prepared by the Solar Energy Applications Laboratory, Colorado State University, Fort Collins, CO, 1980.)

### 40.5.1 Corrections to Collector Performance Parameters

#### 40.5.1.1 Combined Collector-Heat Exchanger Performance

The use of the heat exchanger A in Figure 40.18 imposes a penalty on the performance of the solar system because  $T_{Ci}$  is always higher than  $T_s$ , thereby decreasing  $q_c$  (see Figure 40.23). The collector-heat exchanger can be implicitly accounted for by suitably modifying the collector performance parameters. Recall from basic heat transfer the concept of heat exchanger effectiveness  $E$  defined as the ratio of the actual heat transfer rate to the maximum possible heat transfer rate, that is,

$$E = \frac{(mc_p)_a(T_{ai} - T_{ao})}{(mc_p)_{\min}(T_{ai} - T_{bi})} \quad (40.28a)$$

$$= \frac{(mc_p)_b(T_{bo} - T_{bi})}{(mc_p)_{\min}(T_{ai} - T_{bi})} \quad (40.28b)$$

where

$(mc_p)_x$  is the capacitance rate of fluid  $X$  (with  $X = a$  for the warmer fluid, or  $X = b$  for the cooler fluid)

$(mc_p)_{\min}$  is the lower heat capacitance value of either stream

**FIGURE 40.23**

Heat collection decrease caused by double-loop heat exchangers. (From Cole, R.L. et al. (eds.), Design and installation manual for thermal energy storage, ANL-79-15, Argonne National Laboratory, Argonne, IL, 1979.)

The advantage of this modeling approach is that, to a good approximation,  $E$  can be considered constant in spite of variations in temperature levels provided the mass flow rates of both fluids remain constant. Thus, knowing the two flow rates,  $E$ ,  $T_{air}$  and  $T_{biv}$ , both the exit fluid temperatures can be conveniently deduced. De Winter (1975) has shown that the combined performance of the solar collector and the heat exchanger can be conveniently modeled by replacing the collector heat removal factor  $F_R$  by a combined collector-exchanger heat removal factor  $F'_R$  such that

$$\frac{F'_R}{F_R} = \left[ 1 + \frac{F_R U_L A_C}{(\dot{m}c_p)_C} \left\{ \frac{(\dot{m}c_p)_C}{E_A (\dot{m}c_p)_{\min}} - 1 \right\} \right]^{-1} \quad (40.29)$$

where

$(\dot{m}c_p)_C$  is the capacitance rate of the fluid through the collector

$E_A$  is the effectiveness of heat exchanger A

The variation of  $F'_R/F_R$  is shown in Figure 40.24. The plots exhibit the same type of asymptotic behavior with mass flow rate as in Figure 40.3.

The design of the collector-heat exchanger also requires care if the penalty imposed by it on the solar collection is to be minimized. Using a large heat exchanger increases the effectiveness and lowers this penalty; that is, the ratio  $(F'_R/F_R)$  is high, but the associated initial and operating costs may be higher. Both these considerations need to be balanced for optimum design (see Figure 40.25). Optimum heat exchanger area  $A_X$  can be found from the following equation proposed by Cole et al. (1979):

$$A_X = A_C \left[ \frac{F_R U_L C_C}{U_X C_X} \right]^{1/2} \quad (40.30)$$

where

$A_C$  is the collector area

$C_C$  is the cost per unit collector area

$C_X$  is the cost per unit heat exchanger area

$U_X$  is the heat loss per unit area of the heat exchanger

**FIGURE 40.24**

Variation of collector-heat exchanger correction factor. (From Duffie, J.A. and Beckman, W.A., *Solar Engineering of Thermal Processes*, Wiley Interscience, New York, 1980.)

**FIGURE 40.25**

Typical heat-exchanger optimization plot. (From Cole, R.L. et al. (eds.), Design and installation manual for thermal energy storage, ANL-79-15, Argonne National Laboratory, Argonne, IL, 1979.)

#### 40.5.1.2 Collector Piping and Shading Losses

Other corrections that can be applied to collector performance parameters include those for thermal losses from the piping (or from ducts) between the collection subsystem and the storage unit. Beckman (1978) has shown that these losses can be conveniently taken into consideration by suitably modifying the  $\eta_n$  and  $U_L$  terms of the solar collectors as follows:

$$\frac{\eta'_n}{\eta_n} = \left[ 1 + \frac{u_d A_0}{(mc_p)_C} \right]^{-1} \quad \text{and} \quad \frac{U'_L}{U_L} = \frac{1 - \frac{U_d A_i}{(mc_p)_C} + \frac{U_d (A_i + A_0)}{A_C F_R U_L}}{1 + \frac{U_d A_0}{(mc_p)_C}} \quad (40.31)$$

where

$U_d$  is the heat coefficient from the pipe or duct

$A_0$  is the heat loss area of the outlet pipe or duct

$A_i$  is the heat loss area of the inlet pipe or duct

When large collector arrays are mounted on flat roofs or level ground, multiple rows of collectors are usually arranged in a sawtooth fashion. These multiple rows must be spaced so that they do not shade each other at low sun angles. Unlimited space is rarely available, and it is desirable to space the rows as close as possible to minimize piping and to keep land costs low. Some amount of shading, especially during early mornings and late evenings during the winter months is generally acceptable. Detailed analysis of shading losses is cumbersome though not difficult and equations presented in standard text books such as Duffie and Beckman (1980) can be used directly.

## 40.6 Thermal Storage Systems

Low-temperature solar thermal energy can be stored in liquids, solids, or phase change materials (PCMs). Water is the most frequently used liquid storage medium because of its low cost and high specific heat. The most widely used solid storage medium is rocks (usually of uniform circular size 25–40 mm in diameter). PCM storage is much less bulky because of the high-latent heat of the PCM material, but this technology has yet to become economical and safe for widespread use.

Water storage would be the obvious choice when liquid collectors are used to supply hot water to a load. When hot air is required (for space heat or for convective drying), one has two options: an air collector with a pebble-bed storage or a system with liquid collectors, water storage, and a load heat exchanger to transfer heat from the hot water to the working air stream. Though a number of solar air systems have been designed and operated successfully (mainly for space heating), water storage is very often the medium selected. Water has twice the heat capacity of rock, so water storage tanks will be smaller than rock-bed containers. Moreover, rock storage systems require higher parasitic energy to operate, have higher installation costs, and require more sophisticated controls. Water storage permits simultaneous charging and discharging while such an operation is not possible for rock storage systems. The various types of materials used as containers for water and rock-bed storage and the types of design, installation, and operation details one needs to take care of in such storage systems are described by Mueller Associates (1985) and SERI (1989).

Sensible storage systems, whether water or rock-bed, exhibit a certain amount of thermal stratification. Standard textbooks present relevant equations to model such effects. In the case of active closed-loop multipass hot-water systems, storage stratification effects can be neglected for long-term system performance with little loss of accuracy. Moreover, this leads to conservative system design (i.e., solar contribution is underpredicted if stratification is neglected). A designer who wishes to account for the effect of stratification in the water storage can resort to a formulation by Phillips and Dave (1982), who showed that this effect can be fairly well modeled by introducing a *stratification coefficient* (which is a system constant that needs to be determined only once) and treating the storage subsystem as fully mixed. However, this approach is limited to the specific case of no (or very little) heat withdrawal from storage during the collection period. Even when water storage systems are highly stratified, simulation studies seem to indicate that modeling storage as a one-dimensional plug-flow three-node heat transfer problem yields satisfactory results of long-term solar system performance.

The thermal losses  $q_w$  from the storage tank can be modeled as

$$q_w = (UA_s)(T_s - T_{\text{env}}) \quad (40.32)$$

where

$(UA_s)$  is the storage overall heat loss per unit temperature difference

$T_{\text{env}}$  is the temperature of the air surrounding the storage tank

Note that  $(UA_s)$  depends (1) on the storage size, which is a parameter to be sized during system design, and (2) on the configuration of the storage tank (i.e., on the length by diameter ratio in case of a cylindrical tank). For storage tanks, this ratio is normally in the range of 1.0–2.0.

## 40.7 Solar System Simulation

A system model is nothing but an assembly of appropriate component modeling equations that are to be solved over time subject to certain forcing functions (i.e., the meteorological data and load data). The resulting set of simultaneous equations can be solved either analytically or numerically.

The analytical method of resolution is appropriate, or possible, only for simplified system configurations and operating conditions. This approach has had some success in the analysis and design of open-loop systems (refer to Reddy 1987, Gordon and Rabl 1986, for more details). On the other hand, numerical simulation can be performed for any system configuration and operating strategy, however, complex. However, this is time-consuming and expensive in computer time and requires a high level of operator expertise.

We shall illustrate the approach of numerical simulation by considering the simple solar system shown in Figure 40.18. Assuming a fully mixed storage tank, the instantaneous energy balance equation is

$$(mc_p)_s(dT_s/dt) = q_c - q_u - q_w \quad (40.33)$$

where

$q_c$  is the useful energy delivered by the solar collector (given by Equation 40.2.)

$q_w$  is the thermal loss from the storage tank (given by Equation 40.32)

$q_u$  is the useful heat transferred through the load heat exchanger, which can be determined as shown in the following text

The maximum hourly rate of energy transfer through the load heat exchanger is

$$q_{\max} = E_B(mc_p)_{\min}(T_s - T_{xi})\delta_L \quad (40.34)$$

where  $\delta_L$  is a control function whose value is either 1 or 0 depending upon whether there is a heat demand or not. Since  $q_{\max}$  can be greater than the amount of thermal energy  $q_L$  actually required by the load, the bypass arrangement can be conveniently modeled as

$$q_u = \min(q_{\max}, q_L) \quad (40.35)$$

where

$$q_L = (mc_p)_L(T_{Li} - T_{xi}) \quad (40.36)$$

for water heating and industrial process heat loads. Space heating and cooling loads can be conveniently determined by one of the several variants of the bin-type methods (ASHRAE 1985).

The amount of energy  $q_{\max}$  supplied by a topping-up type of auxiliary heater is

$$q_{\max} = q_L - q_u \quad (40.37)$$

Assuming  $T_{env} = T_a$ , Equation 40.33 can be expanded into

$$(Mc_p)_s \frac{dT_s}{dt} - A_c F_R [I_T \eta_0 - U_L(T_s - T_a)]^+ - (mc_p)_s(T_s - T_{xi})\delta_L - (UA)_s(T_s - T_a) \quad (40.38)$$

The presence of control functions and time dependence of  $I_T$  and  $T_a$  prevent a general analytical treatment, though, as mentioned earlier, specific cases can be handled. The numerical approach involves expressing this differential equation in finite difference form. After rearranging, one gets

$$T_{S,b} + \frac{\Delta t}{(Mc_p)_S} \{A_C F_R [I_T \eta_0 - U_L (T_{S,b} - T_a)]^+ - (mc_p)_S (T_{S,b} - T_{Xi}) \delta_L - (UA)_S (T_{S,b} - T_a)\} T_{S,f} \quad (40.39)$$

where  $T_{S,b}$  and  $T_{S,f}$  are the storage temperatures at the beginning and the end of the time step  $\Delta t$ . The time step is sufficiently small (say 1 h) that  $I_T$  and  $T_a$  can be assumed constant. This equation is repeatedly used over the time period in question (day, month, or year), and the total energy supplied by the collector or to the load can be estimated.

Such methods of simulation, referred as stepwise steady-state simulations, implicitly assume that the solar thermal system operates in a steady-state manner during one time step, at the end of which it undergoes an abrupt change in operating conditions as a result of changes in the forcing functions, and thereby attains a new steady-state operating level. Although in reality, the system performance varies smoothly over time and is consequently different from that outlined earlier, it has been found that, in most cases, taking time steps of the order of 1 h yields acceptable results of long-term performance.

The objective of solar-supplemented energy systems is to displace part of the conventional fuel consumption of the auxiliary heater. The index used to represent the contribution of the solar thermal system is the *solar fraction*, which is the fraction of the total energy required by the load that is supplied by the solar system. The solar fraction could be expressed over any time scale, with month and year being the most common. Two commonly used definitions of the monthly solar fraction are

1. Thermal solar fraction:

$$f_Y = \frac{Q_{UM}}{Q_{LM}} = 1 - \frac{Q_{aux,M}}{Q_{LM}} \quad (40.40)$$

where

$Q_{UM}$  is the monthly total thermal energy supplied by the solar system

$Q_{LM}$  is the monthly total thermal requirements of the load

$Q_{aux,M}$  is the monthly total auxiliary energy consumed

2. Energy solar fraction (i.e., thermal plus parasitic energy):

$$f'_M = \frac{Q'_{UM}}{Q'_{LM}} \quad (40.41)$$

where

$Q'_{UM}$  is  $Q_{UM}$  minus the parasitic energy consumed by the solar system

$Q'_{LM}$  is  $Q_{LM}$  plus the parasitic energy consumed by the load

### Example 40.5

Simulate the closed-loop solar thermal system shown in Figure 40.18 for each hour of a day assuming both collector and load heat exchangers to be absent (i.e.,  $E_A = E_B = 1$ ). Assume the following data as input for the simulation:  $A_C = 10 \text{ m}^2$ ,  $F_R U_L = 5.0 \text{ W/m}^2 \text{ }^\circ\text{C}$ ,  $F_R \eta_0 = 0.7$ ,  $(mc_p) = 2.0 \text{ MJ/}^\circ\text{C}$  and  $(UA)_S = 3 \text{ W/}^\circ\text{C}$ . Water is withdrawn to meet a load

from 9 a.m. to 7 p.m. (solar time) at a constant rate of 60 kg/h and is replenished from the mains at a temperature of 25°C. The storage temperature at the start (i.e., at 6 a.m.) is 40°C, and the environment temperature is equal to the ambient temperature. The temperature of the water entering the load should not exceed 55°C. The hourly values of the solar radiation on the plane of the collector are given in column 2 of Table 40.3 and the ambient temperature is assumed constant over the day and equal to 25°C. The variation of the optical efficiency with angle of incidence can be neglected.

The results of the simulation are given in Table 40.3. The following equations should permit the reader to verify for himself the results obtained. Simulating the system entails solving the following equations in the sequence given here:

*Column 4.* Useful energy delivered by the collector (Equation 20.2)

$$q_c = 10[0.7 I_T - 5(3600/10^6)T_{s,b} - 25]^+ \text{ (MJ/h)}$$

The term  $(3600/10^6)$  is introduced to convert  $\text{W/m}^2$  (the units in which  $I_T$  is expressed) into  $\text{MJ}/(\text{h m}^2)$ . Note that  $T_{s,b}$  is taken to be equal to  $T_{s,f}$  of the final hour.

*Column 5.* Thermal losses from the storage tank (Equation 40.32)

$$q_w = 3(3600/10^6)(T_{s,b} - 25) \text{ (MJ/h)}$$

*Column 6.* The maximum rate of energy that can be transferred from the load can be calculated from Equation 40.34

$$q_{\max} = 60(4190/10^6)(T_{s,b} - 25) \text{ (MJ/h)}$$

*Column 7.* The thermal energy required by the load (from Equation 40.36)

$$q_L = 60(4190/10^6)(55 - 25) = 7.54 \text{ MJ/h}$$

*Column 8.* The actual amount of heat withdrawn from storage (Equation 40.35)

$$q_w = \min[\text{column 6, column 7}]$$

18–19	0.00	45.23	0.00	0.25	5.85	7.54	5.85	1.69
Total	18.81	—	81.41	3.48	69.24	75.40	67.48	7.94

Column 9. The amount of energy supplied by the auxiliary heater (Equation 40.2.37)

$$q_{\text{aux}} = \text{column 7} - \text{column 8}$$

The final storage temperature  $T_{\text{S},f}$  is now calculated from Equation 40.39

$$T_{\text{S},f} = T_{\text{S},b} + [\text{column 4} - \text{column 8} - \text{column 5}]/2.0$$

From Table 40.3, we note that the solar collector efficiency over the entire day is  $[81.41/(18.81 \times 10)] = 0.43$ . The corresponding daily solar fraction  $= (67.48/75.40) = 0.895$ .

## 40.8 Solar System Sizing Methodology

Sizing of solar systems primarily involves determining the collector area and storage size that are most cost effective. Standalone and solar-supplemented systems have to be treated separately since the basic design problem is somewhat different. The interested reader can refer to Gordon (1987) for sizing standalone systems.

### 40.8.1 Solar-Supplemented Systems

#### 40.8.1.1 Production Functions

Because of the annual variation of incident solar radiation, it is not normally economical to size a solar subsystem such that it provides 100% of the heat demand. Most solar energy systems follow the *law of diminishing returns*. This implies that increasing the size of the solar collector subsystem results in a less than proportional increase in the annual fuel savings (or alternatively, in the annual solar fraction).

Any model has two types of variables: exogenous and endogenous. The *exogenous parameters* are also called the input variables, and these in turn may be of two kinds. *Variable exogenous parameters* are the collector area  $A_C$ , the collector performance parameters  $F_R \eta_n$  and  $F_R U_L$ , the collector tilt, the thermal storage capacity  $(mc_p)_S$ , the heat exchanger size, and the control strategies of the solar thermal system. On the other hand, the climatic data specified by radiation and the ambient temperature, as well as the end use thermal demand characteristics, are called *constrained exogenous parameters* because they are imposed externally and cannot be changed. The *endogenous parameters* are the output parameters whose values are to be determined, the annual solar fraction being one of the parameters most often sought.

Figure 40.26 illustrates the law of diminishing results. The annual solar fraction  $f_Y$  is seen to increase with collector area but at a decreasing rate and at a certain point will reach saturation. Variation of any of the other exogenous parameters also exhibits a similar trend. The technical relationship between  $f_Y$  and one or several variable exogenous parameters for a given location is called the *yearly production function*.

It is only for certain simple types of solar thermal systems that an analytical expression for the production can be deduced directly from theoretical considerations. The most common approach is to carry out computer simulations of the particular system (solar plus auxiliary) over the complete year for several combinations of values of the exogenous parameters. The production function can subsequently be determined by an empirical curve fit to these discrete sets of points.

**FIGURE 40.26**

A typical solar system production function (see Example 41.6).

**Example 40.6**

Kreider (1979) gives the following expression for the production function of an industrial solar water heater for a certain location:

$$f_Y = \frac{Q_{UY}}{Q_{LY}} = \left( 0.35 - \frac{F_R U_L}{100 F_R \eta_n} \right) \ln \left( 1 + \frac{20 F_R \eta_n A_C}{Q_{LY}} \right) \quad (40.42)$$

where

$Q_{UY}$  is the thermal energy delivered by the solar thermal system over the year in GJ/y

$Q_{LY}$  is the yearly thermal load demand, also in GJ/y

$F_R U_L$  is in  $W/(m^2 \text{ } ^\circ\text{C})$

Note that only certain solar system exogenous parameters figure explicitly in this expression, thereby implying that other exogenous parameters (for example, storage volume) have not been varied during the study. As an illustration, let us assume the following nominal values:  $Q_{LY} = 100$  GJ/year,  $F_R U_L = 2.0$   $W/(m^2 \text{ } ^\circ\text{C})$ , and  $F_R \eta_n = 0.7$ . For a 1% increase in collector area  $A_C$ , the corresponding percentage increase in  $Q_{UY}$  (called elasticity) can be determined:

$$\frac{dQ_{UY}}{Q_{UY}} = \frac{dA_C}{A_C} \left[ \left( \frac{Q_{LY}}{20 F_R \eta_n A_C} + 1 \right) \ln \left( 1 + \frac{20 F_R \eta_n A_C}{Q_{LY}} \right) \right]^{-1} \quad (40.43)$$

From this, we obtain the expression for *marginal productivity*

$$\frac{dQ_{UY}}{dA_C} = \frac{Q_{UY}}{A_C} \left[ \left( \frac{Q_{LY}}{20 F_R \eta_n A_C} + 1 \right) \ln \left( 1 + \frac{20 F_R \eta_n A_C}{Q_{LY}} \right) \right]^{-1} \quad (40.44)$$

Numerical values can be obtained from the preceding expression. Though  $Q_{UY}$  increases with  $A_C$ , the marginal productivity of  $Q_{UY}$  goes on decreasing with increasing  $A_C$ , thus illustrating the law of diminishing returns. A qualitative explanation of this phenomenon is that as  $A_C$  increases, the mean operating temperature level of the collector increases, thus leading to decreasing solar collection rates. Figure 40.26 illustrates the variation of  $f_Y$  with  $A_C$  as given by Equation 40.42 when the preceding numerical values are used.

The objective of the sizing study in its widest perspective is to determine, for a given specific thermal end use, the size and configuration of the solar subsystem that results in the most economical operation of the entire system. This economical optimum can be determined using the production function along with an appropriate economic analysis. Several authors—for example, Duffie and Beckman (1980) or Rabl (1985)—have presented fairly rigorous methodologies of economic analysis, but a simple approach is adequate to illustrate the concepts and for preliminary system sizing.

#### 40.8.1.2 Simplified Economic Analysis

It is widely recognized that *discounted cash flow analysis* is most appropriate for applications such as sizing an energy system. This analysis takes into account both the initial cost incurred during the installation of the system and the annual running costs over its entire life span.

The economic objective function for optimal system selection can be expressed in terms of either the energy cost incurred or the energy savings. These two approaches are basically similar and differ in the sense that the objective function of the former has to be minimized while that of the latter has to be maximized. In our analysis, we shall consider the latter approach, which can further be subdivided into the following two methods:

1. Present worth or life cycle savings, wherein all running costs are discounted to the beginning of the first year of operation of the system.
2. Annualized life cycle savings, wherein the initial expenditure incurred at the start as well as the running costs over the life of the installation are expressed as a yearly mean value.

---

## 40.9 Solar System Design Methods

### 40.9.1 Classification

Design methods may be separated into three generic classes. The *simple* category, usually associated with the prefeasibility study phase involves quick manual calculations of solar collector/system performance and rule-of-thumb engineering estimates. For example, the generalized yearly correlations proposed by Rabl (1981) and described in Section 40.2 could be conveniently used for year-round, more or less constant loads. The approach is directly valid for open-loop solar systems, while it could also be used for closed-loop systems if an *average* collector inlet temperature could be determined. A simple manner of

selecting this temperature  $\bar{T}_m$  for domestic closed-loop multipass systems is to assume the following empirical relation:

$$\bar{T}_m - T_{\text{mains}}/3 + (2/3)T_{\text{set}} \quad (40.45)$$

where

$T_{\text{mains}}$  is the average annual supply temperature

$T_{\text{set}}$  is the required hot-water temperature (about 60°C–80°C in most cases)

These manual methods often use general guidelines, graphs, and/or tables for sizing and performance evaluation. The designer should have a certain amount of knowledge and experience in solar system design in order to make pertinent assumptions and simplifications regarding the operation of the particular system.

*Mid-level* design methods are resorted to during the feasibility phase of a project. The main focus of this chapter has been toward this level, and a few of these design methods will be presented in this section. A personal computer is best suited to these design methods because they could be conveniently programmed to suit the designer's tastes and purpose (spreadsheet programs, or better still one of the numerous equation-solver software packages, are most convenient). Alternatively, commercially available software packages such as *f-chart* (Beckman et al. 1977) could also be used for certain specific system configurations.

*Detailed* design methods involve performing hourly simulations of the solar system over the entire year from which accurate optimization of solar collector and other equipment can be performed. Several simulation programs for active solar energy systems are available, TRNSYS (Klein et al. 1975, 1979) developed at the University of Wisconsin-Madison being perhaps the best known. This public-domain software has technical support and is being constantly upgraded. TRNSYS contains simulation models of numerous subsystem components (solar radiation, solar equipment, loads, mechanical equipment, controls, etc.) that comprise a solar energy system. A user can conveniently hook up components representative of a particular solar system to be analyzed and then simulate that system's performance at a level of detail that the user selects. Thus TRNSYS provides the design with large flexibility, diversity, and convenience of usage.

As pointed out by Rabl (1985), the detailed computer simulations approach, though a valuable tool, has several problems. Judgment is needed both in the selection of the input and in the evaluation of the output. The very flexibility of big simulation programs has drawbacks. So many variables must be specified by the user that errors in interpretation or specification are common. Also, learning how to use the program is a time-consuming task. Because of the numerous system variables to be optimized, the program may have to be run for numerous sets of combinations, which adds to expense and time. The inexperienced user can be easily misled by the second-order details while missing first-order effects. For example, uncertainties in load, solar radiation, and economic variables are usually very large, and long-term performance simulation results are only accurate to within a certain degree. Nevertheless, detailed simulation programs, if properly used by experienced designers, can provide valuable information on system design and optimization aspects at the final stages of a project design.

There are basically three types of mid-level design approaches: the empirical correlation approach, the analytical approach, and the one-day repetitive methods (described fully in Reddy 1987). We shall illustrate their use by means of specific applications.

### 40.9.2 Active Space Heating

The solar system configuration for this particular application has become more or less standardized. For example, for a liquid system, one would use the system shown in Figure 40.27. One of the most widely used design methods is the  $f$ -chart method (Beckman et al. 1977; Duffie and Beckman 1980), which is applicable for standardized liquid and air heating systems as well as for standardized domestic hot-water systems. The  $f$ -chart method basically involves using a simple algebraic correlation that has been deduced from numerous TRNSYS simulation runs of these standard solar systems subject to a wide range of climates and solar system parameters (see Figure 40.28). Correlations were developed between monthly solar fractions and two easily calculated dimensionless variables  $X$  and  $Y$ , where

$$X = \frac{(A_C F'_R U_L (T_{\text{Ref}} - \bar{T}_a) \Delta t)}{Q_{\text{LM}}} \quad (40.46)$$

$$Y = A_C F'_R \bar{\eta}_0 \bar{H}_T N / Q_{\text{LM}} \quad (40.47)$$

where

$A_C$  collector area ( $\text{m}^2$ )

$F'_R$  collector-heat exchanger heat removal factor (given by Equation 40.29)

$U_L$  collector overall loss coefficient ( $\text{W}/(\text{m}^2 \text{ } ^\circ\text{C})$ )

$\Delta t$  total number of seconds in the month =  $3600 \times 24 \times N = 86,400 \times N$

$\bar{T}_a$  monthly average ambient temperature ( $^\circ\text{C}$ )

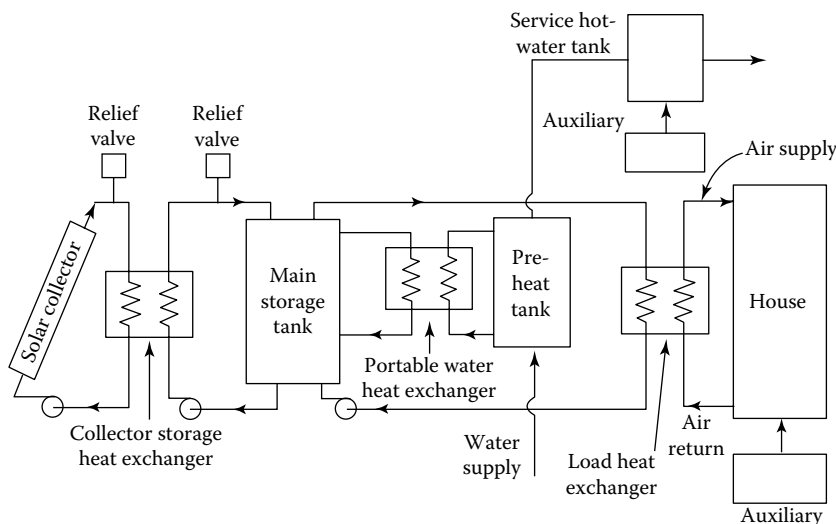

$T_{\text{Ref}}$  an empirically derived reference temperature, taken as  $100^\circ\text{C}$

$Q_{\text{LM}}$  monthly total heating load for space heating and/or hot water (J)

$\bar{H}_T$  monthly average daily radiation incident on the collector surface per unit area ( $\text{J}/\text{m}^2$ )

$N$  number of days in the month

$\bar{\eta}_0$  monthly average collector optical efficiency

**FIGURE 40.27**

Schematic of the standard space heating liquid system configuration for the  $f$ -chart method. (From Duffie, J.A. and Beckman, W.A., *Solar Engineering of Thermal Processes*, Wiley Interscience, New York, 1980.)

**FIGURE 40.28**

The  $f$ -chart correlation for liquid system configuration. (From Duffie, J.A. and Beckman, W.A., *Solar Engineering of Thermal Processes*, Wiley Interscience, New York, 1980.)

The dimensionless variable  $X$  is the ratio of reference collector losses over the entire month to the monthly total heat load; the variable  $Y$  is the ratio of the monthly total solar energy absorbed by the collectors to the monthly total heat load. It will be noted that the collector area and its performance parameters are the predominant exogenous variables that appear in these expressions. For changes in secondary exogenous parameters, the following corrective terms  $X_C$  and  $Y_C$  should be applied for liquid systems:

1. For changes in storage capacity:

$$\frac{X_C}{X} = \left( \frac{\text{actual storage capacity}}{\text{standard storage capacity}} \right)^{-0.25} \quad (40.48)$$

where the standard storage volume is 75 L/m<sup>2</sup> of collector area.

2. For changes in heat exchanger size:

$$\frac{Y_C}{Y} = \frac{0.39 + 0.65 \exp[-(0.139(UA)_B]}{(E_L(mc_p)_{\min})] \quad (40.49)$$

The monthly solar fraction for liquid space heating can then be determined from the following empirical correlation:

$$f_M = 1.029Y - 0.065X - 0.245Y^2 + 0.0018X^2 + 0.0215Y^3 \quad (40.50)$$

subject to the conditions that  $0 \leq X \leq 15$  and  $0 \leq Y \leq 3$ . This empirical correlation is shown graphically in Figure 40.28.

A similar correlation has also been proposed for space heating systems using air collectors and pebble-bed storage. The procedure for exploiting the preceding empirical correlations is as follows. For a predetermined location, specified by its 12 monthly radiation and ambient temperature values, Equation 40.50 is repeatedly used for each month of the year for a particular set of variable exogenous parameters. The monthly solar fraction  $f_M$  and thence the annual thermal energy delivered by the solar thermal system are easily deduced. Subsequently, the

entire procedure is repeated for different values and combinations of variable exogenous parameters. Finally, an economic analysis is performed to determine optimal sizes of various solar system components. Care must be exercised that the exogenous parameters considered are not outside the range of validity of the  $f$ -chart empirical correlations.

#### Example 40.7

(Adapted from Duffie and Beckman 1980). A solar heating system is to be designed for Madison, Wisconsin (latitude  $43^\circ\text{N}$ ) using one-cover collectors with  $F_R\eta_n = 0.74$  and  $F_RU_L = 4\text{W}/(\text{m}^2\text{ }^\circ\text{C})$ . The collector faces south with a slope of  $60^\circ$  from the horizontal. The average daily radiation on the tilted surface in January is  $12.9\text{ MJ}/\text{m}^2$ , and the average ambient temperature is  $-7^\circ\text{C}$ . The heat load is  $36\text{ GJ}$  for space heating and hot water. The collector-heat exchanger correction factor is  $0.97$  and the ratio of monthly average to normal incidence optical efficiency is  $0.96$ . Calculate the energy delivered by the solar system in January if  $50\text{ m}^2$  of collector area is to be used.

From Equations 40.46 and 40.47, with  $A_C = 50\text{ m}^2$ ,

$$X = 4.0 \times 0.97[100 - (-7)]31 \times 86,400 \times 50/(36 \times 10^9) = 1.54$$

$$Y = 0.74 \times 0.97 \times 0.96 \times 12.9 \times 10^6 \times 31 \times 50/(36 \times 10^9) = 0.38$$

From Equation 40.50, the solar fraction for January is  $f_M = 0.26$ . Thus the useful energy delivered by the solar system =  $0.26 \times 36 = 9.4\text{ GJ}$ .

In an effort to reduce the tediousness involved in having to perform 12 monthly calculations, two analogous approaches that enable the annual solar fraction to be determined directly have been developed by Barley and Winn (1978) and Lameiro and Bendt (1978). These involve the computation of a few site-specific empirical coefficients, thereby rendering the approach less general. For example, the *relative-area* method suggested by Barley and Winn enable the designer to directly calculate the annual solar fraction of the corresponding system using four site-specific empirical coefficients. The approach involves curve fits to simulation results of the  $f$ -chart method for specific locations in order to deduce a correlation such as:

$$f = c_1 + c_2 \ln(A/A_{0.5}) \quad (40.51)$$

where

$c_1$  and  $c_2$  are location-specific parameters that are tabulated for several United States locations

$A_{0.5}$  is the collector area corresponding to an annual solar fraction of  $0.5$  given by

$$A_{0.5} = \frac{A_s(UA)}{(F'_R\eta_0 - F'_R U_L Z)} \quad (40.52)$$

where

$A_s$  and  $Z$  are two more location specific parameters

$UA$  is the overall heat loss coefficient of the building

$F'_R\eta_0$  and  $F'_R U_L$  are the corresponding solar collector performance parameters corrected for the effect of the collector-heat exchanger

Barley and Winn also proposed a simplified economic life-cycle analysis whereby the optimal collector area could be determined directly. Another well-known approach is the *Solar Load Ratio* (SLR) method for sizing residential space heating systems (Hunn 1980).

### 40.9.3 Domestic Water Heating

The  $f$ -chart correlation (Equation 40.50) can also be used to predict the monthly solar fraction for domestic hot-water systems represented by Figure 40.21 provided the water mains temperature  $T_{\text{mains}}$  is between 5°C and 20°C and the minimum acceptable hot-water temperature drawn from the storage for end use (called the set water temperature  $T_w$ ) is between 50°C and 70°C. Further, the dimensionless parameter  $X$  must be corrected by the following ratio

$$\frac{X_w}{X} = \frac{(11.6 + 1.8T_w + 3.86T_{\text{mains}} - 2.32\bar{T}_a)}{(100 - \bar{T}_a)} \quad (40.53)$$

In case the domestic hot-water load is much smaller than the space heat load, it is recommended that Equation 40.50 be used without the above correction.

### 40.9.4 Industrial Process Heat

As discussed in Section 40.4.2.1, two types of solar systems for industrial process heat are currently used: the closed-loop multipass systems (with an added distinction that the auxiliary heater may be placed either in series or in parallel (see Figures 40.18 and 40.19) and the open-loop singlepass system. How such systems can be designed will be described next.

#### 40.9.4.1 Closed-Loop Multipass Systems

##### 40.9.4.1.1 Auxiliary Heater in Parallel

The Phibar- $f$  chart method (Klein and Beckman 1979; Duffie and Beckman 1980; Reddy 1987) is a generalization of the  $f$ -chart method in the sense that no restrictions need be imposed on the temperature limits of the heated fluid in the solar thermal system. However, three basic criteria for the thermal load have to be satisfied for the Phibar- $f$  chart method to be applicable: (1) the thermal load must be constant and uniform over each day and for at least a month, (2) the thermal energy supplied to the load must be above a minimum temperature that completely specifies the temperature level of operation of the load, and (3) either there is no conversion efficiency in the load (as in the case of hot water usage) or the efficiency of conversion is constant (either because the load temperature level is constant or because the conversion efficiency is independent of the load temperature level). The approach is strictly applicable to solar systems with the auxiliary heater in parallel (Figure 40.19).

A typical application for the Phibar- $f$  chart method is absorption air-conditioning. The hot water inlet temperature from the collectors to the generator must be above a minimum temperature level (say, 80°C) for the system to use solar heat. If the solar fluid temperature is less (even by a small amount), the entire energy to heat up the water to 80°C is supplied by the auxiliary system.

As a result of continuous interaction between storage and collector in a closed-loop system, the variation of the storage temperature and hence the fluid inlet temperature to the collectors) over the day and over the month is undetermined. The Phibar- $f$  chart method implicitly takes this into account and reduces these temperature fluctuations down to a monthly mean equivalent storage temperature  $\bar{T}_s$ . The determination of this temperature in conjunction with the daily utilizability approach is the basis of the design approach.

**FIGURE 40.29**

The Phibar- $f$  chart correlation for a storage capacity of 350 kJ/m<sup>2</sup> and for a 12 h/day thermal load. (From Duffie, J.A. and Beckman, W.A., *Solar Engineering of Thermal Processes*, Wiley Interscience, New York, 1980.)

The basic empirical correlation of the Phibar- $f$  chart method, shown graphically in Figure 40.29, is as follows:

$$f_M = Y\bar{\phi} - a[\exp(bf_M) - 1][1 - \exp(cX)] \quad (40.54)$$

with  $0 < X < 20$  and  $0 < Y < 1.6$ , and  $\bar{\phi}$  is the Klein daily utilizability fraction described in Section 40.3.3 and given by Equation 40.24.  $Y$  is given by Equation 40.47, and  $X$  is now slightly different from Equation 40.46 and is defined as:

$$X = \frac{A_c F_R U_L \Delta t (100^\circ \text{C})}{Q_{LM}} \quad (40.55)$$

The values of the constants  $a$ ,  $b$ , and  $c$  are given by the following:

1. For an end use load operating between 6 a.m. and 6 p.m. every day of the month,

$$a = 0.015[(mc_p)_s / 350 \text{ kJ}/(\text{m}^2 \text{ }^\circ\text{C})]^{-0.76} \text{ for } 175 \leq [(mc_p)_s / A_c] \leq 1400 \text{ kJ}/(\text{m}^2 \text{ }^\circ\text{C}),$$

$$b = 3.85 \quad \text{and} \quad c = -0.15 \quad (40.56)$$

2. For an end use load operating 24 h/day over the entire month,

$$a = 0.043 \text{ only for } [(mc_p)_s / A_c] = 350 \text{ kJ}/(\text{m}^2 \text{ }^\circ\text{C}), \quad b = 2.81, \quad \text{and} \quad c = -0.18 \quad (40.57)$$

It will be noted that  $(Y\bar{\phi})$  denotes the maximum solar fraction that would have resulted had  $T_{Ci}$ , the inlet temperature to the collector, been equal to  $T_{Li}$  throughout the month. The term in Equation 40.54 that is subtracted from  $(Y\bar{\phi})$  represents the decrease in the solar fraction as a result of  $T_{Ci} > T_{Li}$ . The solar fraction computed from Equation 40.54 has to be corrected for the effect of thermal losses from the storage as well as the presence of the load-heat exchanger, both of which will decrease the solar fraction. For complete details, refer to Duffie and Beckman (1980) or Reddy (1987). Note that Equation 40.54 needs to be solved for  $f_m$  in an iterative manner.

#### 40.9.4.1.2 Auxiliary Heater in Series

The Phibar- $f$  chart method has also been modified to include solar systems with the auxiliary heater in series as shown in Figure 40.18. This configuration leads to higher solar fractions but retrofit to existing systems may be more costly.

In this case, the empirical correlation given by Equation 40.54 has been modified by Braun et al. (1983) as follows:

$$f_M = Y\bar{\phi} - a[\exp(bf_M) - 1][1 - \exp(cX)]\exp(-1.959Z) \quad (40.58)$$

with  $Z = Q_{lm}/(C_l \times 100^\circ\text{C})$  and (1) when there is no load-heat exchanger,  $C_L$  is the monthly total load heat capacitance, which is the product of the monthly total mass of water used and the specific heat capacity of water, and (2) when there is a load-heat exchanger present  $C_L = E_L \times C_{min}$ , where  $E_L$  is the effectiveness of the load-heat exchanger and  $C_{min}$  is the monthly total heat capacitance, which is the lesser of the two fluids rates across the load heat exchanger.

The modified Phibar- $f$  chart is similar to the original method in respect to load uniformity on a day-to-day basis over the month and in assuming no conversion efficiency. The interested may refer to Braun et al. (1983) or Reddy (1987) for complete details.

#### 40.9.4.2 Open-Loop Single-Pass Systems

The advantages offered by open-loop single-pass systems over closed-loop multipass systems for meeting constant loads has been described in Section 40.4.2. Because industrial loads operate during the entire sun-up hours or even for 24 h daily, the simplest solar thermal system is one with no heat storage (Figure 40.20). A sizable portion (between 25% and 70%) of the daytime thermal load can be supplied by such systems and consequently, the sizing of such systems will be described below (Gordon and Rabl 1982). We shall assume that  $T_{Li}$  and  $T_{Xi}$  are constant for all hours during system operation. Because no storage is provided, excess solar energy collection (whenever  $T_{Ci} > T_{Li}$ ) will have to be dumped out.

The maximum collector area  $\hat{A}_C$  for which energy dumping does not occur at any time of the year can be found from the following instantaneous heat balance equation:

$$P_L = \hat{A}_C \hat{F}_R [I_{max} \eta_n - U_L (T_{Ci} - T_a)] \quad (40.59)$$

where  $P_L$ , the instantaneous thermal heat demand of the load (say, in kW) is given by

$$P_L = m_L c_p (T_{Li} - T_{Xi}) \quad (40.60)$$

and  $F_R$  is the heat removal factor of the collector field when its surface area is  $\hat{A}_C$ . Since  $\hat{A}_C$  is as yet unknown, the value of  $\hat{F}_R$  is also undetermined. (Note that though the *total* fluid flow rate is known, the flow rate per unit collector area is not known.) Recall that the plate efficiency factor  $F'$  for liquid collectors can be assumed constant and independent of fluid flow rate per unit collector area. Equation 40.59 can be expressed in terms of critical radiation level  $I_C$ :

$$P_L = \hat{A}_C \hat{F}_R \eta_n (I_{max} - I_C) \quad (40.61a)$$

or

$$\hat{A}_C \hat{F}_R \eta_n = \frac{P_L}{(I_{\max} - I_C)} \quad (40.61b)$$

Substituting Equation 40.3 in lieu of  $F_R$  and rearranging yields

$$\hat{A}_C = -(m_L c_p / F' U_L) \ln[1 - P_L U_L / (\eta_n (I_{\max} - I_C) m_L c_p)] \quad (40.62)$$

If the actual collector area  $A_C$  exceeds this value, dumping will occur as soon as the radiation intensity reaches a value  $I_D$ , whose value is determined from the following heat balance:

$$P_L = A_C F_R \eta_n (I_D - I_C) \quad (40.63a)$$

Hence

$$I_D = \frac{I_C + P_L}{(A_C F_R \eta_n)} \quad (40.63b)$$

Note that the value of  $I_D$  decreases with increasing collector area  $A_C$ , thereby indicating that increasing amounts of solar energy will have to be dumped out.

Since the solar thermal system is operational during the entire sunshine hours of the year, the yearly total energy collected can be directly determined by the Rabl correlation given by Equation 40.26. Similarly, the yearly total solar energy collected by the solar system which has got to be dumped out is

$$Q_{DY} = A_C F_R \eta_n (\tilde{a} + \tilde{b} I_D + \tilde{c} I_D^2) \quad (40.64)$$

The yearly total solar energy delivered to the load is

$$\begin{aligned} Q_{UY} &= Q_{CY} - Q_{DY} \\ &= A_C F_R \eta_n [\tilde{b} (I_C - I_D) + \tilde{c} (I_C^2 - I_D^2)] \end{aligned} \quad (40.65)$$

$$\begin{aligned} &= -(\tilde{b} + 2\tilde{c} I_C) P_L - \tilde{c} P_L^2 / (A_C F_R \eta_n) \\ &= -(\tilde{b} + 2\tilde{c} I_C) P_L - \tilde{c} P_L^2 / (A_C F_R \eta_n) \end{aligned} \quad (40.66)$$

Replacing the value of  $F_R$  given by Equation 40.3, the annual production function in terms of  $A_C$  is

$$Q_{UY} = -(\tilde{b} + 2\tilde{c} I_C) P_L - \frac{\tilde{c} P_L^2}{\left( \frac{F' \eta_n}{F' U_L} \right) (m_L c_p) \left[ 1 - \exp \left( -\frac{F' U_L A_C}{m_L c_p} \right) \right]} \quad (40.67)$$

subject to the condition that  $A_C > \hat{A}_C$ . If the thermal load is not needed during all days of the year due to holidays or maintenance shutdown, the production function can be reduced proportionally. This is illustrated in the following example.

**Example 40.8**

Obtain the annual production function of an open-loop solar thermal system without storage that is to be set up in Boston, Massachusetts according to the following load specifications: industrial hot water load for 12 h a day (6 a.m. to 6 p.m.) and during 290 days a year, mass flow rate  $m_L = 0.25$  kg/s, required inlet temperature  $T_{Li} = 60^\circ\text{C}$ . Contaminants are picked up in the load, so that all used water is to be rejected and fresh water at ambient temperature is taken in. Flat-plate collectors with tilt equal to latitude with the following parameters are used  $F'\eta_n = 0.75$  and  $F'U_L = 5.5$  W/(m<sup>2</sup> °C). The latitude of Boston is  $42.36^\circ\text{N} = 0.739$  rad. The yearly  $\tilde{K} = 0.45$  and  $\tilde{T}_a = 10.9^\circ\text{C}$ . Use the following Gordon and Rabl (1982) correlation:

$$\begin{aligned} Q_{CY}/A_C F_R \eta_n = & [(5.215 + 6.973 I_{bn}) + (-5.412 + 4.293 I_{bn})L + (1.403 - 0.899 I_{bn})L^2] \\ & + [(-18.596 - 5.931 I_{bn}) + (15.468 + 18.845 I_{bn})L + (-0.164 - 35.510 I_{bn})L^2] I_C \\ & + [(-14.601 - 3.570 I_{bn}) + (13.675 - 15.549 I_{bn})L + (-1.620 + 30.564 I_{bn})L^2] I_C^2 \end{aligned}$$

From Equation 40.27,  $\tilde{I}_{bn} = 1.37 \times 0.45 - 0.34 = 0.276$  kW/m<sup>2</sup>. The critical radiation level  $I_C = 0$ , since  $T_{Ci} = T_a$ . Consequently, Equation 40.26, using the above expression reduces to

$$\begin{aligned} Q_{CY}/(A_C F_R \eta_n) &= 5.215 + 6.973 \times 0.276 + (-5.412 + 4.293 \times 0.276)0.739 \\ &\quad + (1.403 - 0.899 \times 0.276)0.739^2 \\ &= 4.646 \text{ GJ/(m}^2\text{y)}. \end{aligned}$$

The expression for the dumped out energy is found from Equation 40.64 and the previous expression by replacing  $I_C$  by  $I_D$ :

$$\begin{aligned} Q_{CY,dump}/(A_C F_R \eta_n) &= 4.646 + [(-18.596 - 5.931 \times 0.276) + (15.468 + 18.845 \times 0.276)0.739 \\ &\quad + (-0.164 - 35.510 \times 0.276)0.739^2] I_D + [(14.601 - 3.57 \times 0.276) \\ &\quad + (-13.675 - 15.549 \times 0.276)0.739 + (1.620 + 30.564 \times 0.276)0.739^2] I_D^2 \\ &= 4.646 - 10.40 I_D + 5.83 I_D^2 \text{ (GJ/m}^2\text{y)} \end{aligned}$$

The thermal energy demand  $P_L = 0.25 \times 4.19(60 - 10.9) = 51.43$  kW.

The annual production function is

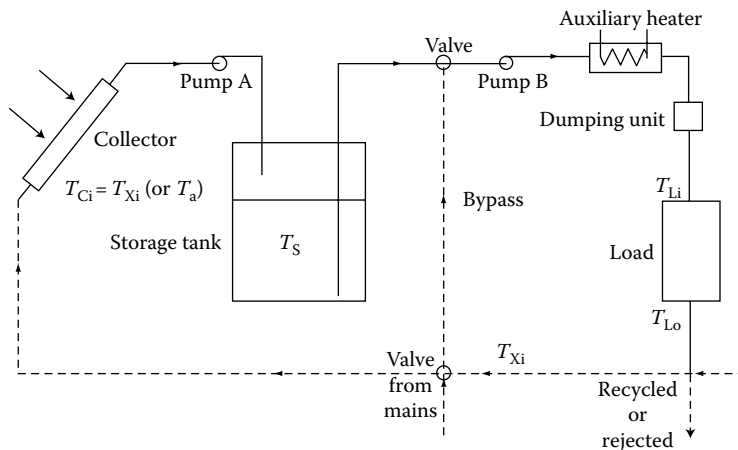

$$\begin{aligned} Q_{UY}(365/290) &= -(-10.40 + 2\tilde{c} \times 0)51.43 - (5.83 \times 51.43^2)/\{(0.75/5.5)(0.25 \times 4.19) \\ &\quad \times [1 - \exp[-(5.5 \times A_C)/(0.25 \times 4190)]]\} \end{aligned}$$

or

$$Q_{UY} = 424.96 - 85.78/[1 - \exp(-A_C/190.45)] \text{ (GJ/y)}$$

Complete details as well as how this approach can be extended to solar systems with storage (see [Figure 40.30](#)) can be found in Rabl (1985) or Reddy (1987).

## 40.10 Design Recommendations and Costs

### 40.10.1 Design Recommendations

As mentioned earlier, design methods reduce computational effort compared to detailed computer simulations. Even with this decrease, the problem of optimal system design and sizing remains formidable because of

- The presence of several solar thermal system configuration alternatives.
- The determination of optimal component sizes for a given system.
- The presence of certain technical and economic constraints.
- The choice of proper climatic, technical, and economic input parameters.
- The need to perform sensitivity analysis of both technical and economic parameters.

For most practical design work, a judicious mix of theoretical expertise and practical acumen is essential. Proper focus right from the start on the important input variables as well as the restriction of the normal range of variation would lead to a great decrease in design time and effort several examples of successful case studies and system design recommendations are described in the published literature (see, for example, Kutcher et al. 1982).

### 40.10.2 Solar System Costs

How the individual components of the solar system contribute to the total cost can be gauged from Table 40.4. We note that collectors constitute the major fraction (from 15% to 30%), thus suggesting that collectors should be selected and sized with great care. Piping costs are next with other collector-related costs like installation and support structure being also important.

**TABLE 40.4**

Percentage of Total System Cost by Component

Cost Component	Percentage Range
Collectors	15–30
Collector installation	5–10
Collector support structure	5–20 <sup>a</sup>
Storage tanks	5–7
Piping and specialties	10–30
Pumps	1–3
Heat exchangers	0–5 <sup>b</sup>
Chiller	5–10
Miscellaneous	2–10
Instrumentation	1–3
Insulation	2–8
Control subsystem	4–9
Electrical	2–6

## 41.1 Introduction

Passive systems are defined, quite generally, as systems in which the thermal energy flow is by natural means: by conduction, radiation, and natural convection. A *passive heating system* is one in which the sun's radiant energy is converted to heat upon absorption by the building. The absorbed heat can be transferred to thermal storage by natural means or used to directly heat the building. *Passive cooling systems* use natural energy flows to transfer heat to the environmental sinks: the ground, air, and sky.

If one of the major heat transfer paths employs a pump or fan to force the flow of a heat transfer fluid, then the system is referred to as having an active component or subsystem. Hybrid systems—either for heating or for cooling—are ones in which there are both passive and active energy flows. The use of the sun's radiant energy for the natural illumination of a building's interior spaces is called *daylighting*. Daylighting design approaches use both solar beam radiation (referred to as *sunlight*) and the diffuse radiation scattered by the atmosphere (referred to as *skylight*) as sources for interior lighting, with historical design emphasis on utilizing skylight.

### 41.1.1 Distinction between a Passive System and Energy Conservation

A distinction is made between the energy conservation techniques and passive solar measures. Energy conservation features are designed to reduce the heating and cooling energy required to thermally condition a building: the use of insulation to reduce either heating or cooling loads, and the use of window shading or window placement to reduce solar gains, reducing summer cooling loads. Passive features are designed to increase the use of solar energy to meet heating and lighting loads, plus the use of ambient *coolth* for cooling. For example, window placement to enhance solar gains to meet winter heating loads and/or to provide daylighting is passive solar use, and the use of a thermal chimney to draw air through the building to provide cooling is also a passive cooling feature.

### 41.1.2 Key Elements of Economic Consideration

The distinction between passive systems, active systems, or energy conservation is not critical for economic calculations, as they are the same in all cases: a trade-off between the life cycle cost of the energy saved (performance) and the life cycle cost of the initial investment, operating, and maintenance costs (cost).

#### 41.1.2.1 Performance: Net Energy Savings

The key performance parameter to be determined is the net annual energy saved by the installation of the passive system. The basis for calculating the economics of any solar energy system is to compare it against a *normal* building; thus, the actual difference in the annual cost of fuel is the difference in auxiliary energy that would be used with and without solar. Therefore, the energy saved rather than energy delivered, energy collected, useful energy, or some other energy measure, must be determined.

#### 41.1.2.2 Cost: Over and above “Normal” Construction

The other significant part of the economic trade-off involves determining the difference between the cost of construction of the passive building and of the *normal* building against which it is to be compared. The convention, adopted from the economics used for active solar systems, is to define a *solar add-on cost*. Again, this may be a difficult definition in the case of passive designs because the building can be significantly altered compared to typical construction since, in many cases, it is not just a one-to-one replacement of a wall with a different wall, but it is more complex and involves assumptions and simulations concerning the *normal* building.

#### 41.1.2.3 General System Application Status and Costs

Almost 500,000 buildings in the United States were constructed or retrofitted with passive features in the 20 years after 1980. Passive heating applications are primarily in single-family dwellings and secondarily in small commercial buildings. Daylighting features that reduce lighting loads and the associated cooling loads are usually more appropriate for large office buildings.

A typical passive heating design in a favorable climate might supply up to one-third of a home's original load at a cost of \$5–\$10 per million Btu net energy saved. An appropriately designed daylighting system can supply lighting at a cost of 2.5¢–5¢ per kWh (Larson et al. 1992a–c).

---

## 41.2 Solar Thermosyphon Water Heating

Solar hot water heating systems are composed of a collector and a storage tank. When the flow between the collector and tank is by natural circulation, these passive solar hot water systems are referred to as *thermosyphon systems*. This ability of thermosyphon systems to heat water without an externally powered pump has spurred its use in regions where both power is unavailable and power is very expensive.

### 41.2.1 Thermosyphon Concept

The natural tendency of a less dense fluid to rise above a more dense fluid can be used in a simple solar water heater to cause fluid motion through a collector. The density difference is created within the solar collector where heat is added to increase the temperature and decrease the density of the liquid. This collection concept is called a *thermosyphon*, and Figure 41.1 schematically illustrates the major components of such a system.

**FIGURE 41.1**

Schematic diagram of thermosyphon loop used in a natural circulation, service water heating system. The flow pressure drop in the fluid loop must equal the buoyant force pressure  $\left[ \int_0^L g\rho(x)dx - \rho_{\text{stor}}gL \right]$ , where  $\rho(x)$  is the local collector fluid density and  $\rho_{\text{stor}}$  is the tank fluid density, assumed uniform.

The flow pressure drop in the fluid loop ( $\Delta P_{\text{FLOW}}$ ) must equal the buoyant force pressure difference ( $\Delta P_{\text{BUOYANT}}$ ) caused by the differing densities in the *hot* and *cold* legs of the fluid loop:

$$\begin{aligned} \Delta P_{\text{FLOW}} &= \Delta P_{\text{BUOYANT}} \\ &= \rho_{\text{stor}}gH - \left[ \int_0^L \rho(x)gdx + \rho_{\text{out}}g(H-L) \right], \end{aligned} \quad (41.1)$$

where

$H$  is the height of the *legs*

$L$  is the height of the collector (see Figure 41.1)

$\rho(x)$  is the local collector fluid density

$\rho_{\text{stor}}$  is the tank fluid density (assumed to be uniform)

$\rho_{\text{out}}$  is the collector outlet fluid density (assumed to be uniform)

The flow pressure term,  $\Delta P_{\text{FLOW}}$ , is related to the flow loop system headloss that is in turn directly connected to friction and fitting losses and the loop flow rate:

$$\Delta P_{\text{FLOW}} = \oint_{\text{LOOP}} \rho d(h_L), \quad (41.2)$$

where

$h_L = KV^2$ , with  $K$  being the sum of the component loss *velocity* factors (see any fluid mechanics text)

$V$  is the flow velocity

### 41.2.2 Thermo-Fluid System Design Considerations

Because the driving force in a thermosyphon system is only a small density difference and not a pump, larger than normal plumbing fixtures must be used to reduce pipe friction losses. In general, one pipe size larger than that would be used with a pump system is satisfactory. Under no conditions should piping smaller than 1/2 in. (12 mm) national pipe thread (NPT) be used. Most commercial thermosyphons use 1 in. (25 mm) NPT pipe. The flow rate through a thermosyphon system is about 1 gal/ft.<sup>2</sup> h (40 L/m<sup>2</sup> h) in bright sun, based on collector area.

Because the hot water system loads vary little during a year, the best angle to tilt the collector is that equal to the local latitude. The temperature difference between the collector inlet water and the collector outlet water is usually 15°F–20°F (8°C–11°C) during the middle of a sunny day (Close 1962). After sunset, a thermosyphon system can reverse its flow direction and lose heat to the environment during the night. To avoid reverse flow, the top header of the absorber should be at least 1 ft. (30 cm) below the cold leg fitting on the storage tank, as shown.

To provide heat during long cloudy periods, an electrical immersion heater can be used as a backup for the solar system. The immersion heater is located near the top of the tank to enhance stratification so that the heated fluid is at the required delivery temperature at the delivery point. Tank stratification is desirable in a thermosyphon to maintain flow rates as high as possible. Insulation must be applied over the entire tank surface to control heat loss. Figure 41.2 illustrates two common thermosyphon system designs.

**FIGURE 41.2**

Passive solar water heaters: (a) compact model using combined collector and storage, (b) section view of the compact model, and (c) tank and collector assembly.

Several features inherent in the thermosyphon design limit its utility. If it is to be operated in a freezing climate, a nonfreezing fluid must be used, which in turn requires a heat exchanger between the collector and potable water storage. (If potable water is not required, the collector can be drained during cold periods instead.) Heat exchangers of either the shell-and-tube type or the immersion-coil type require higher flow rates for efficient operation than that a thermosyphon can provide. Therefore, the thermosyphon is generally limited to nonfreezing climates. A further restriction on thermosyphon use is the requirement for an elevated tank. In many cases, structural or architectural constraints prohibit raised-tank locations. In residences, collectors are normally mounted on the roof, and tanks mounted above the high point of the collector can easily become the highest point in a building. Practical considerations often do not permit this application.

### Example 41.1

Determine the *pressure difference* available for a thermosyphon system with 1 m high collector and 2 m high legs. The water temperature input to the collector is 25°C, and the collector output temperature is 35°C. If the overall system loss velocity factor ( $K$ ) is 15.6, estimate the system flow velocity.

### Solution

Equation 41.1 is used to calculate the pressure difference, with the water densities being found from the temperatures (in steam tables)

$$\rho_{\text{stor}}(25^\circ\text{C}) = 997.009 \text{ kg/m}^3,$$

$$\rho_{\text{out}}(35^\circ\text{C}) = 994.036 \text{ kg/m}^3, \text{ and}$$

$$\rho_{\text{coll,ave.}}(30^\circ\text{C}) = 996.016 \text{ kg/m}^3,$$

(note: average collector temperature used in *temperature*) and with  $H = 2 \text{ m}$  and  $L = 1 \text{ m}$ :

$$\begin{aligned} \Delta P_{\text{BUOYANT}} &= (997.009)9.81(2) - [(996.016)9.81(1) + (994.036)9.81(1)], \\ &= 38.9 \text{ N/m}^2 \text{ (Pa)}. \end{aligned}$$

The system flow velocity is estimated from the *system K* given, the pressure difference calculated earlier, taking the average density of the water around the loop (at 30°C), and substituting into Equation 41.2:

$$\Delta P_{\text{BUOYANT}} = (\rho_{\text{loop,ave}})(h_L)_{\text{loop}} = (\rho_{\text{loop,ave}})KV^2,$$

$$V^2 = 38.9/(996.016)(15.6),$$

$$V = 0.05 \text{ m/s}.$$

---

### 41.3 Passive Solar Heating Design Fundamentals

Passive heating systems contain the five basic components of all solar systems, as described in Chapter 40. Typical passive realizations of these components are

1. Collector: windows, walls, and floors
2. Storage: walls and floors, large interior masses (often, these are integrated with the collector absorption function)
3. Distribution system: radiation, free convection, simple circulation fans
4. Controls: movable window insulation, vents both to other inside spaces or to ambient
5. Backup system: any nonsolar heating system

The design of passive systems requires the strategic placement of windows, storage masses, and the occupied spaces themselves. The fundamental principles of solar radiation geometry and availability are instrumental in the proper location and sizing of the system's *collectors* (windows). Storage devices are usually more massive than those used in active systems and are frequently an integral part of the collection and distribution system.

#### 41.3.1 Types of Passive Heating Systems

A commonly used method of cataloging the various passive system concepts is to distinguish three general categories: direct, indirect, and isolated gain. Most of the physical configurations of passive heating systems are seen to fit within one of these three categories.

For direct gain (Figure 41.3), sunlight enters the heated space and is converted to heat at absorbing surfaces. This heat is then distributed throughout the space and to the various enclosing surfaces and room contents.

For indirect gain category systems, sunlight is absorbed and stored by a mass interposed between the glazing and the conditioned space. The conditioned space is partially enclosed and bounded by this thermal storage mass, so a natural thermal coupling is achieved. Examples of the indirect approach are the thermal storage wall, the thermal storage roof, and the northerly room of an attached sunspace.

In the thermal storage wall (Figure 41.4), sunlight penetrates the glazing and is absorbed and converted to heat at a wall surface interposed between the glazing and the heated space. The wall is usually masonry (Trombe wall) or containers filled with water (waterwall), although it might contain phase-change material. The attached sunspace (Figure 41.5) is actually a two-zone combination of direct gain and thermal storage wall. Sunlight enters and heats a direct gain southerly *sunspace* and also heats a mass wall separating the northerly buffered space, which is indirectly heated. The *sunspace* is frequently used as a greenhouse, in which case, the system is called an *attached greenhouse*. The thermal storage roof (Figure 41.6) is similar to the thermal storage wall except that the interposed thermal storage mass is located on the building roof.

The isolated gain category concept is an indirect system, except that there is a distinct thermal separation (by means of either insulation or physical separation) between the thermal storage and the heated space. The convective (thermosyphon) loop, as depicted in Figure 41.1, is in this category and, while often used to heat domestic water, is also used for building heating. It is most akin to conventional active systems in that there is a separate collector and separate thermal storage. The thermal storage wall, thermal storage roof,

**FIGURE 41.3**  
Direct gain.

**FIGURE 41.4**  
Thermal storage wall.

**FIGURE 41.5**  
Attached sunspace.

**FIGURE 41.6**  
Thermal storage roof.

and attached sunspace approaches can also be made into isolated systems by insulating between the thermal storage and the heated space.

### 41.3.2 Fundamental Concepts for Passive Heating Design

Figure 41.7 is an equivalent thermal circuit for the building illustrated in Figure 41.4, the Trombe wall-type system. For the heat transfer analysis of the building, three temperature nodes can be identified: room temperature, storage wall temperature, and the ambient temperature. The circuit responds to climatic variables represented by a current injection  $I_s$  (solar radiation) and by the ambient temperature  $T_a$ . The storage temperature,  $T_s$ , and room temperature,  $T_r$ , are determined by current flows in the equivalent circuit. By using seasonal and annual climatic data, the performance of a passive structure can be simulated, and the results of many such simulations are correlated to give the design approaches described later in text.

### 41.3.3 Passive Design Approaches

Design of a passive heating system involves selection and sizing of the passive feature type(s), determination of thermal performance, and cost estimation. Ideally, a cost/performance optimization would be performed by the designer. Owner and architect ideas usually establish the passive feature type, with general size and cost estimation available. However, the thermal performance of a passive heating system has to be calculated.

**FIGURE 41.7**  
Equivalent thermal circuit for passively heated solar building in Figure 41.4.

There are several *levels* of methods that can be used to estimate the thermal performance of passive designs. First-level methods involve a rule of thumb and/or generalized calculation to get a starting estimate for size and/or annual performance. A second-level method involves climate, building, and passive system details, which allow annual performance determination, plus some sensitivity to passive system design changes. Third-level methods involve periodic calculations (hourly, monthly) of performance and permit more detailed variations of climatic, building, and passive solar system design parameters.

These three levels of design methods have a common basis in that they all are derived from correlations of a multitude of computer simulations of passive systems (PSDH 1980, 1984). As a result, a similar set of defined terms is used in many passive design approaches:

- $A_p$ , solar projected area,  $m^2$  ( $ft.^2$ ): the net south-facing passive solar glazing area projected onto a vertical plane
- NLC, net building load coefficient,  $kJ/CDD$  ( $Btu/FDD$ ): net load of the nonsolar portion of the building per degree-day of indoor–outdoor temperature difference. The CDD and FDD terms refer to Celsius and Fahrenheit degree-days, respectively
- $Q_{net}$ , net reference load,  $W h$  ( $Btu$ ): heat loss from nonsolar portion of building as calculated by

$$Q_{net} = NLC \times (\text{number of degree-days}). \quad (41.3)$$

- LCR, load collector ratio,  $kJ/m^2 CDD$  ( $Btu/ft.^2 FDD$ ): ratio of NLC to  $A_p$ ,

$$LCR = \frac{NLC}{A_p} \quad (41.4)$$

- SSF, solar savings fraction, %: percentage reduction in required auxiliary heating relative to net reference load,

$$SSF = 1 - \frac{\text{Auxiliary heat required } (Q_{aux})}{\text{Net reference load } (Q_{net})}. \quad (41.5)$$

Therefore, using Equation 41.3, the auxiliary heat required,  $Q_{aux}$ , is given by

$$Q_{aux} = (1 - SSF) \times NLC \times (\text{number of degree-days}). \quad (41.6)$$

The amount of auxiliary heat required is often a basis of comparison between possible solar designs as well as being the basis for determining building energy operating costs. Thus, many of the passive design methods are based on determining SSF, NLC, and the number of degree-days in order to calculate the auxiliary heat required for a particular passive system by using Equation 41.6.

#### 41.3.4 First Level: Generalized Methods

A first estimate or starting value is needed to begin the overall passive system design process. Generalized methods and rules of thumb have been developed to generate initial values for solar aperture size, storage size, solar savings fraction, auxiliary heat required, and other size and performance characteristics. The following rules of thumb are meant to be used with the defined terms presented earlier.

#### 41.3.4.1 Load

A rule of thumb used in conventional building design is that a design heating load of 120–160 kJ/CDD per m<sup>2</sup> of floor area (6–8 Btu/FDD ft.<sup>2</sup>) is considered an energy conservative design. Reducing these nonsolar values by 20% to solarize the proposed south-facing solar wall gives rule-of-thumb NLC values per unit of floor area:

$$\text{NLC/floor area} = 100\text{--}130 \text{ kJ/CDD m}^2 \text{ (4.8--6.4 Btu/FDD ft.}^2\text{)}. \quad (41.7)$$

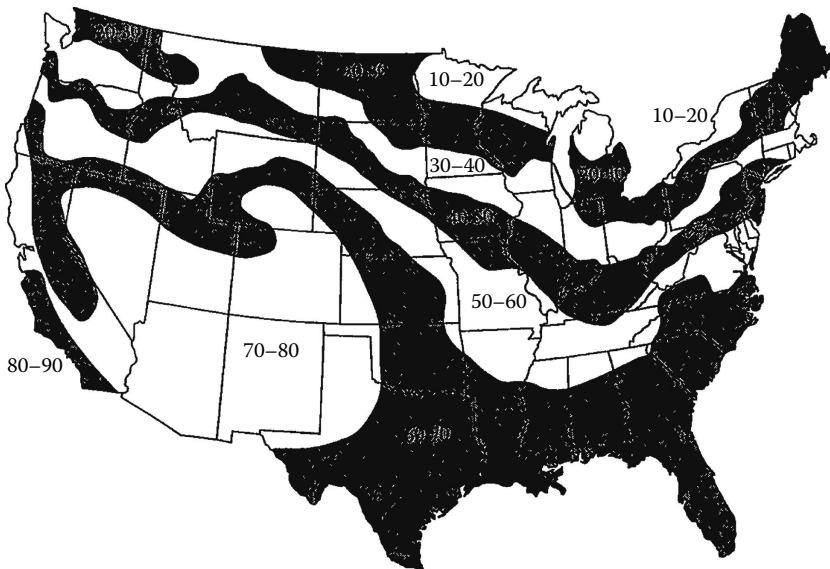

#### 41.3.4.2 Solar Savings Fraction

A method of getting starting-point values for the solar savings fraction is presented in Figure 41.8 (PSDH 1984). The map values represent optimum SSF (in percent) for a particular set of conservation and passive-solar costs for different climates across the United States. With the  $Q_{\text{net}}$  generated from the NLC rule of thumb (see earlier) and the SSF read from the map, the  $Q_{\text{aux}}$  can be determined.

#### 41.3.4.3 Load Collector Ratio

The  $A_p$  can be determined using the NLC given earlier if the LCR is known. The rule of thumb associated with *good* values of LCR (PSDH 1984) differs depending on whether the design is for a *cold* or *warm* climate:

$$\text{"Good" LCR} = \begin{cases} \text{For cold climate: } 410 \text{ kJ/m}^2 \text{ CDD (20 Btu/ft.}^2 \text{ FDD)} \\ \text{For warm climate: } 610 \text{ kJ/m}^2 \text{ CDD (30 Btu/ft.}^2 \text{ FDD)} \end{cases} \quad (41.8)$$

**FIGURE 41.8**

Starting-point values of solar savings fraction (SSF) in percent. (From PSDH, *Passive Solar Design Handbook*, Part One: Total Environmental Action, Inc., Part Two: Los Alamos Scientific Laboratory, Part Three: Los Alamos National Laboratory. Van Nostrand Reinhold, New York, 1984.)

#### 41.3.4.4 Storage

Rules of thumb for thermal mass storage relate storage material total heat capacity to the solar projected area (PSDH 1984). The use of the storage mass is to provide for heating on cloudy days and to regulate sunny day room air temperature swing. When the thermal mass directly absorbs the solar radiation, each square meter of the projected glazing area requires enough mass to store 613 kJ/°C. If the storage material is not in direct sunlight, but heated from room air only, then four times as much mass is needed. In a room with a directly sunlight-heated storage mass, the room air temperature swing will be approximately one-half the storage mass temperature swing. For room air heated storage, the air temperature swing is twice that of the storage mass.

##### Example 41.2

A Denver, Colorado, building is to have a floor area of 195 m<sup>2</sup> (2100 ft.<sup>2</sup>). Determine rule-of-thumb size and performance characteristics.

##### Solution

From Equation 41.5, the NLC is estimated as

$$\begin{aligned} \text{NLC} &= (115 \text{ kJ/CDD m}^2) \times (195 \text{ m}^2) \\ &= 22,400 \text{ kJ/CDD} (11,800 \text{ Btu/FDD}). \end{aligned}$$

Using the *cold* LCR value and Equation 41.4, the passive solar projected area is

$$\begin{aligned} A_p &= \frac{\text{NLC}}{\text{LCR}} = \frac{22,400 \text{ kJ/CDD}}{410 \text{ kJ/m}^2 \text{ CDD}} \\ &= 54.7 \text{ m}^2 (588 \text{ ft.}^2). \end{aligned}$$

Locating Denver on the map of Figure 41.8 gives an SSF value in the 70%–80% range (use 75%). An annual °C-degree-day value can be found in city climate tables (PSDH 1984; NCDC 1992) and is 3491 CDD (6283 FDD) for Denver. Thus, the auxiliary heat required,  $Q_{\text{aux}}$ , is found using Equation 41.6:

$$\begin{aligned} Q_{\text{aux}} &= (1 - 0.75)(22,400 \text{ kJ/CDD})(3491 \text{ CDD}) \\ &= 19,600 \text{ MJ} (18.5 \times 10^6 \text{ Btu}) \text{ annually.} \end{aligned}$$

The thermal storage can be sized using directly solar-heated and/or room air heated mass by using the projected area. Assuming brick with a specific heat capacity of 840 J/kg °C, the storage mass is found by

$$\begin{aligned} A_p \times (613 \text{ kJ/C}) &= m \times (840 \text{ J/kg } ^\circ\text{C}), \\ m_d &= 40,000 \text{ kg} (88,000 \text{ lbm}) \text{ [direct sun]}, \\ \text{or } m_a &= 160,000 \text{ kg} (351,000 \text{ lbm}) \text{ [air heated]}. \end{aligned}$$

A more location-dependent set of rules of thumb is presented in PSDH (1980). The first rule of thumb relates solar projected area as a percentage of floor area to solar savings fraction, with and without night insulation of the solar glazing:

A solar projected area of (B1)% to (B2)% of the floor area can be expected to produce a SSF in (location) of (S1)% to (S2)%, or, if R9 night insulation is used, of (S3)% to (S4)%

The values of B1, B2, S1, S2, S3, and S4 are found using [Table 41.1](#) for the location. The thermal storage mass rule of thumb is again related to the solar projected area:

A thermal storage wall should have  $14 \text{ kg} \times \text{SSF} (\%)$  of water or  $71 \text{ kg} \times \text{SSF} (\%)$  of masonry for each square meter of solar projected area. For a direct gain space, the mass above should be used with a surface area of at least three times the solar projected area, and masonry no thicker than 10–15 cm. If the mass is located in back rooms, then four times the above mass is needed.

### Example 41.3

Determine size and performance passive solar characteristics with the location-dependent set of rules of thumb for the house of the previous example.

#### Solution

Using [Table 41.1](#) with the 195 m<sup>2</sup> house in Denver yields

$$\text{Solar projected area} = 12\%–23\% \text{ of floor area}$$

$$= 23.4–44.9 \text{ m}^2.$$

$$\text{SSF (no night insulation)} = 27\%–43\%.$$

$$\text{SSF (R9 night insulation)} = 47\%–74\%.$$

Using the rule of thumb for the thermal storage mass,

$$m = 17 \text{ kg} \times 43\% \times 44.9 \text{ m}^2$$

$$= 33,000 \text{ kg (72,000 lbm) [Thermal wall or direct gain].}$$

Comparing the results of this example to those of the previous example, the two rules of thumb are seen to produce *roughly* similar answers. General system cost and performance information can be generated with results from rule-of-thumb calculations, but a more detailed level of information is needed to determine design-ready passive system type (direct gain, thermal wall, sunspace), size, performance, and costs.

### 41.3.5 Second Level: LCR Method

The LCR method is useful for making estimates of the annual performance of specific types of passive system(s) combinations. The LCR method was developed by calculating the annual SSF for 94 reference passive solar systems for 219 U.S. and Canadian locations over a range of LCR values. [Table 41.2](#) includes the description of these 94 reference systems for use both with the LCR method and with the solar load ratio (SLR) method described later. Tables were constructed for each city with LCR versus SSF listed for each of the 94 reference passive systems. (Note that the SLR method was used to make the LCR calculations, and this SLR method is described in the next section as the third-level method.) Although the complete LCR tables (PSDH 1984) include 219 locations, [Table 41.3](#) includes only 6 *representative* cities

Source: PSDH, *Passive Solar Design Handbook*, Part One: Total Environmental Action, Inc., Part Two: Los Alamos Scientific Laboratory, Part Three: Los Alamos National Laboratory, Van Nostrand Laboratory, Reinhold, New York, 1984.

<sup>a</sup> The thermal storage capacity is per unit of projected area, or, equivalently, the quantity  $\rho ck$ . The wall thickness is listed only as an appropriate guide by assuming  $\rho c = 30 \text{ Btu/ft}^3/\text{°F}$ .

(Albuquerque, Boston, Madison, Medford, Nashville, and Santa Maria), purely due to space restrictions. The LCR method consists of the following steps (PSDH 1984):

1. Determine the following building parameters:
  - a. Building load coefficient, NLC
  - b. Solar projected area,  $A_p$
  - c. Load collector ratio,  $\text{LCR} = \text{NLC}/A_p$
2. Find the short designation of the reference system closest to the passive system design (Table 41.2).

3. Enter the LCR tables (Table 41.3).
  - a. Find the city
  - b. Find the reference system listing
  - c. Determine annual SSF by interpolation using the LCR value from above
  - d. Note the annual heating degree-days (number of degree-days)
4. Calculate the annual auxiliary heat required:

$$\text{Auxiliary heat required} = (1 - \text{SSF}) \times \text{NLC} \times (\text{number of degree-days}).$$

If more than one reference solar system is being used, then find the *aperture-area-weighted* SSF for the combination. Determine each individual reference system SSF using the total aperture area LCR, then take the *area-weighted* average of the individual SSFs.

The LCR method allows no variation from the 94 reference passive designs. To treat off-reference designs, sensitivity curves have been produced that illustrate the effect on SSF of varying one or two design variables. These curves were produced for the six *representative* cities, chosen for their wide geographical and climatological ranges. Several of these SSF *sensitivity curves* are presented in Figure 41.9 for storage wall (Figure 41.9a through c) and sunspace (Figure 41.9d) design variations.

#### Example 41.4

The previously used 2100 ft.<sup>2</sup> building with NLC = 11,800 Btu/FDD is preliminarily designed to be located in Medford, Oregon, with 180 ft.<sup>2</sup> of 12 in. thick vented Trombe wall and 130 ft.<sup>2</sup> of direct gain, both systems with double glazing, nighttime insulation, and 30 Btu/ft.<sup>2</sup> thermal storage capacity. Determine the annual auxiliary energy needed by this design.

#### Solution

Step 1 yields:

$$\text{NLC} = 11,800 \text{ Btu/FDD}.$$

$$A_p = 180 + 130 = 320 \text{ ft.}^2$$

$$\text{LCR} = 11,800/320 = 36.8 \text{ Btu/FDD ft.}^2$$

Step 2 yields: From Table 41.2, the short designations for the appropriate systems are

TWD4 (Trombe wall)

DGA3 (Direct gain)

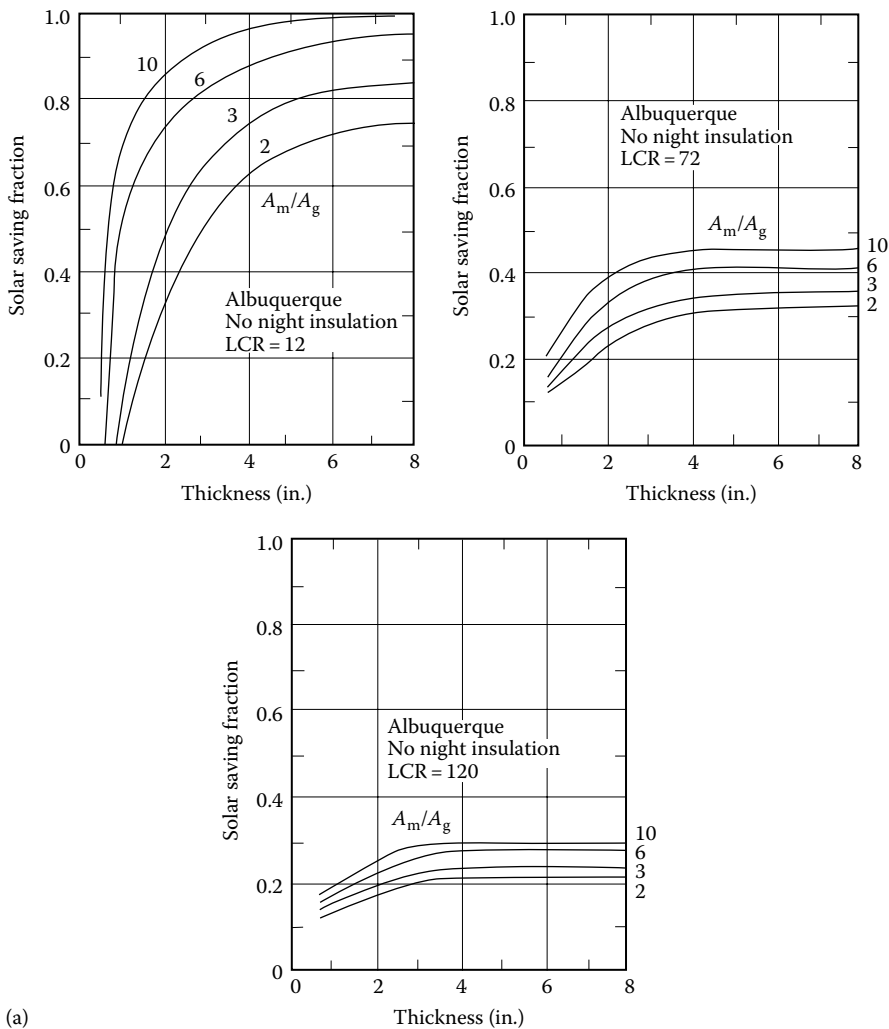

Step 3 yields: From Table 41.3 for Medford, Oregon, with  $\text{LCR} = 36.8$ ,

TWD4:  $\text{SSF}(\text{TW}) = 0.42$ .

DGA3:  $\text{SSF}(\text{DG}) = 0.37$ .

Determine the *weighted area average* SSF:

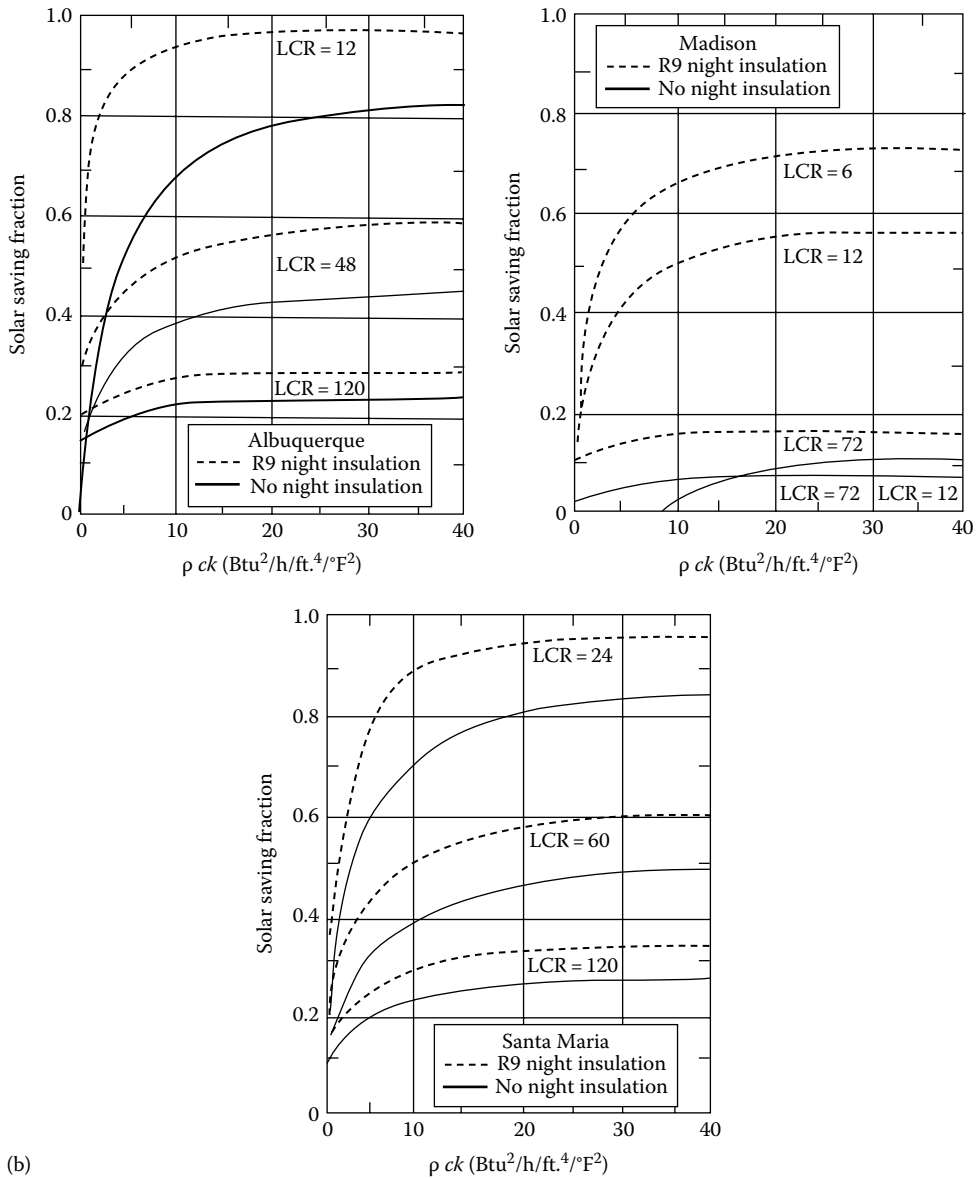

$$\text{SSF} = \frac{180(0.42) + 130(0.37)}{320} = 0.39.$$

(Continued)

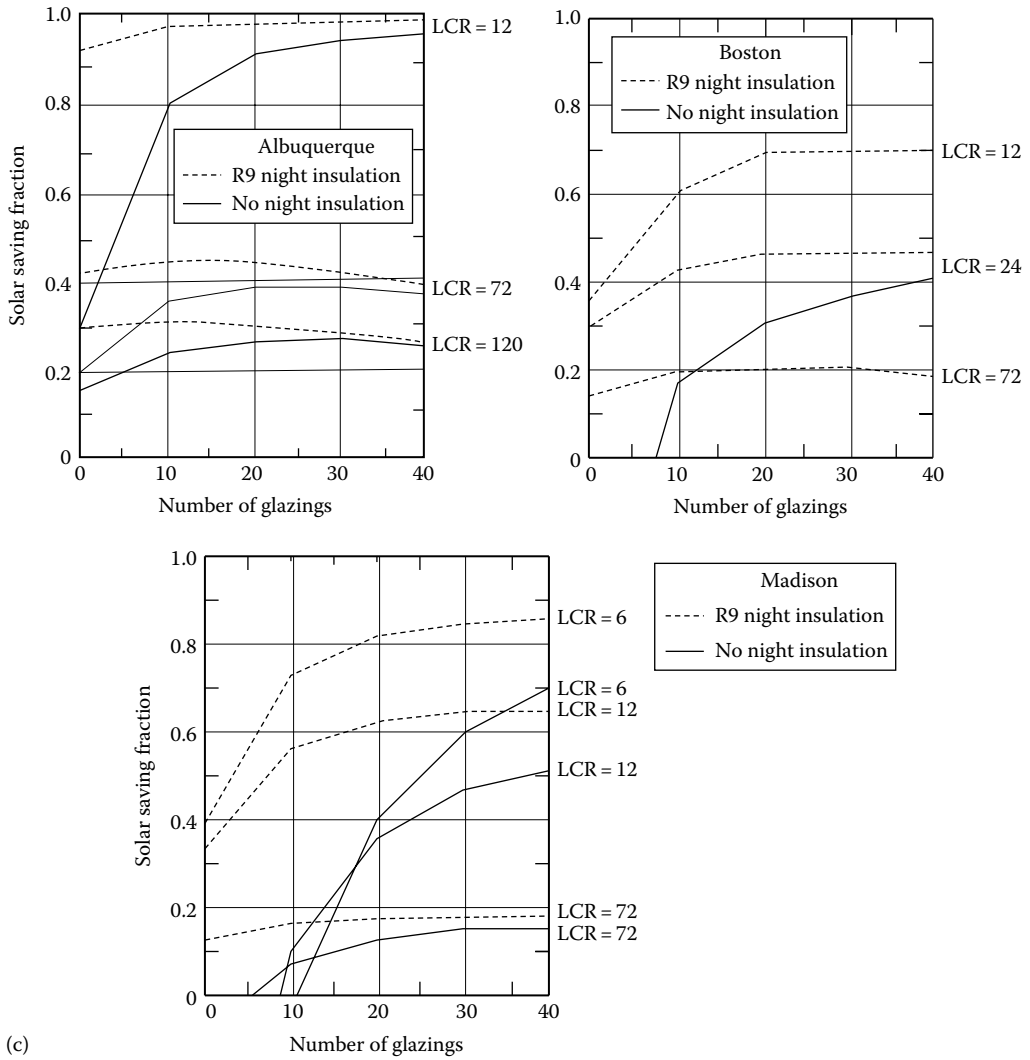

FIGURE 41.9 (Continued)

(c) Storage wall: number of glazings.

(Continued)

**FIGURE 41.9 (Continued)**

(d) Sunspace: storage-volume-to-projected-area ratio. (From PSDH, *Passive Solar Design Handbook*, Volume One: Passive Solar Design Concepts, DOE/CS-O127/1, March 1980. Prepared by Total Environmental Action, Inc. (B. Anderson, C. Michal, P. Temple, and D. Lewis); Volume Two: *Passive Solar Design Analysis*, DOE/CS-O127/2, January 1980, Prepared by Los Alamos Scientific Laboratory (J. D. Balcomb, D. Barley, R. McFarland, J. Perry, W. Wray and S. Noll), U.S. Department of Energy, Washington, DC, 1980.)

Step 4 yields: Using Equation 41.6 and reading 4930 FDD from [Table 41.3](#),

$$Q_{\text{aux}} = (1 - 0.39) \times 11,800 \text{ Btu} \times 4,930 \text{ FDD} = 35.5 \times 10^6 \text{ Btu annually.}$$

Using the reference system characteristics yields, the thermal storage size: Trombe wall ( $\rho k = 30$ , concrete properties from [Table 41.2c](#)):

$$\begin{aligned} m(\text{TW}) &= \text{density} \times \text{area} \times \text{thickness} \\ &= 150 \text{ lbm/ft.}^3 \times 180 \text{ ft.}^2 \times 1 \text{ ft.} \\ &= 27,000 \text{ lbm.} \end{aligned}$$

Direct gain ( $\rho k = 30$ , concrete properties), using mass-area-to-glazing-area ratio of 6:

$$\text{Mass area} = 6 \times 130 = 780 \text{ ft.}^2 \text{ of 2 in. thick concrete}$$

$$\begin{aligned} m(\text{DG}) &= 150 \text{ lbm/ft.}^3 \times 780 \text{ ft.}^2 \times 1/6 \text{ ft.} \\ &= 19,500 \text{ lbm.} \end{aligned}$$

Using the LCR method allows a basic design of passive system types for the 94 reference systems and the resulting annual performance. A bit more design variation can be obtained by using the sensitivity curves of Figure 41.9 to modify the SSF of a particular reference system. For instance, a direct gain system SSF of 0.37 would increase by approximately 0.03 if the mass–glazing-area ratio (assumed 6) were increased to 10 and would decrease by about 0.04 if the mass–glazing-area ratio were decreased to 3. This information provides a designer with quantitative information for making trade-offs.

### 41.3.6 Third Level: SLR Method

The SLR method calculates monthly performance, and the terms and values used are monthly based. The method allows the use of specific location weather data and the 94 reference design passive systems (Table 41.2). In addition, the sensitivity curves (Figure 41.9) can again be used to define performance outside the reference design systems. The result of the SLR method is the determination of the monthly heating auxiliary energy required that is then summed to give the annual requirement for auxiliary heating energy. Generally, the SLR method gives annual values within  $\pm 3\%$  of detailed simulation results, but the monthly values may vary more (PSDH 1984; Duffie and Beckman 1991). Thus, the monthly SLR method is more *accurate* than the rule-of-thumb methods, plus providing the designer with system performance on a month-by-month basis.

The SLR method uses equations and correlation parameters for each of the 94 reference systems combined with the insolation absorbed by the system, the monthly degree-days, and the system's LCR to determine the monthly SSF. These correlation parameters are listed in Table 41.4 as  $A$ ,  $B$ ,  $C$ ,  $D$ ,  $R$ ,  $G$ ,  $H$ , and LCRs for each reference system (PSDH 1984). The correlation equations are

$$\text{SSF} = 1 - K(1 - F), \quad (41.9)$$

where

$$K = 1 + G/\text{LCR}, \quad (41.10)$$

$$F = \begin{cases} AX, & \text{when } X < R \\ B - C \exp(-DX), & \text{when } X > R \end{cases} \quad (41.11)$$

$$X = \frac{S/DD - (\text{LCRs})H}{(\text{LCR})K}, \quad (41.12)$$

and  $X$  is called the *generalized solar load ratio*. The term  $S$  is the monthly insolation absorbed by the system per unit of solar projected area. Monthly average daily insolation data on a vertical south-facing surface can be found and/or calculated using various sources (PSDH 1984; McQuiston and Parker 1994), and the  $S$  term can be determined by multiplying by a transmission and an absorption factor and the number of days in the month. Absorption factors for all systems are close to 0.96 (PSDH 1984), whereas the transmission is approximately 0.9 for single glazing, 0.8 for double glazing, and 0.7 for triple glazing.

**Example 41.5**

For a vented, 180 ft.<sup>2</sup>, double-glazed with night insulation, 12 in. thick Trombe wall system (TWD4) in an NLC = 11,800 Btu/FDD house in Medford, Oregon, determine the auxiliary energy required in January.

**Solution**

Weather data for Medford, Oregon (PSDH 1984), yields for January ( $N = 31$ , days): daily vertical surface insolation = 565 Btu/ft.<sup>2</sup> and 880 FDD, so  $S = (31)(565)(0.8)(0.96) = 13,452$  Btu/ft.<sup>2</sup> month.

$$\text{LCR} = \frac{\text{NLC}}{A_p} = \frac{11,800}{180} = 65.6 \text{ Btu/FDD ft.}^2$$

From Table 41.4 at TWD4:  $A = 0$ ,  $B = 1$ ,  $C = 1.0606$ ,  $D = 0.977$ ,  $R = -9$ ,  $G = 0$ ,  $H = 0.85$ , LCRs = 5.8 Btu/FDD ft.<sup>2</sup>

Substituting into Equation 41.10 gives

$$K = 1 + 0/65.6 = 1.$$

Equation 41.12 gives

$$X = \frac{(13,452/880) - (5.8 \times 0.85)}{65.6 \times 1} = 0.16.$$

Equation 41.11 gives

$$F = 1 - 1.0606e^{-0.977 \times 0.16} = 0.09,$$

and Equation 41.9 gives

$$\text{SSF} = 1 - 1(1 - 0.09) = 0.09.$$

The January auxiliary energy required can be calculated using Equation 41.6:

$$\begin{aligned} Q_{\text{aux}}(\text{Jan}) &= (1 - \text{SSF}) \times \text{NLC} \times (\text{number of degree-days}) \\ &= (1 - 0.09) \times 11,800 \times 880 \\ &= 9,450,000 \text{ Btu.} \end{aligned}$$

As mentioned, the use of sensitivity curves (PSDH 1984) as in Figure 41.9 will allow SSF to be determined for many off-reference system design conditions involving storage mass, number of glazings, and other more esoteric parameters. Also, the use of multiple

passive system types within one building would be approached by calculating the SSF for each type system individually using a *combined area* LCR, and then a weighted-area (aperture) average SSF would be determined for the building.

## 41.4 Passive Space Cooling Design Fundamentals

Passive cooling systems are designed to use natural means to transfer heat from buildings, including convection/ventilation, evaporation, radiation, and conduction. However, the most important element in both passive and conventional cooling design is to prevent heat from entering the building in the first place. Cooling conservation techniques involve building surface colors, insulation, special window glazings, overhangs and orientation, and numerous other architectural/engineering features.

### 41.4.1 Solar Control

Controlling the solar energy input to reduce the cooling load is usually considered a passive (versus conservation) design concern because solar input may be needed for other purposes, such as daylighting throughout the year and/or heating during the winter. Basic architectural solar control is normally *designed in* via the shading of the solar windows, where direct radiation is desired for winter heating and needs to be excluded during the cooling season.

The shading control of the windows can be of various types and *controllability*, ranging from drapes and blinds, use of deciduous trees, to the commonly used overhangs and vertical louvers. A rule-of-thumb design for determining proper south-facing window overhang for both winter heating and summer shading is presented in Table 41.5. Technical details on calculating shading from various devices and orientations are found in Olgyay and Olgyay (1977) and ASHRAE (1993).

### 41.4.2 Natural Convection/Ventilation

Air movement provides cooling comfort through convection and evaporation from human skin. ASHRAE (1993) places the comfort limit at 79°F for an air velocity of 50 ft./min (fpm), 82°F for 160 fpm, and 85°F for 200 fpm. To determine whether or not comfort conditions can be obtained, a designer must calculate the volumetric flow rate,  $Q$ , which is passing through the occupied space. Using the cross-sectional area,  $A_x$ , of the space and the room air velocity,  $V_a$ , required, the flow is determined by

$$Q = A_x V_a \quad (41.13)$$

The proper placement of windows, *narrow* building shape, and open landscaping can enhance natural wind flow to provide ventilation. The air flow rate through open windows for wind-driven ventilation is given by ASHRAE (1993):

$$Q = C_v V_w A_w \quad (41.14)$$

where

$Q$  is the air flow rate ( $\text{m}^3/\text{s}$ )

$A_w$  is the free area of inlet opening ( $\text{m}^2$ )

$V_w$  is the wind velocity ( $\text{m}/\text{s}$ )

$C_v$  is the effectiveness of opening that is equal to 0.5–0.6 for wind perpendicular to opening and 0.25–0.35 for wind diagonal to opening

**TABLE 41.5**

South-Facing Window Overhang Rule of Thumb

Length of the overhang = $\frac{\text{window height}}{F}$	
(a) Overhang Factors	(b) Roof Overhang Geometry
North Latitude	$F^a$
28	5.5–11.1
32	4.0–6.3
36	3.0–4.5
40	2.5–3.4
44	2.0–2.7
48	1.7–2.2
52	1.5–1.8
56	1.3–1.5

Properly sized overhangs shade out hot summer sun but allow winter sun (which is lower in the sky) to penetrate windows

Source: Halacy, 1984.

<sup>a</sup> Select a factor according to your latitude. Higher values provide complete shading at noon on June 21; lower values, until August 1.

The stack effect can induce ventilation when warm air rises to the top of a structure and exhausts outside, while cooler outside air enters the structure to replace it. Figure 41.10 illustrates the solar chimney concept, which can easily be adapted to a thermal storage wall system. The greatest stack effect flow rate is produced by maximizing the stack height and the air temperature in the stack, as given by

$$Q = 0.116A_j\sqrt{h(T_s - T_o)} \quad (41.15)$$

where

$Q$  is the stack flow rate ( $\text{m}^3/\text{s}$ )

$A_j$  is the area of inlets or outlets, whichever is smaller ( $\text{m}^2$ )

$h$  is the inlet-to-outlet height (m)

$T_s$  is the average temperature in stack ( $^{\circ}\text{C}$ )

$T_o$  is the outdoor air temperature ( $^{\circ}\text{C}$ )

If inlet or outlet area is twice the other, the flow rate will increase by 25%, and by 35% if the areas' ratio is 3:1 or larger (Table 41.6).

#### Example 41.6

A two-story (5 m) solar chimney is being designed to produce a flow of  $0.25 \text{ m}^3/\text{s}$  through a space. The preliminary design features include a  $25 \text{ cm} \times 1.5 \text{ m}$  inlet, a  $50 \text{ cm} \times 1.5 \text{ m}$  outlet, and an estimated  $35^{\circ}\text{C}$  average stack temperature on a sunny  $30^{\circ}\text{C}$  day. Can this design produce the desired flow?

**FIGURE 41.10**

The stack-effect/solar chimney concept to induce convection/ventilation. (From PSDH, *Passive Solar Design Handbook*, Volume One: Passive Solar Design Concepts, DOE/CS-0127/1, March 1980, Prepared by Total Environmental Action, Inc. (B. Anderson, C. Michal, P. Temple, and Lewis); Volume Two: *Passive Solar Design Analysis*, DOE/CS-0127/2, January 1980, Prepared by Los Alamos Scientific Laboratory (J. D. Balcomb, D. Barley, R McFarland, J. Perry, W. Wray and S. Noll), U.S. Department of Energy, Washington, DC, 1980.)

**TABLE 41.6**

## Ground Reflectivities

Material	$\rho$ (%)

Vegetation	25
Snow	70
Red brick	30
Gravel	15
White paint	55–75

Source: Murdoch, J.B., *Illumination Engineering—From Edison's Lamp to the Laser*, Macmillan, New York, 1985.

**Solution**

Substituting the design data into Equation 41.15,

$$\begin{aligned} Q &= 0.116(0.25 \times 1.5)[5(5)]^{1/2} \\ &= 0.2 \text{ m}^3/\text{s}. \end{aligned}$$

Because the outlet area is twice the inlet area, the 25% flow increase can be used:

$$Q = 0.2(1.25) = 0.25 \text{ m}^3/\text{s}.$$

(Answer: Yes, the proper flow rate is obtained.)

**41.4.3 Evaporative Cooling**

When air with less than 100% relative humidity moves over a water surface, the evaporation of water causes both the air and the water itself to cool. The lowest temperature that can be reached by this direct evaporative cooling effect is the wet-bulb temperature of the air, which is directly related to the relative humidity, with lower wet-bulb temperature associated with lower relative humidity. Thus, dry air (low relative humidity) has a low wet-bulb temperature and will undergo a large temperature drop with evaporative cooling, while humid air (high relative humidity) can be only slightly cooled evaporatively. The wet-bulb temperature for various relative humidity and air temperature conditions can be found via the *psychrometric chart* available in most thermodynamic texts. Normally, an evaporative cooling process cools the air only part of the way down to the wet-bulb temperature. To get the maximum temperature decrease, it is necessary to have a large water surface area in contact with the air for a long time, and interior ponds and fountain sprays are often used to provide this air–water contact area.

The use of water sprays and open ponds on roofs provides cooling primarily via evaporation. The hybrid system involving a fan and wetted mat, the *swamp cooler*, is by far the most widely used evaporative cooling technology. Direct, indirect, and combined evaporative cooling system design features are described in ASHRAE (1993, 1995).

**41.4.4 Nocturnal and Radiative Cooling Systems**

Another approach to passive convective/ventilative cooling involves using cooler night air to reduce the temperature of the building and/or a storage mass. Thus, the building/storage mass is prepared to accept part of the heat load during the hotter daytime. This type of convective system can also be combined with evaporative and radiative modes of heat transfer, utilizing air and/or water as the convective fluid. Work in Australia (Close et al. 1968) investigated rock storage beds that were chilled using evaporatively cooled night air. Room air was then circulated through the bed during the day to provide space cooling. The use of encapsulated roof ponds as a thermal cooling mass has been tried by several investigators (Hay and Yellott 1969; Marlatt et al. 1984; Givoni 1994) and is often linked with nighttime radiative cooling.

All warm objects emit thermal infrared radiation; the hotter the body, the more energy it emits. A passive cooling scheme is to use the cooler night sky as a sink for thermal radiation emitted by a warm storage mass, thus chilling the mass for cooling

**FIGURE 41.11**

Average monthly sky temperature depression ( $I_{\text{AIR}} - I_{\text{SKY}}$ ) for July in °F. (Adapted from Martin, M. and Berdahl, P., *Solar Energy*, 33(314), 321–336, 1984.)

use the next day. The net radiative cooling rate,  $Q_r$ , for a horizontal unit surface (ASHRAE 1993) is

$$Q_r = \varepsilon \sigma (T_{\text{body}}^4 - T_{\text{sky}}^4), \quad (41.16)$$

where

$Q_r$  is the net radiative cooling rate,  $\text{W/m}^2$  ( $\text{Btu/h ft.}^2$ )

$\varepsilon$  is the surface emissivity fraction (usually 0.9 for water)

$\sigma$  is  $5.67 \times 10^{-8} \text{ W/m}^2 \text{ K}^4$  ( $1.714 \times 10^{-9} \text{ Btu/h ft.}^2 \text{ R}^4$ )

$T_{\text{body}}$  is the warm body temperature, Kelvin (Rankine)

$T_{\text{sky}}$  is the effective sky temperature, Kelvin (Rankine)

The monthly average air–sky temperature difference has been determined (Martin and Berdahl 1984), and Figure 41.11 presents these values for July (in °F) for the United States.

### Example 41.7

Estimate the overnight cooling possible for a  $10 \text{ m}^2$ ,  $85^\circ\text{F}$  water thermal storage roof during July in Los Angeles.

### Solution

Assume the roof storage unit is black with  $\varepsilon = 0.9$ . From Figure 41.11,  $T_{\text{air}} - T_{\text{sky}}$  is approximately  $10^\circ\text{F}$  for Los Angeles. From weather data for LA airport (PSDH 1984; ASHRAE 1993), the July average temperature is  $69^\circ\text{F}$  with a range of  $15^\circ\text{F}$ . Assuming night temperatures vary from the average ( $69^\circ\text{F}$ ) down to half the daily range ( $15/2$ ), then the average nighttime temperature is chosen as  $69 - (1/2)(15/2) = 65^\circ\text{F}$ . Therefore,  $T_{\text{sky}} = 65 - 10 = 55^\circ\text{F}$ . From Equation 41.16,

$$\begin{aligned} Q_r &= 0.9(1.714 \times 10^{-9})[(460 + 85)^4 - (460 + 55)^4] \\ &= 27.6 \text{ Btu/h ft.}^2. \end{aligned}$$

For a 10 h night and 10 m<sup>2</sup> (107.6 ft.<sup>2</sup>) roof area,

$$\begin{aligned}\text{Total radiative cooling} &= 27.6(10)(107.6) \\ &= 29,700 \text{ Btu.}\end{aligned}$$

Note that this does not include the convective cooling possible, which can be approximated (at its maximum rate) for still air (ASHRAE 1993) by

$$\begin{aligned}\text{Maximum total } Q_{\text{conv}} &= hA(T_{\text{roof}} - T_{\text{air}})(\text{Time}) \\ &= 5(129)(85 - 55)(10) \\ &= 161,000 \text{ Btu.}\end{aligned}$$

This is a maximum since the 85°F storage temperature will drop as it cools; this is also the case for the radiative cooling calculation. However, convection is seen to usually be the more dominant mode of nighttime cooling.

#### 41.4.5 Earth Contact Cooling (or Heating)

Earth contact cooling or heating is a passive summer cooling and winter heating technique that utilizes underground soil as the heat sink or source. By installing a pipe underground and passing air through the pipe, the air will be cooled or warmed depending on the season. A schematic of an open-loop system and a closed-loop air-conditioning system are presented in Figures 41.12 and 41.13, respectively (Goswami and Biseli 1994).

**FIGURE 41.12**  
Open-loop underground air tunnel system.

**FIGURE 41.13**  
Schematic of closed-loop air-conditioning system using air tunnel.

The use of this technique can be traced back to 3000 BC when Iranian architects designed some buildings to be cooled by natural resources only. In the nineteenth century, Wilkinson (USDA 1960) designed a barn for 148 cows where a 500 ft. long underground passage was used for cooling during the summertime. Since that time, a number of experimental and analytical studies of this technique have continued to appear in the literature (Krarti and Kreider 1996; Hollmuller and Lachal 2001; De Paepe and Janssens 2003). Goswami and Dhaliwal (1985) have given a brief review of the literature as well as presented an analytical solution to the problem of transient heat transfer between the air and the surrounding soil as the air is made to pass through a pipe buried underground.

#### 41.4.5.1 Heat Transfer Analysis

The transient thermal analysis of the air and soil temperature fields (Goswami and Dhaliwal 1985) is conducted using finite elements with the convective heat transfer between the air and the pipe and using semi-infinite cylindrical conductive heat transfer to the soil from the pipe. It should be noted that the thermal resistance of the pipe (whether of metal, plastic, or ceramic) is negligible relative to the surrounding soil.

##### 41.4.5.1.1 Air and Pipe Heat Transfer

The pipe is divided into a large number of elements and a psychrometric energy balance written for each, depending on whether the air leaves the element (1) unsaturated or (2) saturated.

1. If the air leaves an element as unsaturated, the energy balance on the element is

$$mC_p(T_1 - T_2) = hA_p(T_{\text{air}} - T_{\text{pipe}}). \quad (41.17)$$

$T_{\text{air}}$  can be taken as  $(T_1 + T_2)/2$ . Substituting and simplifying,

$$T_2 = \frac{(1 - (U/2))T_1 + UT_{\text{pipe}}}{1 + (U/2)}, \quad (41.18)$$

where  $U$  is defined as

$$U = \frac{A_p h}{mC_p}$$

2. If the air leaving the element is saturated, the energy balance is

$$mC_p T_1 + m(W_1 - W_2)H_{fg} = mC_p T_2 + hA_p(T_{\text{air}} - T_{\text{pipe}}). \quad (41.19)$$

Simplifying gives

$$T_2 = \frac{(1 - (U/2))T_1 + ((W_1 - W_2)/C_p)H_{fg} + UT_{\text{pipe}}}{1 + (U/2)}. \quad (41.20)$$

The convective heat transfer coefficient  $h$  in the preceding equations depends on Reynolds number, the shape, and roughness of the pipe.

Using the exit temperature from the first element as the inlet temperature for the next element, the exit temperature for the element can be calculated in a similar way. Continuing this way from one element to the next, the temperature of air at the exit from the pipe can be calculated.

#### 41.4.5.1.2 Soil Heat Transfer

The heat transfer from the pipe to the soil is analyzed by considering the heat flux at the internal radius of a semi-infinite cylinder formed by the soil around the pipe. For a small element, the problem can be formulated as

$$\frac{\partial^2 T(r,t)}{\partial r^2} + \frac{1}{r} \frac{\partial T(r,t)}{\partial r} = \frac{1}{\alpha} \frac{\partial T(r,t)}{\partial t}, \quad (41.21)$$

with initial and boundary conditions as

$$T(r,0) = T_e$$

$$T(\infty,t) = T_e$$

$$-K \frac{\partial T}{\partial r}(r,t) = q'',$$

where

$T_e$  is the bulk earth temperature

$q''$  is also given by the amount of heat transferred to the pipe from the air by convection, that is,  $q'' = h(T_{\text{air}} - T_{\text{pipe}})$

#### 41.4.5.2 Soil Temperatures and Properties

Kusuda and Achenbach (1965) and Labs (1981) studied the earth temperatures in the United States. According to both of these studies, temperature swings in the soil during the year are dampened with depth below the ground. There is also a phase lag between the soil temperature and the ambient air temperature, and this phase lag increases with depth below the surface. For example, the soil temperature for light dry soil at a depth of about 10 ft. (3.05 m) varies by approximately  $\pm 5^\circ\text{F}$  ( $2.8^\circ\text{C}$ ) from the mean temperature (approximately equal to mean annual air temperature) and has a phase lag of approximately 75 days behind ambient air temperature (Labs 1981).

The thermal properties of the soil are difficult to determine. The thermal conductivity and diffusivity both change with the moisture content of the soil itself, which is directly affected by the temperature of and heat flux from and to the buried pipe. Most researchers have found that using constant property values for soil taken from standard references gives reasonable predictive results (Goswami and Ileslamlou 1990).

#### 41.4.5.3 Generalized Results from Experiments

Figure 41.14 presents data from Goswami and Biseli (1994) for an open system, 100 ft. long, 12 in. diameter pipe, buried 9 ft. deep. The figure shows the relationship between the pipe

**FIGURE 41.14**

Air temperature drop through a 100 ft. long, 12 in. diameter pipe buried 9 ft. underground.

inlet-to-outlet temperature reduction ( $T_{in} - T_{out}$ ) and the initial soil temperature with ambient air inlet conditions of 90°F, 55% relative humidity for various pipe flow rates.

Other relations from this same report that can be used with Figure 41.14 data include the following: (1) the effect of increasing pipe/tunnel length on increasing the inlet-to-outlet air temperature difference is fairly linear up to 250 ft.; and (2) the effect of decreasing pipe diameter on lowering the outlet air temperature is slight, and only marginally effective for pipes less than 12 in. in diameter.

### Example 41.8

Provide the necessary 12 in. diameter pipe length(s) that will deliver 1500 cfm of 75°F air if the ambient temperature is 85°F and the soil at 9 ft. is 65°F.

### Solution

From Figure 41.14, for 100 ft. of pipe at 65°F soil temperature, the pipe temperature reduction is

$$\begin{aligned}
 T_{in} - T_{out} &= 6^\circ\text{F} \text{ (at 250 cfm)} \\
 &= 5^\circ\text{F} \text{ (at 750 cfm)} \\
 &= 4.5^\circ\text{F} \text{ (at 1250 cfm).}
 \end{aligned}$$

Because the *length versus temperature reduction* is linear (see earlier text), the 10°F reduction required (85°F down to 75°F) would be met by the 750 cfm case (5°F for 100 ft.) if 200 ft. of pipe is used. Then, two 12 in. diameter pipes would be required to meet the 1500 cfm requirement.

### Answer

Two 12 in. diameter pipes, each 200 ft. long. (*Note:* see what would be needed if the 250 cfm or the 1250 cfm cases had been chosen. Which of the three flow rate cases leads to the *cheapest* installation?)

---

## 41.5 Daylighting Design Fundamentals

Daylighting is the use of the sun's radiant energy to illuminate the interior spaces in a building. In the nineteenth century, electric lighting was considered an alternative technology to daylighting. Today, the situation is reversed, primarily due to the economics of energy use and conservation. However, there are good physiological reasons for using daylight as an illuminant. The quality of daylight matches the human eye's response, thus permitting lower light levels for task comfort, better color rendering, and clearer object discrimination (Robbins 1986; McCluney 1998; Clay 2001).

### 41.5.1 Lighting Terms and Units

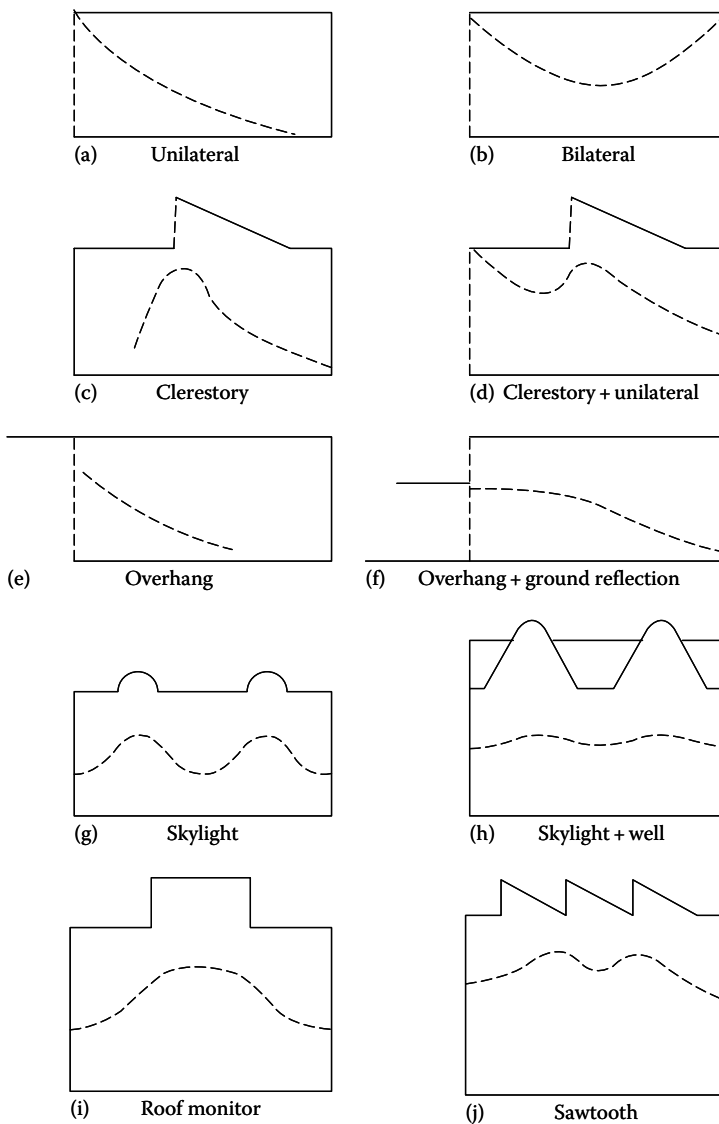

Measurement of lighting level is based on the *standard candle*, where the lumen (lm), the unit of luminous flux ( $\phi$ ), is defined as the rate of luminous energy passing through a 1 m<sup>2</sup> area located 1 m from the candle. Thus, a standard candle generates  $4\pi$  lumens, which radiate away in all directions. The illuminance ( $E$ ) on a surface is defined as the luminous flux on the surface divided by the surface area,  $E = \phi/A$ . Illuminance is measured in either lux (lx), as lm/m<sup>2</sup>, or footcandles (fc), as lm/ft.<sup>2</sup>.

Determination of the daylighting available at a given location in a building space at a given time is important to evaluate the reduction possible in electric lighting and the associated impact on heating and cooling loads. Daylight provides about 110 lm/W of solar radiation, fluorescent lamps about 75 lm/W of electrical input, and incandescent lamps about 20 lm/W; thus, daylighting generates only half to one-fifth the heating that equivalent electric lighting does, significantly reducing the building cooling load.

### 41.5.2 Approach to Daylighting Design

Aperture controls such as blinds and drapes are used to moderate the amount of daylight entering the space, as are the architectural features of the building itself (glazing type, area, and orientation; overhangs and wingwalls; lightshelves; etc.). Many passive and *active* reflective, concentrating, and diffusing devices are available to specifically gather and direct both the direct and diffuse components of daylight to areas within the space (Kinney et al. 2005). Electric-lighting dimming controls are used to adjust the electric light level based on the quantity of daylighting. With these two types of controls (aperture and lighting), the electric lighting and cooling energy use and demand, as well as cooling system sizing, can be reduced. However, the determination of the daylighting position and time illuminance value within the space is required before energy usage, and demand reduction calculations can be made.

Daylighting design approaches use both solar beam radiation (referred to as sunlight) and the diffuse radiation scattered by the atmosphere (referred to as skylight) as sources for interior lighting, with historical design emphasis being on utilizing skylight. Daylighting is provided through a variety of glazing features, which can be grouped as sidelighting (light enters via the side of the space) and toplighting (light enters from the ceiling area). Figure 41.15 illustrates several architectural forms producing sidelighting and toplighting, with the dashed lines representing the illuminance distribution within the space. The calculation of work-plane illuminance

**FIGURE 41.15**

(a–j) Examples of sidelighting and toplighting architectural features (dashed lines represent illuminance distributions). (From Murdoch, J.B., *Illumination Engineering—From Edison's Lamp to the Laser*, Macmillan, New York, 1985.)

depends on whether sidelighting and/or toplighting features are used and the combined illuminance values are additive.

### 41.5.3 Sun-Window Geometry

The solar illuminance on a vertical or horizontal window depends on the position of the sun relative to that window. In the method described here, the sun and sky illuminance values are determined using the sun's altitude angle ( $\alpha$ ) and the sun-window azimuth

angle difference ( $\Phi$ ). These angles need to be determined for the particular time of day, day of year, and window placement under investigation.

#### 41.5.3.1 Solar Altitude Angle

The solar altitude angle,  $\alpha$ , is the angle swept out by a person's arm when pointing to the horizon directly below the sun and then raising the arm to point at the sun. The equation to calculate solar altitude,  $\alpha$ , is

$$\sin \alpha = \cos L \delta \cos H + \sin L \sin \delta, \quad (41.22)$$

where

$L$  is the local latitude (degrees)

$\delta$  is the earth–sun declination (degrees) given by  $\delta = 23.45 \sin[360(n - 81)/365]$

$n$  is the day number of the year

$H$  is the hour angle (degrees) given by

$$H = \frac{(12 \text{ noon} - \text{time}) \text{ min}}{4}; \quad (+, \text{morning}, -, \text{afternoon}). \quad (41.23)$$

#### 41.5.3.2 Sun-Window Azimuth Angle Difference

The difference between the sun's azimuth and the window's azimuth,  $\Phi$ , needs to be calculated for vertical window illuminance. The window's azimuth angle,  $\gamma_w$ , is determined by which way it faces, as measured from south (east of south is positive, westward is negative). The solar azimuth angle,  $\gamma_s$ , is calculated by

$$\sin \gamma_s = \frac{\cos \delta \sin H}{\cos \alpha}. \quad (41.24)$$

The sun-window azimuth angle difference,  $\Phi$ , is given by the absolute value of the difference between  $\gamma_s$  and  $\gamma_w$ :

$$\Phi = |\gamma_s - \gamma_w|. \quad (41.25)$$

#### 41.5.4 Daylighting Design Methods

To determine the annual lighting energy saved ( $ES_L$ ), calculations using the lumen method described later should be performed on a monthly basis for both clear and overcast days for the space under investigation. Monthly weather data for the site would then be used to prorate clear and overcast lighting energy demands monthly. Subtracting the calculated daylighting illuminance from the design illuminance leaves the supplementary lighting needed, which determines the lighting energy required.

The approach in the following method is to calculate the *sidelighting* and the *skylighting* of the space separately and then combine the results. This procedure has been computerized (Lumen II/Lumen Micro) and includes many details of controls, daylighting technologies, and weather. ASHRAE (1993) lists many of the methods and simulation techniques currently used with daylighting and its associated energy effects.

**FIGURE 41.16**

Location of illumination points within the room (along centerline of window) determined by lumen method of sidelighting.

#### 41.5.4.1 Lumen Method of Sidelighting (Vertical Windows)

The lumen method of sidelighting calculates interior horizontal illuminance at three points, as shown in Figure 41.16, at the 30 in. (0.76 m) work-plane on the room-and-window centerline. A vertical window is assumed to extend from 36 in. (0.91 m) above the floor to the ceiling. The method accounts for both direct and ground-reflected sunlight and skylight, so both horizontal and vertical illuminances from sun and sky are needed. The steps in the lumen method of sidelighting are presented next.

As mentioned, the incident direct and ground-reflected window illuminances are normally calculated for both a cloudy and a clear day for representative days during the year (various months), as well as for clear or cloudy times during a given day. Thus, the interior illumination due to sidelighting and skylighting can then be examined for effectiveness throughout the year.

**Step 1: Incident direct sky and sun illuminances**—The solar altitude and sun-window azimuth angle difference are calculated for the desired latitude, date, and time using Equations 41.22 and 41.25, respectively. Using these two angles, the total illuminance on the window ( $E_{sw}$ ) can be determined by summing the direct sun illuminance ( $E_{uw}$ ) and the direct sky illuminance ( $E_{kw}$ ), each determined from the appropriate graph in Figure 41.17.

**Step 2: Incident ground-reflected illuminance**—The sun illuminance on the ground ( $E_{ug}$ ), plus the overcast or clear sky illuminance ( $E_{kg}$ ) on the ground, makes up the total horizontal illuminance on the ground surface ( $E_{sg}$ ). A fraction of the ground surface illuminance is then considered diffusely reflected onto the vertical window surface ( $E_{gw}$ ), where gw indicates from the ground to the window.

The horizontal ground illuminances can be determined using Figure 41.18, where the clear sky plus sun case and the overcast sky case are functions of solar altitude. The fractions of the ground illuminance diffusely reflected onto the window depend on the reflectivity ( $\rho$ ) of the ground surface (see Table 41.6) and the window-to-ground surface geometry.

**FIGURE 41.17**

Illuminance on a vertical surface from (a) direct sunlight and from (b–e) skylight for various sun-window azimuth angle differences. (From IES, *Lighting Handbook, Applications Volume*, Illumination Engineering Society, New York, 1987.)

**FIGURE 41.18**

Horizontal illuminance for overcast sky, clear sky, direct sun, and clear sky plus direct sun. (From Murdoch, J.B., *Illumination Engineering—From Edison's Lamp to the Laser*, Macmillan, New York, 1985.)

If the ground surface is considered uniformly reflective from the window outward to the horizon, then the illuminance on the window from ground reflection is

$$E_{gw} = \frac{\rho E_{sg}}{2}. \quad (41.26)$$

A more complicated ground-reflection case is illustrated in Figure 41.19, where multiple *strips* of differently reflecting ground are handled using the angles to the window where a strip's illuminance on a window is calculated by

$$E_{gw(\text{strip})} = \frac{\rho_{\text{strip}} E_{sg}}{2} (\cos \theta_1 - \cos \theta_2). \quad (41.27)$$

**FIGURE 41.19**

Geometry for ground *strips*. (From Murdoch, J.B., *Illumination Engineering—From Edison's Lamp to the Laser*, Macmillan, New York, 1985.)

And the total reflected onto the window is the sum of the strip illuminances:

$$E_{\text{gw}} = \frac{E_{\text{sg}}}{2} [\rho_1(\cos 0 - \cos \theta_1) + \rho_2(\cos \theta_1 - \cos \theta_2) + \cdots + \rho_n(\cos \theta_{n-1} - \cos 90)]. \quad (41.28)$$

*Step 3: Luminous flux entering space*—The direct sky–sun and ground-reflected luminous fluxes entering the building are attenuated by the transmissivity of the window. Table 41.7 presents the transmittance fraction ( $\tau$ ) of several window glasses. The fluxes entering the space are calculated from the total sun–sky and the ground-reflected illuminances by using the area of the glass,  $A_w$ :

$$\begin{aligned} \phi_{\text{sw}} &= E_{\text{sw}} \tau A_w \\ \phi_{\text{gw}} &= E_{\text{gw}} \tau A_w \end{aligned} \quad (41.29)$$

*Step 4: Light loss factor*—The light loss factor ( $K_m$ ) accounts for the attenuation of luminous flux due to dirt on the window (WDD, window dirt depreciation) and on the room surfaces (RSDD, room surface dirt depreciation). WDD depends on how often the window is cleaned, but a 6-month average for offices is 0.83 and for factories is 0.71 (Murdoch 1985).

The RSDD is a more complex calculation involving time between cleanings, the direct–indirect flux distribution, and room proportions. However, for rooms cleaned regularly, RSDD is around 0.94, and for once-a-year-cleaned dirty rooms, the RSDD would be around 0.84.

The light loss factor is the product of the preceding two fractions:

$$K_m = (\text{WDD})(\text{RSDD}). \quad (41.30)$$

**Step 5: Work-plane illuminances**—As discussed earlier, Figure 41.16 illustrates the location of the work-plane illuminances determined with this lumen method of sidelighting. The three illuminances (max, mid, min) are determined using two coefficients of utilization, the  $C$  factor, and the  $K$  factor. The  $C$  factor depends on room length and width and wall reflectance. The  $K$  factor depends on ceiling–floor height, room width, and wall reflectance. Tables 41.8 through 41.10 presents  $C$  and  $K$  values for the three cases of incoming fluxes: sun plus clear sky, overcast sky, and ground reflected. Assumed ceiling and floor reflectances are given for this case with no window controls (shades, blinds, overhangs, etc.). These further window control complexities can be found in Libbey-Owens-Ford Company (1976), IES (1987), and others. A reflectance of 70% represents light-colored walls, with 30% representing darker walls.

The work-plane max, mid, and min illuminances are each calculated by adding the sun-sky and ground-reflected illuminances, which are given by

$$\begin{aligned} E_{sp} &= \phi_{sw} C_s K_s K_m, \\ E_{gp} &= \phi_{gw} C_g K_g K_m, \end{aligned} \quad (41.31)$$

where the “sp” and “gp” subscripts refer to the sky-to-work-plane and ground-to-work-plane illuminances.

### Example 41.9

Determine the clear-sky illuminances for a 30 ft. long, 30 ft. wide, 10 ft. high room with a 20 ft. long window with a 3 ft. sill. The window faces 10°E of south, the building is at 32°N latitude, and it is January 15 at 2 p.m. The ground cover outside is grass, the glass is 1/4 in. clear, and the walls are light colored.

### Solution

Following the steps in the *sidelighting* method

Step 1: With  $L = 32$ ,  $n = 15$ ,  $H = (12 - 14)60/4 = -30$ ,

$$\delta = 23.45 \sin[360(15 - 81)/365] = -21.3^\circ.$$

Then, Equation 41.22 yields  $\alpha = 41.7^\circ$ , Equation 41.24 yields  $\gamma_s = -38.7^\circ$ , and Equation 41.25 yields

$$\Phi = |-38.7 - (+10)| = 48.7^\circ.$$

From Figure 41.17 with  $\alpha = 41.7^\circ$  and  $\Phi = 48.7^\circ$

- (a) For clear sky (winter, no sun):  $E_{kw} = 875$  fc.
- (b) For direct sun:  $E_{uw} = 4,100$  fc.
- (c) Total clear sky plus direct:  $E_{sw} = 4,975$  fc.

(Note: A high  $E_{uw}$  value probably indicates a glare situation!)

Step 2: Horizontal illuminances from Figure 41.18:  $E_{sg} = 4007$  fc.

Then, Equation 41.26 yields, with  $\rho_{grass} = 0.06$ ,  $E_{gw} = 222$  fc.

Step 3: From Equation 41.29, with  $\tau = 0.87$  and  $A_w = 140$  ft.<sup>2</sup>,

$$\Phi_{sw} = 4975(0.87)(140) = 605,955 \text{ lm.}$$

$$\Phi_{gw} = 222(0.87)(140) = 27,040 \text{ lm.}$$

Source: IES, 1979.  
<sup>a</sup> Ceiling reflectance, 80%; floor reflectance, 30%.

Step 4: For a clean office room,

$$K_m = (0.83)(0.94) = 0.78.$$

Step 5: From Tables 41.8 through 41.10, for 30 ft. width, 30 ft. length, 10 ft. ceiling, and wall reflectivity 70%,

a. Clear sky

$$C_{s, \max} = 0.0137; K_{s, \max} = 0.125,$$

$$C_{s, \text{mid}} = 0.0062; K_{s, \text{mid}} = 0.110,$$

$$C_{s, \min} = 0.0047; K_{s, \min} = 0.107.$$

b. Ground reflected

$$C_{g, \max} = 0.0098; K_{g, \max} = 0.140.$$

$$C_{g, \text{mid}} = 0.0062; K_{g, \text{mid}} = 0.107.$$

$$C_{g, \min} = 0.0041; K_{g, \min} = 0.0984.$$

Then, using Equation 41.31,

$$E_{\text{sp}, \max} = 605,955(0.0137)(0.125)(0.78) = 809 \text{ fc.}$$

$$E_{\text{sp}, \text{mid}} = 605,955(0.0062)(0.110)(0.78) = 322 \text{ fc.}$$

$$E_{\text{sp}, \min} = 605,955(0.0047)(0.107)(0.78) = 238 \text{ fc.}$$

$$E_{\text{gp}, \max} = 27,040(0.0098)(0.140)(0.78) = 29 \text{ fc.}$$

$$E_{\text{gp}, \text{mid}} = 27,040(0.0062)(0.107)(0.78) = 14 \text{ fc.}$$

$$E_{\text{gp}, \min} = 27,040(0.0041)(0.0984)(0.78) = 9 \text{ fc.}$$

Thus,

$$E_{\max} = 838 \text{ fc.}$$

$$E_{\text{mid}} = 336 \text{ fc.}$$

$$E_{\min} = 247 \text{ fc.}$$

#### 41.5.4.2 Lumen Method of Skylighting

The lumen method of skylighting calculates the average illuminance at the interior work-plane provided by horizontal skylights mounted on the roof. The procedure for skylighting is generally the same as that described earlier for sidelighting. As with windows, the illuminance from both overcast sky and clear sky plus sun cases is determined for specific days in different seasons and for different times of the day, and a judgment is then made as to the number and size of skylights and any controls needed.

The procedure is presented in four steps: (1) finding the horizontal illuminance on the outside of the skylight, (2) calculating the effective transmittance through the skylight and

**TABLE 41.11**

Flat-Plate Plastic Material Transmittance for Skylights

Type	Thickness (in.)	Transmittance (%)
Transparent	1/8–3/16	92

Light translucent	3/16	68

Source: Murdoch, J.B., *Illumination Engineering—From Edison's Lamp to the Laser*, Macmillan, New York, 1985.

its well, (3) figuring the interior space light loss factor and the utilization coefficient, and finally, (4) calculating illuminance on the work-plane.

*Step 1: Horizontal sky and sun illuminances*—The horizontal illuminance value for an over-cast sky or a clear sky plus sun situation can be determined from Figure 41.18 knowing only the solar altitude.

*Step 2: Net skylight transmittance*—The transmittance of the skylight is determined by the transmittance of the skylight cover(s), the reflective efficiency of the skylight well, the net-to-gross skylight area, and the transmittance of any light-control devices (lenses, louvers, etc.).

The transmittance for several flat-sheet plastic materials used in skylight domes is presented in Table 41.11. To get the effective dome transmittance ( $T_D$ ) from the flat-plate transmittance ( $T_F$ ) value (AAMA 1977), use

$$T_D = 1.25T_F(1.18 - 0.416T_F). \quad (41.32)$$

If a double-domed skylight is used, then the single-dome transmittances are combined as follows (Pierson 1962):

$$T_D = \frac{T_{D1}T_{D2}}{T_{D1}T_{D2} - T_{D1}T_{D2}}. \quad (41.33)$$

If the diffuse and direct transmittances for solar radiation are available for the skylight glazing material, it is possible to follow this procedure and determine diffuse and direct dome transmittances separately. However, this difference is usually not a significant factor in the overall calculations.

The efficiency of the skylight well ( $N_w$ ) is the fraction of the luminous flux from the dome that enters the room from the well. The well index (WI) is a geometric index (height,  $h$ ; length,  $l$ ; width,  $w$ ) given by

$$WI = \frac{h(w+l)}{2wl}, \quad (41.34)$$

and WI is used with the well-wall reflectance value in Figure 41.20 to determine the well efficiency,  $N_w$ .

**FIGURE 41.20**

Efficiency of well versus well index. (From IES (Illumination Engineering Society), *Lighting Handbook, Applications Volume*, Illumination Engineering Society, New York, 1987)

With  $T_D$  and  $N_w$  determined, the net skylight transmittance for the skylight and well is given by

$$T_n = T_D N_w R_A T_C \quad (41.35)$$

where

$R_A$  is the ratio of net-to-gross skylight areas

$T_C$  is the transmittance of any light-controlling devices

*Step 3: Light loss factor and utilization coefficient*—The light loss factor ( $K_m$ ) is again defined as the product of the RSDD and the skylight direct depreciation (SDD) fractions, similar to Equation 41.30. Following the reasoning for the sidelighting case, the RSDD value for clean rooms is around 0.94 and 0.84 for dirty rooms. Without specific data indicating otherwise, the SDD fraction is often taken as 0.75 for office buildings and 0.65 for industrial areas.

The fraction of the luminous flux on the skylight that reaches the work-plane ( $K_u$ ) is the product of the net transmittance ( $T_n$ ) and the room coefficient of utilization (RCU).

Dietz et al. (1981) developed RCU equations for office and warehouse interiors with ceiling, wall, and floor reflectances of 75%, 50%, and 30%, and 50%, 30%, and 20%, respectively.

$$\text{RCU} = \frac{1}{1 + A(\text{RCR})^B} \quad \text{if } \text{RCR} < 8, \quad (41.36)$$

where

$A$  is 0.0288 and  $B$  is 1.560 for offices

$A$  is 0.0995 and  $B$  is 1.087 for warehouses

Room cavity ratio (RCR) is given by

$$\text{RCR} = \frac{5h_c(l + w)}{lw}, \quad (41.37)$$

where

$h_c$  is the ceiling height above the work-plane

$l$  and  $w$  are the room length and width, respectively

The RCU is then multiplied by the previously determined  $T_n$  to give the fraction of the external luminous flux passing through the skylight and incident on the workplace:

$$K_u = T_n(\text{RCU}). \quad (41.38)$$

*Step 4: Work-plane illuminance*—The illuminance at the work-plane ( $E_{\text{TWP}}$ ) is given by

$$E_{\text{TWP}} = E_H \left( \frac{A_T}{A_{\text{WP}}} \right) K_u K_m, \quad (41.39)$$

where

$E_H$  is the horizontal overcast or clear sky plus sun illuminance from step 1

$A_T$  is the total gross area of the skylights (number of skylight times skylight gross area)

$A_{\text{WP}}$  is the work-plane area (generally room length times width)

Note that in Equation 41.39, it is also possible to fix the  $E_{\text{TWP}}$  at some desired value and determine the required skylight area.

Rules of thumb for skylight placement for uniform illumination include 4%–8% of roof area and spacing less than 1.5 times ceiling-to-work-plane distance between skylights (Murdoch 1984).

#### Example 41.10

Determine the work-plane *clear sky plus sun* illuminance for a  $30 \times 30 \times 10$  ft.<sup>3</sup> office with 75% ceiling, 50% wall, and 30% floor reflectance with four  $4 \times 4$  ft.<sup>2</sup> double-domed skylights at 2:00 p.m. on January 15 at 32° latitude. The skylight well is 1 ft. deep at with 60% reflectance walls, and the outer- and inner-dome flat-plastic transmittances are 0.85 and 0.45, respectively. The net skylight area is 90%.

#### Solution

Follow the four steps in the lumen method for skylighting.

*Step 1:* Use Figure 41.18 with the solar altitude of 41.7° (calculated from Equation 41.26) for the clear sky plus sun curve to get horizontal illuminance:

$$E_H = 7400 \text{ fc.}$$

Step 2: Use Equation 41.32 to determine domed transmittances from the flat-plate plastic transmittances given

$$T_{D_1} = 1.25(0.85)[1.18 - 0.416(0.85)] = 0.89,$$

$$T_{D_2}(T_F = 0.45) = 0.56,$$

and use Equation 41.33 to get total dome transmittance from the individual dome transmittances:

$$T_D = \frac{(0.89)(0.56)}{(0.89) + (0.56) - (0.89)(0.56)} = 0.52.$$

To determine well efficiency, use  $WI = 0.25$  from Equation 41.34 with 60% wall reflectance in Figure 41.20 to give  $N_w = 0.80$ . With  $R_A = 0.90$ , use Equation 41.35 to calculate net transmittance:

$$T_n = (0.52)(0.80)(0.90)(1.0) = 0.37.$$

Step 3: The light loss factor is assumed to be from *typical* values in Equation 41.30:  $K_m = (0.75)(0.94) = 0.70$ . The room utilization coefficient is determined using Equations 41.36 and 41.37:

$$RCR = \frac{5(7.5)(30 + 30)}{(30)(30)} = 2.5,$$

$$RCU = [1 + 0.0288(2.5)^{1.560}]^{-1} = 0.89.$$

Equation 41.37 yields  $K_u = (0.37)(0.89) = 0.33$ .

Step 4: The work-plane illuminance is calculated by substituting these values into Equation 41.39:

$$E_{TWP} = 7400 \left[ \frac{4(16)}{30(30)} \right] 0.33(0.70),$$

$$E_{TWP} = 122 \text{ fc.}$$

#### 41.5.5 Daylighting Controls and Economics

The economic benefit of daylighting is directly tied to the reduction in lighting electrical energy operating costs. Also, lower cooling-system operating costs are possible due to the reduction in heating caused by the reduced electrical lighting load. The reduction in lighting and cooling system electrical power during peak demand periods could also beneficially affect demand charges.

The reduction of the design cooling load through the use of daylighting can also lead to the reduction of installed or first-cost cooling system dollars. Normally, economics dictate that an automatic lighting control system must take advantage of the reduced lighting/cooling effect, and the control system cost minus any cooling system cost savings should

be expressed as a *net* first cost. A payback time for the lighting control system (*net* or not) can be calculated from the ratio of first costs to yearly operating savings. In some cases, these paybacks for daylighting controls have been found to be in the range of 1–5 years for office building spaces (Rundquist 1991).

Controls, both aperture and lighting, directly affect the efficacy of the daylighting system. As shown in Figure 41.21, aperture controls can be architectural (overhangs, light shelves, etc.) and/or window shading devices (blinds, automated louvers, etc.). The aperture controls generally moderate the sunlight entering the space to maximize/minimize solar thermal gain, permit the proper amount of light for visibility, and prevent glare and beam radiation onto the workplace. Photosensor control of electric lighting allows the dimming (or shutting off) of the lights in proportion to the amount of available daylighting illuminance.

In most cases, increasing the solar gain for daylighting purposes, with daylighting controls, saves more in electrical lighting energy, and the cooling energy associated with the lighting then is incurred with the added solar gain (Rundquist 1991). In determining the annual energy savings total from daylighting,  $ES_T$ , the annual lighting energy saved from daylighting,  $ES_L$ , is added with the reduction in cooling system energy,  $\Delta ES_C$ , and with the negative of the heating system energy increase  $\Delta ES_H$ :

$$ES_T = ES_L + \Delta ES_C - \Delta ES_H. \quad (41.40)$$

A simple approach to estimating the heating and cooling energy changes associated with the lighting energy reduction is by using the fraction of the year associated with the cooling or heating season ( $f_C, f_H$ ) and the seasonal coefficient of performance ( $COP_C, COP_H$ ) of the cooling or heating equipment. Thus, Equation 41.40 can be expressed as

$$ES_T = ES_L + \frac{f_C ES_L}{COP_C} - \frac{f_H ES_L}{COP_H},$$

**FIGURE 41.21**

Daylighting system controls. (From Rundquist, R.A., *ASHRAE J.*, 11, 30–34, November 1991.)

$$ES_T = ES_L + \left( \frac{f_C}{COP_c} - \frac{f_H}{COP_H} \right). \quad (41.41)$$

It should be noted that the increased solar gain due to daylighting has not been included here but would reduce summer savings and increase winter savings. If it is assumed that the increased wintertime daylighting solar gain approximately offsets the reduced lighting heat gain, then the last term in Equation 41.41 becomes negligible.

To determine the annual lighting energy saved ( $ES_L$ ), calculations using the lumen method described earlier should be performed on a monthly basis for both clear and overcast days for the space under investigation. Monthly weather data for the site would then be used to prorate clear and overcast lighting energy demands monthly. Subtracting the calculated (controlled) daylighting illuminance from the design illuminance leaves the supplementary lighting needed, which determines the lighting energy required.

This procedure has been computerized and includes many details of controls, daylighting methods, weather, and heating and cooling load calculations. ASHRAE (1989) lists many of the methods and simulation techniques currently used with daylighting and its associated energy effects.

#### Example 41.11

A  $30 \times 20$  ft<sup>2</sup> space has a photosensor dimmer control with installed lighting density of 2.0 W/ft<sup>2</sup>. The required workplace illuminance is 60 fc, and the available daylighting illuminance is calculated as 40 fc on the summer peak afternoon. Determine the effect on the cooling system (adapted from Rundquist 1991).

*Solution.* The lighting power reduction is  $(2.0 \text{ W/ft}^2) (30 \times 20) \text{ ft}^2 \times (40 \text{ fc}/60 \text{ fc}) = 800 \text{ W}$ . The space cooling load would also be reduced by this amount (assuming CLF = 1.0):

$$\frac{800 \text{ W} \times 3.413 \text{ Btu h/W}}{12,000 \text{ Btu h/ton}} = 0.23 \text{ ton}.$$

Assuming 1.5 ton nominally installed for 600 ft<sup>2</sup> of space at \$2200/ton, the 0.23 ton reduction is *worth*  $0.23 \times \$2200/\text{ton} = \$506$ . The lighting controls cost about \$1/ft<sup>2</sup> of controlled area, so the net installed first cost is

$$\text{Net first cost} = \$600 \text{ controls} - \$500 \text{ A/C savings} = \$100.$$

Assuming the day-to-monthly-to-annual illuminance calculations gave a 30% reduction in annual lighting, the associated operating savings can be determined. Lighting energy savings are

$$ES_L = 0.30 \times 2.0 \text{ W/ft}^2 \times 600 \text{ ft}^2 \times 2500 \text{ h/year} = 900 \text{ kWh}.$$

Using Equation 41.41 to also include cooling energy saved due to lighting reduction (with  $COP_c = 2.5$ ,  $f_c = 0.5$ , and neglecting heating) gives

$$ES_T = 900(1 + 0.5/2.5 - 0) = 1080 \text{ kWh}.$$

At \$0.10 per kWh, the operating costs savings are  $\$0.10/\text{kWh} \times 1080 \text{ kWh} = \$108/\text{year}$ .

Thus, the simple payback is approximately 1 year (100/108) for the *net* situation and a little over 5.5 years (600/108) against the *controls* cost alone. It should also be noted that the 800 W lighting electrical reduction at peak hours, with an associated cooling energy reduction of  $800 \text{ W}/2.5 \text{ COP} = 320 \text{ W}$ , provides a peak demand reduction for the space of 1.1 kW, which can be used as the *first-cost savings* to offset control system costs.

---

## Glossary

**Active system:** A system employing a forced (pump or fan) convection heat transfer fluid flow.

**Daylighting:** The use of the sun's radiant energy for illumination of a building's interior space.

**Hybrid system:** A system with parallel passive and active flow systems or one using forced convection flow to distribute from thermal storage.

**Illuminance:** The density of luminous flux incident on a unit surface. Illuminance is calculated by dividing the luminous flux (in lumens) by the surface area ( $\text{m}^2$ ,  $\text{ft}^2$ ). Units are lux (lx) ( $\text{lumens}/\text{m}^2$ ) in SI and footcandles (fc) ( $\text{lumens}/\text{ft}^2$ ) in English systems.

**Luminous flux:** The time rate of flow of luminous energy (lumens). A lumen (lm) is the rate that luminous energy from a 1 candela (cd) intensity source is incident on a  $1 \text{ m}^2$  surface 1 m from the source.

**Passive cooling system:** A system using natural energy flows to transfer heat to the environmental sinks (ground, air, and sky).

**Passive heating system:** A system in which the sun's radiant energy is converted to heat by absorption in the system, and the heat is distributed by naturally occurring processes.

**Sidelighting:** Daylighting by light entering through the wall/side of a space.

**Skylight:** The diffuse solar radiation from a clear or overcast sky, excluding the direct radiation from the sun.

**Sunlight:** The direct solar radiation from the sun.

**Toplighting:** Daylighting by light entering through the ceiling area of a space.

## For Further Information

### General Background Information

The most complete basic reference for passive system heating design is still the 1980 Los Alamos Lab's *Passive Solar Design Handbook*, all three parts. The *ASHRAE Handbook of Fundamentals* is a good general introduction to passive cooling techniques and calculations, with an emphasis on evaporative cooling. *Passive Solar Buildings* and *Passive Cooling*, both published by MIT Press, contain a large variety of techniques and details concerning passive system designs and economics. All the major building energy simulation codes (DOE-2, EnergyPlus, TRNSYS, TSB13, etc) now include passive heating and cooling technologies.

The Illumination Engineering Society's *Lighting Handbook* presents the basis for and details of daylighting and artificial lighting design techniques. However, most texts on illumination present simplified format daylighting procedures. Currently used daylighting computer programs include various versions of Lumen Micro, Lightscape, and Radiance.

*Solar Today* magazine, published by the American Solar Energy Society, is a readily available source for current practice designs and economics, as well as a source for passive system equipment suppliers.

### Technical Publication Information

Many of the current and archival passive solar technical papers are found from the conference proceedings and journals associated with the International Solar Energy Society (ISES), its affiliated American Solar Energy Society (ASES), the American Society of Mechanical Engineering (ASME), and ASHRAE. Also, many of the early passive solar practitioners were architects and builders who published in their specific industry trade journals, as is still the case today. As an Internet search for passive solar articles today will reveal, there are several *new* energy/solar/sustainable technical journals that publish passive solar-related articles.

## 42.1 Introduction and Context

Solar energy has a high exergetic value since it originates from processes occurring at the sun's surface at a blackbody equivalent temperature of approximately 5777 K. Because of this, more than 93% of the energy may be theoretically converted to mechanical work by thermodynamic cycles (Winter et al., 1991) or to Gibbs free energy of chemicals by solarized chemical reactions (Kodama, 2003), including promising hydrogen production processes (Romero and Steinfeld, 2012). According to thermodynamics and Planck's equation, the conversion of solar heat to mechanical work or Gibbs free energy is limited by the Carnot efficiency, and therefore to achieve maximum conversion rates, the energy should be transferred to a thermal fluid, or reactants, at temperatures close to that of the sun.

Even though solar radiation is a source of high temperature and exergy at origin, with a high radiosity of 63 MW/m<sup>2</sup>, sun–earth geometrical constraints lead to a dramatic dilution of flux and to irradiance available for terrestrial use only slightly higher than 1 kW/m<sup>2</sup> and, consequently, supply of low temperatures to the thermal fluid. It is therefore an essential requisite for solar thermal power (STP) plants and high-temperature solar chemistry applications to make use of optical concentration devices that enable the thermal conversion to be carried out at high solar flux and with relatively little heat loss. A simplified model of an STP plant, also known as concentrating solar power (CSP) plant, is depicted in [Figure 42.1](#).

The optimum STP system design combines a relatively large, efficient optical surface (e.g., a field of high-reflectivity mirrors), harvesting the incoming solar radiation and concentrating it onto a solar receiver with a small aperture area. The solar receiver is a high-absorptance and high-transmittance, low-reflectance, radiative/convective heat exchanger that emulates as closely as possible the performance of a radiative blackbody. An ideal solar receiver would thus have negligible convection and conduction losses. In the case of an STP plant, the solar energy is transferred to a thermal fluid at an outlet temperature high enough to feed a heat engine or a turbine that produces electricity. The solar thermal element can be a parabolic-trough field, a linear Fresnel (LF) reflector field, a central receiver system (CRS), or a field of parabolic dishes, normally designed for a normal incident radiation of 800–900 W/m<sup>2</sup>. Annual normal incident radiation varies from 1600 to more than 3000 kWh/m<sup>2</sup>, allowing from 2000 to more than 3500 annual full-load operating hours with the solar element, depending on the available radiation at the particular site.

Solar transients and fluctuation in irradiance can be mitigated by using an oversized mirror field (solar multiple higher than 1) and then making use of the excess energy to load a thermal or chemical storage system. Hybrid plants with fossil backup burners connected in series or in parallel are also possible. The use of heat storage systems and fossil backup makes STP systems highly flexible for integration with conventional power plant design and

**FIGURE 42.1**

Flow diagram for a typical solar thermal power plant.

operation and for blending the thermal output with fossil fuel, biomass, and geothermal resources (Mancini et al., 1997). The use of large solar multiples with low-cost heat storage systems of up to 12 h (equivalent at nominal power) facilitates the design of secure-capacity plants supplying between 2000 and 6000 h of operation (equivalent at full load). In addition, hybridization is possible in conventional power plants by using a solar field as a booster or fuel saver in natural gas combined cycles and coal-fired Rankine plants, and may accelerate near-term deployment of projects due to improved economics and reduced overall project risk (Kolb, 1998). Hybridization of a natural gas combined-cycle plant with a solar field acting as a booster is called *integrated solar combined-cycle system (ISCCS)* plant. Three ISCCS plants were implemented in Kuraymat (Egypt), Hassi R'mel (Algeria), and Ain Beni Matar (Morocco) from 2009 to 2012. It is therefore evident that STP can currently supply dispatchable power and meet peaking and intermediate loads at an affordable electricity cost.

Additional advantages of STP are (Morse, 2000) the following:

- Proven capabilities, for example, 354 MW of trough plants in operation in California since 1985 have selectively demonstrated excellent performance, availability, a reduction in investment cost of almost 50%, and significant reductions in O&M cost.
- Modular and thus suitable for large central facilities in the hundreds of MW down to distributed generation in the tens of kW.
- Can be rapidly deployed using entirely domestic resources and existing infrastructure.

- Scale can be significant enough to impact climate-change targets.
- Suitable for both independent power producer and turnkey projects.
- Proven potential for further cost reduction, including those resulting from economies of scale, that is, from mass production of glass, steel, etc.

Electricity production with concentrating solar thermal technologies is not an innovation of the last few years. The French mathematician Augustin Mouchot built a machine able to convert CSP into mechanical work to run a printing press by generating steam (Pifre, 1882). A showcase with a parabolic dish connected to an engine and producing electricity was presented in Paris in 1878. Other remarkable pioneers that deserve recognition are Ericsson (1888), Eneas (1901), Shuman (1913), and Francia (1968). However, solar thermal concentrating technologies were not sufficiently developed for industrial use till the 1970s. The oil crisis triggered R&D on concentrating STP, and several pilot plants were built and tested around the world during the 1980s (Winter et al., 1991). Nevertheless, most of these experiences ended without having reached the final goal of making the concentrating solar thermal technologies commercial. The only exception is the experience accumulated by the LUZ International company in the nine 354 MW total capacity Solar Electricity Generating System (SEGS) plants, which were built between 1984 and 1991, and which have injected more than 16,000 GWh into the Southern California grid since then. All SEGS plants were developed, financed, built, and are still operated on a purely private basis.

However, after the inauguration of the last SEGS plant built by LUZ in 1990 (the plant SEGS IX), no new commercial STP plant was built until 2007, when the plant PS10 was built in Spain and Nevada Solar One was built in the United States. The favorable feed-in tariff implemented in Spain in 2007 led to the construction of more than 40 STP plants in the period 2007–2013, with a total installed power higher than 2.2 GW<sub>e</sub>. Public support in the United States led to the construction of more STP plants during the second decade of this century (e.g., SOLANA and Ivanpah plants). Important initiatives are launched in different countries like Chile, South Africa, Morocco, Algeria, India, and others. The main reasons why no commercial plant was built in the period 1991–2007 were (Becker et al., 2002) as follows:

- Financial uncertainties caused by delayed renewal of favorable tax provisions for solar systems in California
- Financial problems and subsequent bankruptcy of the U.S./Israeli LUZ group in 1991, the first commercial developer of private solar power projects
- Rapid drop in fossil energy prices followed by years of worldwide stability at those low levels
- The large STP station unit capacities required to meet competitive conditions for the generation of bulk electricity, resulting in financial constraints due to their inherently large share of capital costs
- Rapidly decreasing depreciation times of capital investments in power plants due to the deregulation of the electricity market and the worldwide shift to private investor ownership of new plant projects
- Drops in cost and enhanced efficiencies of installed conventional power plants, particularly in combined-cycle power plants
- Lack of a favorable financial and political environment for the development of STP plant project initiatives in sunbelt countries

In spite of that, the Cost Reduction Study for Solar Thermal Power Plants prepared for the World Bank in early 1999 (Enermodal, 1999) already concluded that the potential STP market could reach an annual installation rate of 2000 MW of electricity. In the foregoing scenario, this rate would be reached by 2020. Assuming that advanced low-cost STP systems were likely to offer energy output at an annual capacity factor of 0.22 or more, the contribution of STP would be about 24–36 TWh of electricity by 2020 and 1600–2400 TWh by 2050. However, the same study estimated that the current STP capital cost is 2.5–3.5 times higher than the capital cost of a conventional fossil-fueled thermal power plant and showed that the price of electricity generation is between two and four times the conventional generation price. But the potential learning curve is enormous, and technology roadmaps predict that over a 60% cost reduction is possible by 2020, when production costs for solar-only plants could descend below €0.12 per kWh, by combining innovation, mass production, and scaling-up factors (Sargent & Lundy, 2003; Pitz-Paal et al., 2005; Kearney and ESTELA, 2010; IRENA, 2012).

Given the huge solar resource on Earth and the earlier-mentioned cost scenarios, STP is foreseen to impact enormously on the world's bulk power supply by the middle of the century. In Southern Europe alone, the technical potential of STP is estimated at 2000 TWh and in Northern Africa beyond any quantifiable guess (Nitsch et al., 2004). Worldwide, the exploitation of less than 1% of the total STP plant potential would be enough to meet the recommendations of the United Nations "Intergovernmental Panel on Climate Change for Long-Term Climate Stabilization" (Aringhoff et al., 2003; Philibert, 2004). In contrast to conventional fossil plants, concentrating STP plants do not produce CO<sub>2</sub> during operation and are therefore suitable to meet the challenge of keeping standards of living without compromising environmental issues. One MW installed of concentrating STP avoids 688 tons of CO<sub>2</sub> compared to a combined-cycle conventional plant and 1360 tons of CO<sub>2</sub> compared to a conventional coal/steam plant. A 1 m<sup>2</sup> mirror in the primary solar field produces 400 kWh of electricity/year, avoids 12 tons of CO<sub>2</sub>, and contributes to a 2.5 tons savings of fossil fuels during its 25 year operation lifetime. The energy payback time of CSP systems is less than 1 year, and most solar-field materials and structures can be recycled and used again for further plants.

But in terms of electricity grid and quality of bulk power supply, it is the ability to provide dispatchability on demand that makes STP stand out from other renewable energy technologies like PV or wind. Even though the sun is an intermittent source of energy, STP systems offer the advantage of being able to run the plant continuously at a predefined load. Thermal energy storage systems store excess thermal heat collected by the solar field. A typical storage concept consists of two storage tanks filled with a liquid storage medium at different temperatures (Falcone, 1986). When storage is charged, the medium is pumped from the *cold* to the *hot* tank being heated up (directly or indirectly) by the solar heat collected. When storage is discharged, the medium is pumped from the *hot* to the *cold* tank extracting the heat in a steam generator that drives the power cycle. Storage systems, alone or in combination with some fossil fuel backup, keep the plant running under full-load conditions. When solar thermal energy is stored, it is already clear hours in advance when the plant will stop supplying energy. [Figure 42.2](#) shows how stable operation can be extended for several hours after sunset. With an appropriate weather forecast, a 24–48 h prediction of solar capacity appears to be feasible. It should be kept in mind that thermal energy storage systems are designed only to shift the energy a few hours (e.g., from daytime to evening) or days. It cannot compensate the seasonal difference in the solar input, which comes from the changing

**FIGURE 42.2**

Extended operation with an only-solar STP plant by using some hours of thermal energy storage.

**FIGURE 42.3**

Example of operational strategy for an STP plant with thermal storage and fuel backup to maintain a constant firm capacity supply round the clock.

duration of sunlight from summer to winter, but with an appropriately small percentage of fossil fuel hybridization, secure capacity can be ensured and investment can be reduced by 30% (Kolb, 1998). Figure 42.3 shows an STP plant providing secure capacity. The thermal storage system supplies most of the energy required by the turbine after sunset. Overnight and early in the morning, operation is ensured by fossil fuel backup. The example shown is a *fuel saver* scheme in which solar energy is used to save fossil fuel during the daytime. There are also other options, like the *power booster* scheme, in which the fossil burner is kept constant all the time, and solar energy is fed into the turbine for peaks during solar hours, in which case the power block can absorb power increments to some extent.

This specific capability of storing high-temperature thermal energy leads to early economically competitive design options, since only the solar portion has to be oversized. This means that there is an incremental cost for the storage system and additional solar field, while the size of the conventional part of the plant (power block) remains the same. Furthermore, storage system efficiencies are high, over 95%. Specific investment costs of less than \$10–\$30 per kWh<sub>th</sub>, resulting in \$25–\$75 per

kWh<sub>e</sub>, are possible today. This STP plant feature is tremendously relevant, since penetration of solar energy into the bulk electricity market is possible only when substitution of intermediate-load power plants of about 4000–5000 h/year is achieved (Pitz-Paál et al., 2005b).

New opportunities are opening up for STP as a result of the global search for clean energy solutions, and new plants are being constructed after more than two decades of interruption (IEA, 2010). Feed-in tariffs, green portfolios, and other environmentally related incentives have been pushing since 2006 for new projects to become a reality in Spain, the United States, Australia, Algeria, and elsewhere (IRENA, 2012).

## 42.2 Solar Concentration and STP Systems

### 42.2.1 Why Use Concentrating Solar Energy Systems?: Dependence of Efficiency with $T$

Explained simply, solar concentration allows *higher-quality* energy to be collected, since higher temperatures, and thereby greater capacity for generating mechanical work, can be achieved. According to the second law of thermodynamics, the higher the operating temperature,  $T_{op}$ , is, the better is the efficiency of a heat engine (e.g., the one in an STP plant). The heat engine operating temperature  $T$  is directly dependent on the solar receiver, or absorber, outlet temperature.

Moreover, with solar concentration, the receiver–absorber aperture area can be reduced, minimizing infrared losses, which are directly proportional to the emission surface for a given operating temperature. Finally, concentration of solar radiation leads to greater technological development of the absorber and, consequently, to a greater cost reduction potential.

Maximum attainable temperatures in typical fossil fuel burners are on the order of 2100°C. For nuclear fission, the expected maximum useful temperature in Generation-IV gas-cooled reactors is below 1000°C. If higher temperatures are required, a classical solution is to make use of electricity as the heating source, for example, in electric furnaces. The use of electricity for this purpose represents about a 50%–75% conversion loss. In contrast, solar radiation has the potential to reach temperatures close to the apparent temperature of the sun (5777 K).

Solar concentrating systems are characterized by the use of devices, like mirrors or lenses, able to redirect the incident solar radiation received onto a particular surface, collector surface  $A_c$ , and concentrate it onto a smaller surface, absorber surface  $A_{abs}$ , or absorber. The quotient of these two areas is called the geometric concentration ratio,  $\text{Conc} = A_{abs}/A_c$ .

Let us assume a simplified model of an STP plant, like the one represented in [Figure 42.1](#), made up of an ideal optical concentrator, a solar receiver performing as a blackbody and therefore having only emission losses (cavity receivers and volumetric receivers theoretically approach this condition), and a turbine or heat engine with Carnot ideal efficiency. System efficiency will depend on the balance of radiative and convective losses in the solar receiver, as shown in Equation 42.1. When the concentrated solar flux impinges on the absorber, its temperature augments and, simultaneously, radiation losses from the absorber surface to the ambient increase. With a thermal fluid cooling the absorber,

when equilibrium, or steady state, is reached, the solar radiation gain equals the sum of infrared emission losses plus the useful energy rejected.

$$\frac{Q_{gain}^*}{A} = \alpha * \text{Conc} * \phi - \sigma * \varepsilon * (T_{abs}^4 - T_{amb}^4) \quad (42.1)$$

where

$Q_{gain}$  is the power gain or useful power outlet from solar receiver (W)

$A$  is the absorber aperture area (m<sup>2</sup>)

$\alpha$  is the hemispherical absorptivity of absorber

Conc is the geometrical concentration ratio

$\sigma$  is the Stefan–Boltzmann constant (=5.67E–08 W/m<sup>2</sup> K<sup>4</sup>)

$\varepsilon$  is the hemispherical emissivity of absorber

$\phi$  is the direct normal irradiance (W/m<sup>2</sup>)

$T_{abs}$  is the temperature (homogeneous) of the absorber (K)

$T_{amb}$  is the effective temperature of ambient or atmosphere *viewed* by the absorber (K)

Solar receiver efficiency, defined as the quotient of power gain flux and concentrated solar radiation flux incident on the receiver (absorber), can be formulated as

$$\eta_{rec} = \frac{(Q_{gain}^*/A)}{\text{Conc} * \phi} \quad (42.2)$$

By substituting Equation 42.1 in 42.2, the dependence of thermal efficiency versus parameters and variables of the receiver is observed.

$$\eta_{rec} = \alpha - \sigma * \varepsilon * \frac{(T_{abs}^4 - T_{amb}^4)}{\text{Conc} * \phi} \quad (42.3)$$

Equation 42.3 is plotted for different concentration ratios in [Figure 42.4](#). This graphic representation, valid for flat absorbers, leads to the following conclusions:

- The maximum theoretical optical efficiency (when  $T_{abs} \geq T_{amb}$ ) is the effective absorptivity of the receiver,  $\alpha$ .
- The higher the incident solar flux (Conc\* $\phi$ ), the better the optical efficiency.
- The higher the absorber temperature is, the higher the radiative loss is and, therefore, the lower the optical efficiency.
- The higher the effective emissivity,  $\varepsilon$ , the lower the optical efficiency.

Figure 42.4 shows the evolution of optical efficiency versus temperature and concentration ratio. It also includes the Carnot cycle efficiency, defined as

$$\eta_{Carnot} = \frac{T_{abs} - T_{amb}}{T_{abs}} \quad (42.4)$$

The Carnot cycle efficiency is the ideal efficiency (for reversible processes) that, as observed, increases with temperature and sets the thermodynamic limit of the conversion efficiency of the outlet heat delivered to mechanical work by the receiver.

**FIGURE 42.4**

Efficiency of the solar receiver versus  $T_{abs}$  and versus solar concentration ratio, assuming  $T_{amb} = 20^\circ\text{C}$ ,  $\phi = 770 \text{ W/m}^2$ , and  $\alpha = \varepsilon = 0.95$ .

As ideal absorber temperature increases, thermal radiation losses increase as well. When losses and gains are equal, the net useful heat is zero, and the receiver should have achieved the maximum temperature or stagnation temperature. The stagnation temperature is described in the following equation and [Figure 42.5](#):

$$T_{abs\_max} = \left[ \frac{\alpha * \text{Conc} * \phi}{\varepsilon * \sigma} + T_{amb}^4 \right]^{1/4} \quad (42.5)$$

It should be noted that

- A nonselective absorber ( $\alpha = \varepsilon = 1$ ) reaches  $95^\circ\text{C}$  in stagnation conditions, without concentration and for the given solar irradiance.
- A selective coating can enable much higher stagnation temperatures to be reached. For instance, at  $\text{Conc} = 1000$ , the maximum temperature is higher than  $1600^\circ\text{C}$ , for  $\alpha/\varepsilon = 1$ , and about  $3200^\circ\text{C}$ , for  $\alpha/\varepsilon = 10$  ( $\alpha = 1$ ;  $\varepsilon = 0.1$ ).

From these correlations, it may clearly be concluded that, in terms of solar receiver efficiency, high solar concentrations and low temperatures are the best compromise. For a given concentration ratio, there is an absorber threshold temperature at which radiation losses increase dramatically. However, when analyzing a theoretical STP system, the

**FIGURE 42.5**

Stagnation temperatures for a given solar absorber as a function of concentration ratio, for a direct normal irradiance of  $770 \text{ W/m}^2$ , ambient temperature of  $20^\circ\text{C}$ ,  $\alpha = 1$ , and different values of emissivity,  $\epsilon$ .

convolution of the solar receiver and the heat engine should also be taken into consideration. What is the optimum temperature for a complete system including receiver and Carnot cycle? The combined efficiency of both systems can easily be visualized by multiplying the optical efficiency of the absorber (Equation 42.2) and the Carnot cycle efficiency (Equation 42.4). The result would represent the ideal conversion efficiency of our system from solar radiation to work.

$$\eta_{\text{tot\_rec}} = \eta_{\text{rec}} * \eta_{\text{Carnot}} \quad (42.6)$$

Figure 42.6 depicts the combined efficiency of the receiver/heat engine system versus concentration and temperature. It may be observed that for each concentration, the efficiency increases with temperature up to a maximum (Carnot term prevails). Once this peak is achieved, a temperature increment represents a decrement in efficiency (infrared losses at receiver prevail).

As a result, it may be concluded that for any ideal receiver working at a given concentration, there is an optimum temperature, and this temperature can be obtained by

$$\frac{d\eta_{\text{tot\_rec}}}{dT} = 0 \quad (42.7)$$

Substituting Equations 42.1 through 42.5 into Equation 42.6 and obtaining the derivative, we find a polynomial expression in  $T_{\text{abs}}$ , and its real (positive) roots give the optimum temperature.

$$4 * \sigma * T_{\text{abs}}^5 - 3 * \sigma * \epsilon * T_{\text{amb}} * T_{\text{abs}}^4 - (\sigma * T_{\text{amb}}^5 + \alpha * \text{Conc} * \phi * T_{\text{amb}}) = 0 \quad (42.8)$$

**FIGURE 42.6**

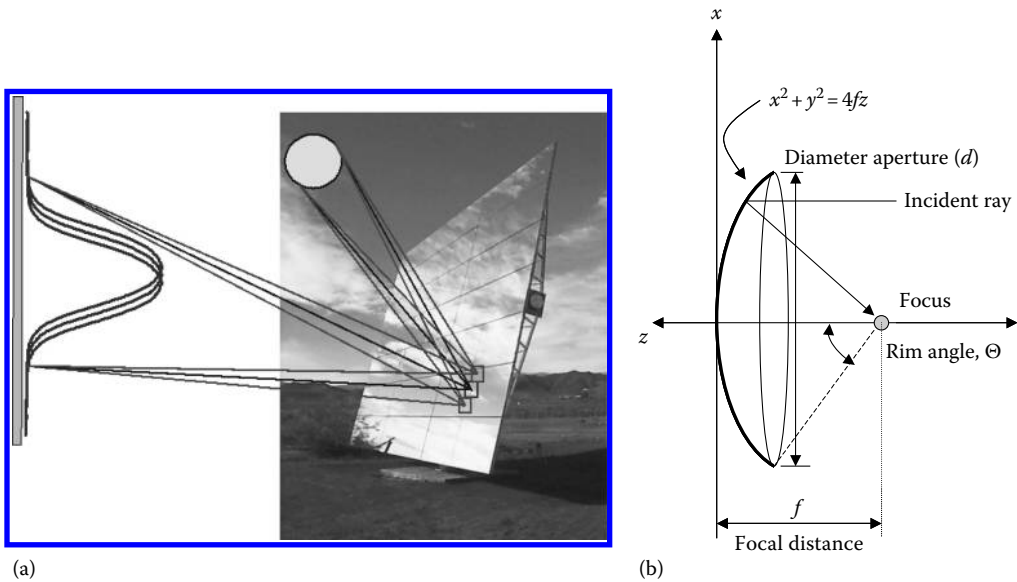

Combined efficiency of the solar receiver/heat engine system for different solar concentration factors and operation temperatures of the absorber. Direct normal irradiance of  $770 \text{ W/m}^2$ , ambient temperature of  $20^\circ\text{C}$ ,  $\alpha = \varepsilon = 1$ .

Figure 42.6 includes the optimum temperature for the different solar concentrations as calculated from Equation 42.8.

In conclusion, solar concentration is necessary to convert solar energy into mechanical work, and for each geometrical concentration, there is a theoretical optimum absorber operating temperature.

### 42.2.2 Solar Concentrator Beam Quality

Optical concentration leads to two significant limitations on the practical use of solar radiation that are intrinsic to the characteristics of the radiation source. First, the nonnegligible diffuse solar rays reaching the surface of Earth that do not have a preferential direction are not reflected by the concentrating surface onto the target absorber (energy spillage); therefore, only direct solar radiation from the solar disk can be used. Second, and because of this first restriction, costly mechanical devices are required to track the sun. Consequently, there are practical physical limitations to the concentration level depending on the application (Sizmann, 1991). Sun tracking and use of beam radiation are not the only restrictions. It should also be taken into account that the sun is not a point source of energy at an infinite distance. This means that when solar rays directly from the solar disk reach our observation point at Earth, they are not completely collimated, but at a certain solid angle. The subtended solid angle is  $32'$ ; this means an angular radius of  $4.653 \text{ mrad}$  or  $16'$  of arc; therefore, even an ideal parabolic concentrator would reflect the image of the sun on a spot having the same target-to-mirror solid angle. This means that for an ideal heliostat located  $500 \text{ m}$  from the optical target or focal point, the theoretical diameter of the spot would be  $4.7 \text{ m}$  only because of the size

**FIGURE 42.7**

Configuration of an ideal parabolic concentrator (b) and effect of the size of the sun on the reflected image with a real reflectant surface, heliostat (a).

of the sun. The effect of the size of the sun on the reflected cone for a heliostat and the size of the spot on the target can be observed in Figure 42.7.

Therefore, when designing a real solar concentrator and the aperture of a solar receiver, it is necessary to take into account the minimum size of the spot at a given distance. One additional characteristic of the sun must be considered, the sunshape. Dispersion and absorption effects on the solar photosphere modify the uniform distribution of the expected radiance of an ideal blackbody. Because of that it is more realistic to substitute a *limb-darkened* distribution for the ideal uniform distribution, since the sun is darker near the rim than at the center (Vant-Hull, 1991). Assuming that the sun is an ideal Lambertian emitter, a uniform distribution of radiance (pill-box) with a constant value of  $L_0 = 13.23$  MW/m<sup>2</sup> would be required over the entire solar disk, providing the integrated value of the solar irradiance  $E = \int L d\Omega = \pi\theta^2 L_0$ , where  $\theta = R/D_{ES} = 4.653$  mrad is the ratio between the radius of the solar disk and the Earth–sun distance and  $\Omega$  the solid angle. For the *limb-darkened* distribution, the following expression of radiance is obtained:

$$\frac{L}{L_0} = 0.36 + 0.84 \sqrt{1 - \frac{\xi^2}{\theta_s^2}} - 0.20 \left( 1 - \frac{\xi^2}{\theta_s^2} \right) \quad (42.9)$$

where

$L$  is the radiance (MW/(m<sup>2</sup> sr))

$L_0$  is the radiance at the center of the disk (13.23 MW/m<sup>2</sup>), for  $\xi = 0$

$\xi = r/D_{ES} \leq \theta$  is the radial coordinate normalized to  $D_{ES}$

$\theta_s = R/D_{ES} = 4.653$  mrad

The extraterrestrial irradiance is modified as it enters the atmosphere because of absorption and multiple dispersions, producing the well-known aureole. That is why

better sunshape fit is obtained if the previous radiance distribution is separated into two regions, the central solar disk and the circumsolar region (Rabl, 1985). The ratio between the circumsolar irradiance and direct irradiance varies depending on atmospheric conditions, but in typical sites with good solar radiation, the monthly average does not exceed 5%, provided the operating threshold for system start-up is above  $300 \text{ W/m}^2$ . A detailed *ray tracing* analysis reproducing reflection on our solar concentrating surface should take into account the sunshape. To this effect, other factors, like curvature and waviness errors of the reflecting surface, as well as the possible tracking errors in the drive mechanism, must be added. It is relatively simple to approximate all these nonsystematic errors of the concentrator to a standard deviation,  $\sigma^2 = \sum \sigma_i^2$ , to quantify the beam quality of the reflector. The consequence of the convolution of all the mentioned errors from sun, tracking system, and reflecting surface leads to the real fact that instead of an ideal point-focus parabolic concentrator, Figure 42.7b, the spot and energy profile obtained on a flat absorber can be approximated to a Gaussian shape, Figure 42.7a. The real image obtained is also known as *degraded sunshape*. Subsequently, the designer of a solar receiver should take into account the beam quality of the solar concentrator and the concentrated flux distribution to optimize the heat transfer process.

However, the main interest of a solar concentrator is the energy flux and not the quality of the image. Because of that,  $4.65 \text{ mrad}$  is a good reference for comparing the extent of optical imperfections. Those errors deflecting the reflected ray significantly less than  $4.65 \text{ mrad}$  are of minor importance, while deviations over  $6 \text{ mrad}$  contribute drastically to the reduction of concentration and energy spillage at the receiver aperture.

Solar concentrators follow the basic principles of Snell's law of reflection (Rabl, 1985), as depicted in Figure 42.8. On a specular surface like the mirrors used in STP plants, the reflected solar ray forms an angle with the mirror normal equal to the angle formed by the incoming ray with the normal. On a real mirror with intrinsic and constructional errors, the reflected ray distribution can be described with *cone optics*. The reflected ray direction has an associated error that can be described with a normal distribution function. The errors of a typical reflecting solar concentrator may be either microscopic (specularity) or macroscopic (waviness of the mirror and error of curvature). All the errors together end up modifying the direction of the normal compared to the reference reflecting element. However, it is necessary to discriminate between microscopic and macroscopic errors. Microscopic errors are intrinsic to the material itself and depend on the fabrication process, and can be measured at the lab with mirror samples.

**FIGURE 42.8**

Geometry of reflection according to the principles of Snell.

**FIGURE 42.9**

Normal error produced by grainy texture of the material and deficient curvature of the concentrator.

Macroscopic errors are characteristic of the concentrator itself and the erection process; therefore, they should be measured and quantified with the final system in operation (Biggs and Vittitoe, 1979).

The parameter best defining the *macroscopic* quality of a reflective concentrator is the slope error ( $\beta$ ) as shown in Figure 42.9. The slope error is the angle between the normal to the reference surface ( $\vec{N}_0$ ) and the normal to the real reflecting surface ( $\vec{N}$ ). The root mean square or RMS, a statistical mean distribution of slope errors, is used to specify the distribution of  $\beta$  on a real surface. For a given differential element of surface ( $dA$ ), the RMS is obtained as

$$\text{RMS} = \langle \beta^2 \rangle^{1/2} = \left[ \frac{\int \beta^2 dA}{\int dA} \right]^{1/2} \quad (42.10)$$

RMS is a deterministic value of the surface errors, but it can be expressed with a probabilistic value as the standard deviation. Since it is more practical to determine the probabilistic error in the reflected image, it is a good idea to translate the RMS of the normals on the reflector to the standard deviation of the reflected rays. For convenience, the value of  $\sigma$  is expressed on a line that intersects and is orthogonal to the normal of the reflector. Assuming a new reference plane  $r$ - $s$  placed at a unitary distance, the probability of  $\vec{N}$  intersecting the element of surface  $dr \cdot ds$  is  $F(r, s) \cdot dr \cdot ds$  where  $F(r, s)$  is a probability density function normalized to 1 when integrated over the entire plane  $r$ - $s$  (Figure 42.10).

**FIGURE 42.10**

Translation of the normal error to a new reference plane at a distance 1.

In this case, the probability function can be approximated to a normal distribution function, since further convolution with other errors like specularity, solar tracking, or sunshape leads to a damping effect according to the central limit theorem. In addition, since the total error is the convolution of a series of random surface errors, the distribution is circular normal.

If we use the new coordinates defined for the plane as depicted in [Figure 42.10](#),

$$\rho = \tan \beta = (r^2 + s^2)^{1/2} \quad (42.11)$$

and for those values of  $\rho$  close to  $\beta$ , which is the case for actual solar concentrators used in STP plants, the function  $F$  may be expressed as

$$F(\rho) = \frac{1}{2\pi\sigma^2} \exp\left[-\frac{\rho^2}{2\sigma^2}\right] \quad (42.12)$$

where the parameter  $\sigma$  is the standard deviation of the reflected ray, and for circular symmetry,  $\sigma_r = \sigma_s = \sigma$ .

By integrating the previous expression to obtain the RMS of  $\rho$ ,  $\sigma$  is correlated with  $\beta$  and with the RMS, by the following equation (Biggs and Vittitoe, 1979; Vant-Hull, 1991):

$$\text{RMS} = \langle \rho^2 \rangle^{1/2} = \sigma\sqrt{2} = \langle \beta^2 \rangle^{1/2} \quad (42.13)$$

Summarizing, the beam quality of the concentrating reflector may be expressed by means of three parameters related to the inclination error of the surface elements, the RMS of  $\beta$ , the dispersion  $\sigma$  of the normal, or the dispersion  $\sigma$  of the reflected beam. The total standard deviation of a solar concentrator or beam quality would be the sum of several sources of error:

$$\sigma_C^2 = \sigma_{sp+wav}^2 + \sigma_{curvature}^2 + \sigma_{tracking}^2 \quad (42.14)$$

The total error of the image, also known as degraded sun, would be the convolution of the beam quality of the concentrator with the sunshape:

$$\sigma_D^2 = \sigma_{sunshape}^2 + \sigma_C^2 \quad (42.15)$$

where

- $\sigma_{sunshape}$  is the beam standard deviation due to the sunshape effect (approximately 2.19 mrad)
- $\sigma_{sp+wav}$  is the beam standard deviation due to specularity and waviness (measured with reflected rays from material samples using a reflectometer)
- $\sigma_{curvature}$  is the beam standard deviation due to curving (should be measured on the concentrator itself)
- $\sigma_{tracking}$  is the beam standard deviation due to aiming point and other drive-mechanism-related sources of error

The association of the flux profile on the target with a Gaussian shape and the determination of the beam quality of the concentrator are useful in identifying the optimum

aperture area of the receiver for a specific fraction of intercepted power. For a given receiver aperture radius length ( $\rho_A$ ), the probability of  $\rho < \rho_A$  may be obtained by integrating (42.12)

$$P(\rho < \rho_A) = 2\pi \int_0^{\rho_A} \rho F(\rho) d\rho = 1 - \exp\left[-\frac{\rho_A^2}{2\sigma^2}\right] \quad (42.16)$$

With this simple correlation, the beam standard deviation ( $\sigma$ ) and cone radius ( $\rho_A$ ) can be correlated by intercepting a certain percentage of reflected power or the probability of  $\rho < \rho_A$  ( $P$ ).

### 42.2.3 Solar Concentration Ratio: Principles and Limitations of STP Systems

The most practical and simplest primary geometrical concentrator typically used in STP systems is the parabola. Even though there are other concentrating devices like lenses or compound parabolic concentrators (Welford and Winston, 1989), the reflective parabolic concentrators and their analogues are the systems with the greatest potential for scaling up at a reasonable cost. Parabolas are imaging concentrators able to focus all incident paraxial rays onto a focal point located on the optical axis (see Figure 42.7). The paraboloid is a surface generated by rotating a parabola around its axis. The parabolic dish is a truncated portion of a paraboloid. For optimum sizing of the parabolic dish and absorber geometries, the geometrical ratio between the focal distance,  $f$ , the aperture diameter of the concentrator,  $d$ , and the rim angle,  $\Theta$ , must be taken into account. The ratio can be deduced from the equation describing the geometry of a truncated paraboloid,  $x^2 + y^2 = 4fz$ , where  $x$  and  $y$  are the coordinates on the aperture plane, and  $z$  is the distance from the plane to the vertex. For small rim angles, the paraboloid tends to be a sphere, and in many cases, spherical facets are used; therefore, in most solar concentrators, the following correlation is valid:

$$\frac{f}{d} = \frac{1}{4 \tan(\Theta/2)} \quad (42.17)$$

For example, a paraboloid with a rim angle of  $45^\circ$  has an  $f/d$  of 0.6 (see Figure 42.11). The ratio  $f/d$  increases as the rim angle decreases. A parabolic concentrator with a very small rim angle has very little curvature and the focal point far from the reflecting surface. Because of that, STP systems making use of cavity receivers with small apertures should use small rim angles. Conversely, those STP systems using external or tubular receivers will make use of large rim angles and short focal lengths.

The maximum solar concentration ratio for an ideal perfectly specular 3D paraboloid of rim angle  $\Theta$  aligned to the sun is (Goswami et al., 2000)

$$C_{\max} = \frac{\sin^2 \Theta}{(4 \sin^2 \theta_s)} \quad (42.18)$$

where  $\theta_s$  is the semi-angle subtended by the sun, 4.653 mrad ( $16'$ ). For  $\Theta = 90^\circ$ ,  $C_{\max} \sim 11,547$ .

The thermodynamic limit or maximum concentration ratio for an ideal solar concentrator would be set by the size of the sun and not by the beam quality. By applying the

**FIGURE 42.11**

Schematic diagrams of the four CSP systems scaled up to pilot and demonstration sizes: (a) parabolic trough, (b) linear Fresnel, (c) dish/engine, and (d) central receiver.

geometrical conservation of energy in a solar concentrator, the following expressions are obtained for 3D and 2D systems (for a refraction index,  $n = 1$ ):

$$C_{\max,3D} = \frac{1}{\sin^2 \theta_s} \leq 46,200 \quad (42.19)$$

$$C_{\max,2D} = \frac{1}{\sin \theta_s} \leq 215 \quad (42.20)$$

For real concentrators, the maximum ratios of concentration are much lower, because of microscopic and macroscopic, tracking and mechanical, sunshape, and other errors. Engineers designing a specific STP plant should give special attention to the expected real beam quality and rim angle of the reflecting system to obtain an appropriate sizing of the solar receiver.

### 42.3 Solar Thermal Power Plant Technologies

STP plants with optical concentration technologies are important candidates for providing the bulk solar electricity needed within the next few decades, even though they still suffer from a lack of public awareness and confidence, especially among scientists and decision makers. Four CSP technologies are today represented at pilot and demonstration scale

(Mills, 2004; Romero and Gonzalez-Aguilar, 2014): parabolic-trough collectors (PTCs), LF concentrator systems, power towers or CRSs, and dish/engine (DE) systems. All the existing pilot plants mimic parabolic geometries with large mirror areas and work under real operating conditions. Reflective concentrators are usually selected since they have better perspectives for scale-up (Figure 42.11).

PTC and LF are 2D concentrating systems in which the incoming solar radiation is concentrated onto a focal line by one-axis tracking mirrors. They are able to concentrate the solar radiation flux 30–80 times, heating the thermal fluid in the receiver. Although commercial PTC and LF plants built until 2013 had a maximum thermal fluid temperature of 395°C, these technologies can achieve higher temperatures if the thermal oil traditionally used is replaced by another working fluid (direct steam generation [DSG] and molten salts), and commercial plants with temperatures up to 500°C are therefore likely to be implemented in a medium term. Although the scale-up effect leads to a significant cost reduction in these plants, thus making implementation of unit powers higher than 50 MW<sub>e</sub> advisable, there are also small commercial plants in operation (i.e., the 1 MW<sub>e</sub> PTC Saguaro plant in the United States and the 1.4 MW<sub>e</sub> LF Puerto Errado plant in Spain). These two STP technologies are well suited for centralized power generation with a Rankine steam turbine/generator cycle in dispatchable markets.

CRS optics is more complex, since the solar receiver is mounted on top of a tower and sunlight is concentrated by means of a large paraboloid that is discretized into a field of heliostats. This 3D concentrator is therefore off-axis, and heliostats require two-axis tracking. Concentration factors are between 200 and 1000, and unit sizes are between 10 and 200 MW, and they are therefore well suited for dispatchable markets and integration into advanced thermodynamic cycles. A wide variety of thermal fluids, like saturated steam, superheated steam, molten salts, atmospheric air, or pressurized air, can be used, and temperatures vary between 300°C and above 1000°C.

Finally, DE systems are small modular units with autonomous generation of electricity by Stirling engines or Brayton mini-turbines located at the focal point. Dishes are parabolic 3D concentrators with high concentration ratios (1000–4000) and unit sizes of 5–25 kW. Their current market niche is in both distributed on-grid and remote/off-grid power applications (Becker et al., 2002).

Typical solar-to-electric conversion efficiencies and annual capacity factors are listed in Table 42.1 (Romero and Steinfeld, 2012). These values have been demonstrated commercially. With current investment costs, all current STP technologies generally thought to require a public financial support strategy for market deployment. Although an independent study promoted by the World Bank at the end of last century (Enermodal, 1999) stated that STP was the most economical technology for solar production of bulk electricity at that time, the significant cost reduction experienced by the photovoltaic panels during the first decade of current century has changed the situation, and STP plants are cheaper only in those places with a high level of direct normal irradiance. However, the added value of dispatchability is still a valuable asset for STP plants when compared with PV plants. Cost data delivered by commercial STP plants show a direct capital costs of 2.5–3.5 times those of a fossil-fueled power plant, and therefore, generation costs of the electricity produced are 2–4 times higher (IRENA, 2012).

Every square meter of STP field can produce up to 1200 kWh thermal energy/year or up to 500 kWh of electricity/year. That means, a cumulative savings of up to 12 tons of carbon dioxide and 2.5 tons of fossil fuel per square meter of STP system over its 25-year lifetime (Geyer, 2002). Although most of the commercial plants installed up

to 2012 used parabolic troughs (11 plants in the United States totaling 415 MW<sub>e</sub>, 38 plants in Spain totaling 1975 MW<sub>e</sub>, and 3 plants in Morocco, Algeria, and Egypt respectively), this tendency could change because the number of projects promoted with CRS and LF plants is increasing nowadays. The high initial investment required by early commercial plants (\$3000–\$6000 per kW) and the restricted modularity generally motivated by their expensive thermodynamic cycle, combined with the lack of appropriate power purchase agreements and fair taxation policies, led to a vicious circle in which the first generation of commercial grid-connected plants became difficult to implement without market incentives. After two decades of frozen or failed projects, approval in the first decade of this century of specific financial incentives in Europe, the United States, Australia, Algeria, and South Africa paved the way for the launching of the first commercial ventures, and more than 40 STP plants were implemented from 2007 to 2012.

The *parabolic trough* is today considered a fully mature technology (Price et al., 2002). Costs are in the range of \$0.16–\$0.21 per kWh, depending on the boundary conditions for each project (direct normal irradiance available, loan interest rate, etc.), and even up to 30% less in hybrid systems, and technological and financial risks are low. The five plants at the Kramer Junction site (SEGS III–VII) achieved a 30% reduction in operating and maintenance costs, a record annual plant efficiency of 14%, and a daily solar-to-electric efficiency near 20%, as well as peak efficiencies up to 21.5%. Annual plant availability exceeded 98%, and collector field availability was over 99% (Cohen et al., 1999). In view of this advanced state of development, investors were keener to support projects with parabolic troughs, and many companies promoted projects with this technology as soon as public subsidies became available. This was the main reason why most of the commercial STP plants built during the period 2007–2012 used parabolic-trough technology, with either a similar configuration of the SEGS plants or with various hybridization options, including ISCCSs.

LF reflector systems are conceptually simple, using inexpensive, compact optics that can produce saturated steam at 150°C–360°C (higher temperatures of about 500°C are pursued for the next generation of LF plants) with land use of less than 10 m<sup>2</sup>/kW. Therefore the STP technology is best suited for integration with combined-cycle recovery boilers, to replace the steam bled in regenerative Rankine power cycles or for saturated steam turbines. The first commercial experience with LF was the prototype-scale plant developed at the University of Sydney in Australia (Mills and Morrison, 2000). The biggest LF

STP plant in operation in 2012 was Puerto Errado-2 (Spain), with a unit power of 30 MW<sub>e</sub>. Taking into account the scale-up effect, LF plants with the unit power of about 100 MW<sub>e</sub> were soon promoted after the first small commercial experiences. LF technology is being used in Australian coal-fired power plants as a fuel-saver option to supply 270°C preheat thermal energy to either replace the steam bled in the regenerative Rankine power cycle or for water preheating in the boiler.

*Power tower* technology, after a proof-of-concept stage, has already started its commercial deployment, although less mature than the parabolic-trough technology. To date, a few CRS commercial plants have been implemented and are in daily operation. At an earlier stage, more than 10 different experimental plants were tested worldwide, generally small demonstration systems of between 0.5 and 10 MW, and most of them operated in the 1980s (Romero et al., 2002). That experience demonstrated the technical feasibility of the CRS power plants and their capability of operating with large heat storage systems. The most extensive operating experience was in the European pilot projects located in Spain on the premises of the Plataforma Solar de Almería (PSA) and in the United States at the 10 MW Solar One and Solar Two facilities located in California. Commercial deployment of CRS plants started in 2007 with the start-up of the Spanish PS10 plant, promoted by the company Abengoa. PS10 plant, with a net unit power of 10 MW<sub>e</sub> and a 40 bar/240°C saturated steam Rankine cycle (Osuna et al., 2004), was the first commercial CRS plant in the world. PS10 was followed by the PS20, with a unit power of 20 MW<sub>e</sub>. The third CRS commercial plant in the world was the Gemasolar plant, promoted by Torresol Energy in the Spanish province of Seville. Gemasolar, with its molten-salt central receiver and 17 h thermal storage system, has been a significant step forward in the CRS technology. With a unit power of 19 MW<sub>e</sub>, this plant can operate round the clock in summertime. The company BrightSource has promoted a challenging CRS plant with 550°C superheated steam receiver, the so-called Ivanpah plant. The 392 MW Ivanpah Plant was connected to the grid in February 2014. Other projects based upon superheated steam and molten salts are under construction in Chile, South Africa, and the United States. In addition to the CRS technologies already implemented in commercial STP plants before 2013 (i.e., saturated steam, superheated steam, and molten salts), the use of open- or closed-loop volumetric air receivers is at R&D stage (Romero et al., 2002).

*DE* systems are absolutely modular and ideal for unit powers between 5 and 25 kW. Two decades ago, dish–Stirling systems had already demonstrated their high conversion efficiency, concentration of more than 3000 suns, and operating temperatures of 750°C at annual efficiencies of 23% and 29% peak (Stine and Diver, 1994). Unfortunately, *DE* systems have not yet surpassed the proof-of-reliability operation phase. Only a limited number of prototypes have been tested worldwide, and annual availability above 90% still remains a challenge. Given the fact that autonomous operation and off-grid markets are the first priorities of this technology, more long-endurance test references must be accumulated. *DE* technology investment costs, which are twice as high as those of parabolic troughs, would have to be dramatically reduced by mass production of specific components, like the engine and the concentrator, although these systems, because of their modular nature, are targeted toward much higher-value markets. *DE* system industries and initiatives are basically confined to the United States and Europe (Mancini et al., 2003). To date, there has been only one *DE* commercial plant (the MARICOPA plant in the United States), built with 25 kW<sub>e</sub> *DE* systems and a total unit power of 1.5 MW<sub>e</sub>. This plant did not achieve the expected performance, and the plant was dismantled in 2012 after 1 year of operation.

## 42.4 Parabolic-Trough Solar Thermal Power Plants

### 42.4.1 Operational Principle and Components of the Parabolic-Trough Collector

PTCs are linear-focus concentrating solar devices that convert direct solar radiation into thermal energy and are suitable for working in the 150°C–400°C temperature range (Price et al., 2002).

A PTC is basically made up of a parabolic-trough-shaped mirror that reflects direct solar radiation, concentrating it onto a receiver tube located in the focal line of the parabola. Concentration of the direct solar radiation reduces the absorber surface area with respect to the collector aperture area and thus significantly reduces the overall thermal losses. The concentrated radiation heats the fluid that circulates through the receiver tube, thus transforming the solar radiation into thermal energy in the form of the sensible heat of the fluid. Since a PTC is an optical solar concentrator, it can use only direct solar radiation, and the diffuse solar radiation is lost. Figure 42.12 shows a typical PTC and its components.

PTCs are dynamic devices because they have to rotate around an axis, the so-called tracking axis, to follow the apparent daily movement of the sun. Otherwise, the solar radiation reflected by the parabolic mirrors would not reach the receiver tube. Collector rotation around its axis requires a drive unit. One drive unit is usually sufficient for several parabolic-trough modules connected in series and driven together as a single collector. The type of drive unit assembly depends on the size and dimensions of the collector. Drive units composed of an electric motor and a gearbox combination are used for small collectors (aperture area < 100 m<sup>2</sup>), while powerful hydraulic drive units are required to rotate large collectors. A drive unit placed on the central pylon is commanded by a local control unit that tells it when and in which direction to rotate the collector to track the sun.

Local control units currently available on the market can be grouped into two categories, depending on the device used to track the sun. These two categories are as follows:

1. Control units based on sun sensors
2. Control units based on astronomical algorithms

Control units in Group (a) use photo cells to detect the sun position, while those in Group (b) calculate the sun vector using very accurate mathematical algorithms that find

**FIGURE 42.12**

A typical parabolic-trough collector.

the sun elevation and azimuth every second and measure the angular position of the rotation axis by means of electronic devices (angular encoders or magnetic coded tapes attached to the rotation axis).

Shadow-band and flux-line trackers are in Group (a). Shadow-band trackers are mounted on the parabolic concentrator and face the sun when the collector is in perfect tracking (i.e., the sun vector is within a plane that includes the receiver tube and is perpendicular to the concentrator aperture plane). Two photo sensors, one on each side of a separating shadow wall, detect the sun's position. When the collector is correctly pointed, the shadow wall shades both sensors equally, and their electric output signals are identical.

Flux-line trackers are mounted on the receiver tube. Two sensors are also placed on both sides of the absorber tube to detect the concentrated flux reaching the tube. The collector is correctly pointed when both sensors are equally illuminated and their electrical signals are of the same magnitude.

At present, all commercial PTC designs use a single-axis sun-tracking system. Though PTC designs with two-axis sun-tracking systems have been designed, manufactured, and tested in the past, evaluation results show that they are less cost-effective. Though the existence of a two-axis tracking system allows the PTC to permanently track the sun with an incidence angle equal to  $0^\circ$  (thus reducing optical losses while increasing the amount of solar radiation available at the PTC aperture plane), the length of passive piping (i.e., connecting pipes between receiver pipes of adjacent parabolic troughs on the same collector) and the associated thermal losses are significantly higher than in single-axis collectors. Furthermore, their maintenance costs are higher and their availability lower because they require a more complex mechanical design.

Thermal oils are commonly used as the working fluid in these collectors for temperatures above  $200^\circ\text{C}$ , because at these operating temperatures, normal water would produce high pressures inside the receiver tubes and piping. This high pressure would require stronger joints and piping, and thus raise the price of the collectors and the entire solar field. However, the main technical challenges of using water as working fluid in the receiver tubes is not related to the higher pressure, but to process instabilities that could arise in the solar field due to the two-phase flow (i.e., steam and liquid water) circulating inside the receiver tubes (Zarza et al., 1999, 2002).

After a fruitful R&D stage at the PSA, the use of demineralized water for high temperatures/pressures has been already implemented in a 5 MW commercial STP plant built in Thailand by the German company Solarlite, and the feasibility of DSG at 100 bar/ $400^\circ\text{C}$  in the receiver tubes of PTCs has already been proven in the DISS project. For temperatures below  $200^\circ\text{C}$ , either a mixture of water/ethylene glycol or pressurized liquid water can be used as the working fluids because only a moderate pressure is required in the liquid phase.

There are many options when choosing the thermal oil to act as working fluid in PTCs. The main limiting factor to be taken into consideration is the maximum oil bulk temperature defined by the manufacturer. Good oil stability is guaranteed by the manufacturer if the maximum bulk temperature is not exceeded. Above this temperature, oil cracking and rapid degradation occur.

The oil most widely used in PTCs for temperatures up to  $395^\circ\text{C}$  is VP-1 or Dowtherm-A, which is a eutectic mixture of 73.5% diphenyl oxide/26.5% diphenyl. The main problem with this oil is its high solidification temperature ( $12^\circ\text{C}$ ), which requires an auxiliary heating system when oil lines run the risk of cooling below this temperature. Since the boiling temperature at 1013 mbar is  $257^\circ\text{C}$ , the oil circuit must be pressurized with nitrogen, argon, or any other inert gas when oil is heated above this temperature. Blanketing of the entire oil circuit with an oxygen-free gas is a must when working at high temperatures because

high-pressure mists can form an explosive mixture with air. Though there are other suitable thermal oils for slightly higher working temperatures with lower solidification temperatures, they are unaffordable for large solar plants due to their much higher price.

The typical PTC receiver tube is composed of an inner steel pipe surrounded by a glass tube to reduce convective heat losses from the hot steel pipe. The steel pipe has a selective high-absorptivity ( $>90\%$ ), low-emissivity ( $<30\%$  in the infrared) coating, which reduces radiative thermal losses. Receiver tubes with glass vacuum tubes and glass pipes with an antireflective coating achieve higher PTC thermal efficiency and better annual performance, especially at higher operating temperatures. Receiver tubes with no vacuum are usually for working temperatures below  $250^{\circ}\text{C}$ , because thermal losses are not so critical at these temperatures. Due to manufacturing constraints, the maximum length of single receiver pipes is less than 6 m, so that the complete receiver tube of a PTC is composed of a number of single receiver pipes welded in series up to the total length of the PTC. The total length of a PTC is usually within 25–150 m.

Figure 42.13 shows a typical PTC vacuum receiver pipe. The outer glass tube is attached to the steel pipe by means of flexible metal differential expansion joints that compensate for the different thermal expansion of glass and steel when the receiver tube is working at nominal temperature. The number of manufacturers of PTC vacuum absorber tubes was small in 2013: the German companies Schott and Siemens, the Italian company Archimede Solar, and the Chinese company HUIYIN. The glass cover is connected to the inner steel tube by means of stainless steel expansion bellows, which compensates the different thermal expansion of the glass cover and steel tubes. The glass-to-metal welding used to connect the glass tube and the expansion bellows is a weak point in the receiver tube and has to be protected from the concentrated solar radiation to avoid high thermal and mechanical stress that could damage the welding. An aluminum shield is usually placed over the bellows to protect the welding.

As seen in Figure 42.13, several chemical getters are placed in the gap between the steel receiver pipe and the glass cover to absorb gas molecules from the fluid that get through the steel pipe wall to the annulus.

PTC reflectors have a high specular reflectance ( $>88\%$ ) to reflect as much solar radiation as possible. Solar reflectors commonly used in PTC are made of back-silvered glass mirrors,

**FIGURE 42.13**

A typical receiver tube of a PTC.

since their durability and solar spectral reflectance are better than the polished aluminum and metallized acrylic mirrors also available on the market. Solar spectral reflectance is typically 0.93 for silvered glass mirrors and 0.87 for polished aluminum.

Low-iron glass is used for the silvered glass reflectors and the glass receiver envelopes since iron has an absorption peak in the solar spectrum, and therefore glass transmissivity to solar radiation is higher when the iron content is low.

The parabolic-trough reflector is held by a steel support structure on pylons in the foundation. At present, there are several commercial PTC designs. Large STP plant designs are much larger than those developed for industrial process heat (IPH) applications in the range of 125°C–300°C. Examples of PTC designs for IPH applications are the designs developed by the American company IST (Industrial Solar Technology, [www.industrial-solartech.com](http://www.industrial-solartech.com)) and the European company Solitem ([www.solitem.de](http://www.solitem.de)). IST and Solitem designs are very similar in size (approx. 50 m total length and 2 m wide) and have aluminum reflectors. SOPOGY ([www.sopogy.com](http://www.sopogy.com)), with head offices in Honolulu (Hawaii), developed a 3.7 m long, 1.35 m wide PTC module marketed as Soponova 4.0, which was suitable for both process heat applications and electricity generation with small STP plants.

Two PTC designs conceived for large STP plants are the URSSATrough and EuroTrough, both of which have a total length of 150 m and a parabola width of 5.76 m, with back-silvered thick-glass mirrors and vacuum absorber pipes (Table 42.2). The initial EuroTrough design (Luepfert et al., 2003) was then improved, leading to its successor, the SKAL-ET, the collector installed at the ANDASOL plants in Spain in 2007–2011. The main difference between the URSSATrough and EuroTrough designs is their steel structure: EuroTrough mechanical rigidity to torsion is assured by a steel *torque box* of trusses and beams, while the URSSATrough ([www.urssa.es](http://www.urssa.es)) steel structure is based on the replacement of the torque box by a central steel tube (called the *Torque Tube*) (Figure 42.14). However, assembly of the steel mirror support frames on this central tube must also be highly accurate. The collector design SenerTrough, developed by the Spanish company SENER ([www.sener.es](http://www.sener.es)), also has a torque tube instead of a torque box. Figure 42.14 shows the steel structures of these two PTC designs: with *torque box* and *torque tube*. The main constraint when developing the mechanical design of a PTC is the maximum torsion at the collector ends, because high torsion would lead to a smaller intercept factor and lower optical efficiency.

PTCs are usually installed with the rotation axis oriented either north–south or east–west; however, any other orientation would be feasible too. The orientation of this type of

**TABLE 42.2**

solar collector is sometimes imposed by the shape and orientation of the site where they are installed. When the solar field designer can choose solar collector orientation, he must take into consideration that the orientation has a significant influence on the sun incidence angle on the aperture plane of the collectors, which, in turn, affects collector performance. The incidence angle is the angle between the normal to the aperture plane of the collector and the sun's vector, both contained on a plane perpendicular to the collector axis.

Seasonal variations in north–south-oriented trough collector output can be quite wide, depending on the site weather conditions and the geographical latitude. Three to four times more energy is delivered daily during summer months than in the winter at latitudes of about  $35^{\circ}\text{N}$ . Seasonal variations in energy delivery are much smaller for an east–west orientation, usually less than 50%. Nevertheless, a north–south sun-tracking axis orientation usually provides more energy on a yearly basis. This difference in energy output is caused by the different incidence angle of the direct solar radiation onto the aperture plane of the concentrators. Daily variation in the incidence angle is always greater for the east–west orientation, with maximum values at sunrise and sunset and a minimum of  $0^{\circ}$  every day at solar noon (Rabl, 1985).

So the orientation of the rotation axis of PTCs is a very important design specification, because it strongly affects their performance, and selection of the best orientation depends on the answers to the following questions:

1. Which season of the year should the solar field produce the most energy? If more energy is needed in summer than in winter, the most suitable orientation is north–south.
2. Is it better for energy to be evenly distributed during the year, although in winter, the production is significantly less than in summer? If the answer is “yes,” the best orientation is north–south.
3. Is the solar field expected to supply similar thermal power in summer and winter? If the answer is “yes,” the proper orientation is east–west.

In a typical PTC field, several collectors connected in series make a row, and a number of rows are connected in parallel to achieve the required nominal thermal power output at design point. The number of collectors connected in series in every row depends on the

temperature increase to be achieved between the row inlet and outlet. In every row of collectors, the receiver tubes in adjacent PTCs have to be connected by flexible joints to allow independent rotation of both collectors as they track the sun during the day. These flexible connections are also necessary to allow the linear thermal expansion of the receiver tubes when their temperature increases from ambient to nominal temperature during system start-up. Two main types of flexible connections are available: flexible hoses and ball joints.

Flexible hoses for temperatures below 300°C are composed of an inner hose that can withstand this maximum temperature and an outer metal-braid shield protecting the inner hose. The outer braid is thermally insulated to reduce thermal loss. For higher temperatures, stainless steel bellows are commonly used. This type of hose is not as flexible and causes a significant pressure drop in the circuit because of its high friction coefficient. The minimum bending radius defined by the manufacturer must be taken into consideration to prevent overstressing of the bellows.

Ball joints are another option for flexible connection between the receiver tubes of adjacent collectors. The main benefit of this option is a significantly lower pressure drop because pressure drop for one ball joint is equivalent to a 90° elbow. Another advantage of ball joints is that the connected pipes have two degrees of freedom of movement, because the connected pipes can rotate freely (360°) simultaneously and with a maximum pivot angle of about  $\pm 15^\circ$ . Ball joints are also provided with an inner graphite sealing to reduce friction and avoid leaks.

Today's PTCs working at temperatures above 300°C are connected by ball joints instead of flexible hoses. Furthermore, the flexible hoses initially installed in the solar power plants in California between 1985 and 1990 are being replaced by ball joints because they are more reliable and have lower maintenance costs. Flexible hoses are likely to suffer from fatigue failures resulting in a leak, while ball joints require only the graphite sealing to be refilled after many thousands of hours of operation. Figure 42.15 shows typical pipe connections: with a flexible hose and with ball joints.

An advanced hybrid element composed of a flex hose and a cylindrical joint has been developed by the German company Senior Flexonics, with a special design to prevent

**FIGURE 42.15**

Flexible hose and ball joint connections to allow collector rotation and linear thermal expansion of receiver tubes: (a) flexible hose and (b) ball joints.

overstressing of the bellows and provide a better reliability. This design (<http://www.seniorflexonics.de>) combines the best features of flex hoses and mechanical seals, while avoiding their disadvantages.

#### 42.4.2 Performance Parameters and Losses in a Parabolic-Trough Collector

Three of the design parameters required for a PTC are the geometric concentration ratio, the acceptance angle, and the rim angle (see Figure 42.16). The concentration ratio is the ratio between the collector aperture area and the total area of the absorber tube, while the acceptance angle is the maximum angle that can be formed by two rays in a plane transversal to the collector aperture so that they intercept the absorber pipe after being reflected by the parabolic mirrors. The concentration ratio,  $C$ , is given by the following equation:

$$C = \frac{l_a \cdot l}{\pi \cdot d_o \cdot l} = \frac{l_a}{\pi \cdot d_o} \quad (42.21)$$

where

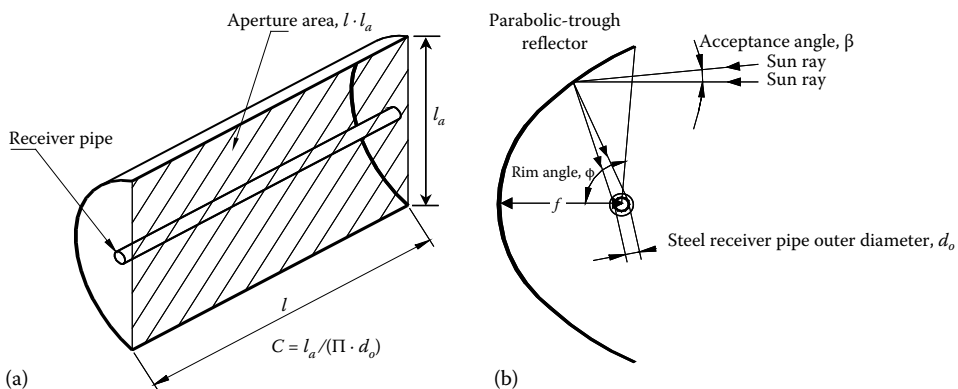

$d_o$  is the outer diameter of receiver steel pipe

$l$  is the collector length

$l_a$  is the parabola width

The wider the collector acceptance angle is, the less accurate the tracking system has to be, as the collector will not need to update its position as frequently. Usual values of the concentration ratio of PTCs are about 20, although the maximum theoretical value is on the order of 70. High concentration ratios are associated with very small acceptance angles, which require very accurate sun-tracking systems and, consequently, higher costs.

The minimum practical acceptance angle is  $32'$  ( $0.53^\circ$ ), which is the average solid angle at which the sun sphere is seen from Earth. This means that any PTC with an acceptance angle smaller than  $32'$  would always lose a fraction of the direct solar radiation. In fact, recommended acceptance angles for commercial PTCs are between  $1^\circ$  and  $2^\circ$ . Smaller angles would demand very accurate sun-tracking system and frequent updating of the

**FIGURE 42.16**

Concentration ratio and acceptance angle of a parabolic-trough collector: (a) concentration ratio and (b) acceptance angle,  $\beta$ .

collector position, while higher values would lead to small concentration ratios and, therefore, lower working temperatures. So acceptance angle values between  $1^\circ$  and  $2^\circ$  are the most cost-effective.

The rim angle,  $\phi$ , is directly related to the concentrator arc length, and its value can be calculated from Equation 42.22 as a function of the parabola focal distance,  $f$ , and aperture width,  $l_a$ :

$$\frac{l_a}{4 \cdot f} = \tan \frac{\phi}{2} \quad (42.22)$$

Usual values for rim angles in a PTC are between  $70^\circ$  and  $110^\circ$ . Smaller rim angles are not advisable because they reduce the aperture surface. Rim angles over  $110^\circ$  are not cost-effective because they increase the total reflecting surface without effectively increasing the aperture width.

When direct solar radiation reaches the surface of a PTC, a significant amount of it is lost due to several different factors. The total loss can be divided into three types, which in the descending order of importance are

1. Optical losses
2. Thermal losses from the absorber pipe to the ambient
3. Geometrical losses

The optical losses are associated with four parameters (see Figure 42.17), which are as follows:

1. *Reflectivity,  $\rho$ , of the collector reflecting surface*: Since the reflectivity of the parabolic-trough concentrator is less than 1, only a fraction of the incident radiation is reflected toward the receiver tube. Typical reflectivity values of clean silvered-glass mirrors are around 0.93. After washing the mirrors, their reflectivity continuously decreases as dirt accumulates until the next washing. Commercial parabolic-trough mirrors are washed when their reflectivity is of about 0.88–0.9.
2. *Intercept factor,  $\gamma$* : A fraction of the direct solar radiation reflected by the mirrors does not reach the steel absorber tube due to either microscopic imperfections of

**FIGURE 42.17**

Optical parameters of a parabolic-trough collector.

the reflectors or macroscopic shape errors in the parabolic-trough concentrators (e.g., imprecision during assembly). These errors cause reflection of some rays at the wrong angle, and therefore they do not intercept the absorber tube. These losses are quantified by an optical parameter called the geometrical intercept factor,  $\Upsilon_g$ , which is typically 0.95. Also the flexible bellows connecting the end of the glass cover and the steel tube (see Figure 42.13) reduce the amount of reflected solar radiation that reaches the steel receiver tube, because a fraction of the concentrated solar radiation reflected by the parabolic mirrors is blocked in its way toward the steel receiver tube. This percentage of reflected solar radiation that is blocked by the bellows is quantified by means of the so-called active length factor of the receiver tube,  $\Upsilon_L$ , which usually has a value of 0.96–0.97. The overall intercept factor,  $\Upsilon$ , is the product of the geometrical intercept factor,  $\Upsilon_g$ , and the *active length factor*,  $\Upsilon_L$ .

3. *Transmissivity of the glass tube,  $\tau$* : The metal absorber tube is placed inside an outer glass tube in order to increase the amount of absorbed energy and reduce thermal losses. A fraction of the direct solar radiation reflected by the mirrors and reaching the glass cover of the absorber pipe is not able to pass through it. The ratio between the radiation passing through the glass tube and the total incident radiation on it gives transmissivity,  $\tau$ , which is typically  $\tau = 0.93$ .
4. *Absorptivity of the absorber selective coating,  $\alpha$* : This parameter quantifies the amount of energy absorbed by the steel absorber pipe, compared with the total radiation reaching the outer wall of the steel pipe. This parameter is typically 0.95 for receiver pipes with a cermet coating, while it is slightly lower for pipes coated with black nickel or chrome.

Multiplication of these four parameters (reflectivity, intercept factor, glass transmissivity, and absorptivity of the steel pipe) when the incidence angle on the aperture plane of the PTC is  $0^\circ$  gives what is called the peak optical efficiency of the PTC,  $\eta_{opt,0^\circ}$ :

$$\eta_{opt,0^\circ} = \rho \times \Upsilon \times \tau \times \alpha \Big|_{\varphi=0^\circ} \quad (42.23)$$

$\eta_{opt,0^\circ}$  is usually in the range of 0.70–0.76 for clean, good-quality PTCs.

Concerning the second type of losses (i.e., the thermal losses), the total thermal loss in a PTC,  $P_{Q, collector \rightarrow ambient}$ , is due to radiative heat loss from the steel absorber pipe to ambient,  $P_{Q, absorber \rightarrow ambient}$ , and convective and conductive heat losses from steel absorber pipe to its outer glass tube,  $P_{Q, absorber \rightarrow glass}$ . Though this heat loss is governed by the well-known mechanisms of radiation, conduction, and convection, it is a good practice to calculate them all together using the *thermal loss coefficient*,  $U_{L,abs}$ , according to the following equation, where  $T_{abs}$  is the mean steel absorber pipe temperature,  $T_{amb}$  is the ambient air temperature,  $d_o$  is the outer diameter of the steel absorber pipe, and  $l$  is the absorber pipe length (PTC length):

$$P_{Q, collector \rightarrow ambient} = U_{L,abs} \cdot \pi \cdot d_o \cdot l \cdot (T_{abs} - T_{amb}) \quad (42.24)$$

In Equation 42.23, the thermal loss coefficient is given in  $(W/m_{abs}^2 K)$  units per square meter of the steel absorber pipe surface. The following equation can be used to find the value of the thermal loss coefficient per square meter of aperture surface of the PTC,  $U_{L,col}$ :

$$U_{L,col} = \frac{U_{L,abs}}{C} \left( W/m_{col}^2 K \right) \quad (42.25)$$

The heat loss coefficient depends on absorber pipe temperature, which is found experimentally by performing specific thermal loss tests with the PTC working at several temperatures within its typical working-temperature range. Variation in the thermal loss coefficient versus the receiver pipe temperature can usually be expressed with a second-order polynomial equation like Equation 42.26, with coefficients  $a$ ,  $b$ , and  $c$  experimentally calculated:

$$U_{L,abs} = a + b \cdot (T_{abs} - T_{amb}) + c \cdot (T_{abs} - T_{amb})^2 \quad (\text{W/m}_{abs}^2 \text{ K}) \quad (42.26)$$

It is sometimes difficult to find values for coefficients  $a$ ,  $b$ , and  $c$  valid for a wide temperature range. When this happens, different sets of values are given for smaller temperature ranges. Table 42.3 gives the values of coefficients  $a$ ,  $b$ , and  $c$  experimentally calculated by Ajona (1999) for receiver tubes initially installed at SEGS VIII and IX.

A typical value of  $U_{L,abs}$  for absorber tubes with vacuum in the space between the inner steel pipe and the outer glass tube is lower than  $5 \text{ (W/m}_{abs}^2 \text{ K)}$ . High-vacuum conditions are not needed to significantly reduce the convective heat losses. However, the low thermal stability in hot air of the cermet coatings currently used in these receiver tubes requires a high vacuum to assure good coating durability.

The optical properties (i.e., absorptivity and emissivity) of selective coatings used in vacuum receiver tubes for PTCs have been improved in the last years, and new correlations have been developed to calculate the overall thermal loss without using a heat loss coefficient. Nowadays, each receiver tube manufacturer gives the proper correlations to calculate the thermal loss of their tubes, so that the customers have to apply only such correlations.

The optimum space between the steel absorber pipe and the outer glass tube for receivers without vacuum to minimize the convective heat loss is calculated as a function of the Rayleigh number (Ratzel and Simpson, 1979). The possible bowing of the steel pipe has to be considered also in determining the minimum gap, because the possibility of contact with the glass cover has to be avoided.

The third type of losses in a PTC are the geometrical losses, which are due to the incidence angle,  $\phi$ , of direct solar radiation on the aperture plane of the collector. The incidence angle is the angle between the normal to the aperture plane of the collector and the sun's vector, both contained on a plane perpendicular to the collector axis. This angle depends on the day of the year and the time of day. The incidence angle of direct solar radiation is a very important factor, because the fraction of direct radiation that is useful to the collector is directly proportional to the cosine of this angle, which also reduces the useful aperture area of the PTC (see Figure 42.18). The incidence angle reduces the aperture area of a PTC

**TABLE 42.3**

Values of Coefficients " $a$ ," " $b$ ," and " $c$ " for a Receiver Tube Installed at SEGS VIII and IX

$T_{abs} \text{ (}^\circ\text{C)}$	$a$	$b$	$c$
<200	0.687257	0.001941	0.000026
>200; <300	1.433242	-0.00566	0.000046
>300	2.895474	-0.0164	0.000065

**FIGURE 42.18**  
Geometrical losses at the end of a parabolic-trough collector.

in an amount  $A_e$  called the *collector geometrical end losses* and is calculated with Equations 42.27 and 42.28 with the following parameters:

$l_a$  is the parabola width

$l$  is the collector length

$f$  is the focal distance of the parabolic-trough concentrator

$f_m$  is the mean focal distance in a cross section of the parabolic-trough concentrator

$\phi$  is the incidence angle of the direct solar radiation

$$A_e = l_a \cdot l_\phi = l_a \cdot f_m \cdot \tan \phi \quad (42.27)$$

$$f_m = f + \left[ \frac{(f \cdot l_a^2)}{(48 \cdot f^2)} \right] \quad (42.28)$$

The incidence angle also affects PTC optical parameters (i.e., mirror reflectivity, selective coating absorptivity, intercept factor, and glass transmissivity) because these parameters are not isotropic. The effect of the incidence angle on the optical efficiency and useful aperture area of a PTC is quantified by the incidence angle modifier,  $K(\phi)$ , because this parameter includes all optical and geometric losses due to an incidence angle greater than  $0^\circ$ .

The incidence angle modifier, which directly depends on the incidence angle, is usually given by a polynomial equation so that it is equal to 0 for  $\phi = 90^\circ$  and 1 for  $\phi = 0^\circ$ . So, for instance, the incidence angle modifier for an LS-3 collector is given by

$$\begin{aligned} K(\varphi) &= 1 - 2.23073E - 4x\varphi - 1.1E - 4x\varphi^2 \\ &\quad + 3.18596E - 6x\varphi^3 - 4.85509E - 8x\varphi^4 \quad (0^\circ < \varphi < 80^\circ) \\ K(\varphi) &= 0 \quad (85^\circ < \varphi < 90^\circ) \end{aligned} \quad (42.29)$$

Coefficients of Equation 42.29 are calculated experimentally by means of tests performed with different incidence angles (Gonzalez et al., 2001). The incidence angle of direct solar radiation depends on PTC orientation and sun position, which can be easily calculated by means of the azimuth,  $AZ$ , and elevation,  $EL$ , angles. For horizontal north–south and east–west PTC orientations, the incidence angle is given by Equations 42.30 and 42.31, respectively. The sun elevation angle is measured with respect to the horizon (positive upward), while azimuth is  $0^\circ$  to the south and positive clockwise.

$$\varphi = \arccos \left[ 1 - \cos^2(EL) \cdot \sin^2(AZ) \right]^{1/2} \quad (42.30)$$

$$\varphi = \arccos \left[ 1 - \cos^2(EL) \cdot \cos^2(AZ) \right]^{1/2} \quad (42.31)$$

#### 42.4.3 Efficiencies and Energy Balance in a Parabolic-Trough Collector

The combination of three different efficiencies

$\eta_{global}$  is the global efficiency

$\eta_{opt,0^\circ}$  is the peak optical efficiency (optical efficiency with an incidence angle of  $0^\circ$ )

$\eta_{th}$  is the thermal efficiency

and one parameter

$K(\varphi)$  is the incidence angle modifier

describe the performance of a PTC. Their definition is graphically represented in the diagram shown in Figure 42.19, which clearly shows that a fraction of the energy flux incident on the collector aperture plane is lost due to the optical losses accounted for by the peak optical efficiency, while another fraction is lost because of an incidence angle  $\varphi > 0^\circ$ , which is taken into account by the incidence angle modifier,  $K(\varphi)$ . The remaining PTC losses are thermal losses at the absorber tube.

As explained earlier, the peak optical efficiency,  $\eta_{opt,0^\circ}$ , considers all optical losses that occur with an incidence angle of  $\phi = 0^\circ$  (reflectivity of the mirrors, transmissibility of the glass tube, absorptivity of the steel absorber pipe, and the intercept factor). The incidence angle modifier,  $K(\phi)$ , considers all optical and geometrical losses that occur in the PTC because the incidence angle is  $>0^\circ$  (collector end losses, collector center losses, blocking losses due to absorber tube supports, angle dependence of the intercept factor, angle dependence of reflectivity, transmissivity, and absorptivity). Thermal efficiency,  $\eta_{th}$ , includes all absorber tube heat losses from conduction, radiation, and convection.

**FIGURE 42.19**

Diagram of efficiencies and losses in a parabolic-trough collector.

Global efficiency,  $\eta_{global}$ , includes the three kinds of losses that occur in the PTC (optical, geometrical, and heat) and can be calculated as a function of the peak optical efficiency, incidence angle modifier, and thermal efficiency using

$$\eta_{global} = \eta_{opt, 0''} \cdot K(\varphi) \cdot \eta_{th} \quad (42.32)$$

The global efficiency can also be calculated as the ratio between the net thermal output power delivered by the collector,  $P_{Q, collector \rightarrow fluid}$ , and the solar energy flux incident on the collector aperture plane,  $P_{Q, sun \rightarrow collector}$  by Equations 42.33 through 42.35:

$$\eta_{global} = \frac{P_{Q, collector \rightarrow fluid}}{P_{Q, sun \rightarrow collector}} \quad (42.33)$$

$$P_{Q, sun \rightarrow collector} = A_c \cdot E_d \cdot \cos(\varphi) \quad (42.34)$$

$$P_{Q, collector \rightarrow fluid} = \dot{m} \cdot (h_{out} - h_{in}) \quad (42.35)$$

where

$A_c$  is the collector aperture surface

$E_d$  is the direct solar irradiance

$\varphi$  is the incidence angle

$\dot{m}$  is the fluid mass flow through the absorber tube of the collector

$h_{in}$  is the fluid specific mass enthalpy at the collector inlet

$h_{out}$  is the fluid specific mass enthalpy at the collector outlet

The net output thermal power delivered by a PTC can be calculated by means of Equation 42.35 if the fluid mass flow and the inlet and outlet temperatures are known when the collector is in operation. However, these data are not known during the solar field design phase, and the expected net thermal output has to be calculated starting from the values of the direct solar irradiance, ambient air temperature, incidence angle, and PTC optical, thermal, and geometrical parameters. Equation 42.36 can be used for this purpose.

$$P_{Q, collector \rightarrow fluid} = P_{Q, sun \rightarrow collector} \cdot \eta_{global} = A_c \cdot E_d \cdot \cos(\varphi) \cdot \eta_{opt, 0''} \cdot K(\varphi) \cdot \eta_{th} \cdot F_e \quad (42.36)$$

From a practical standpoint, calculation of the net thermal output power during the design phase is easier if thermal losses in the PTC,  $P_{Q, \text{collector} \rightarrow \text{ambient}}$ , are used instead of the thermal efficiency,  $\eta_{th}$ . In this case, the net thermal output power is given by the following equation, which must be used in combination with Equation 42.23:

$$P_{Q, \text{collector} \rightarrow \text{fluid}} = A_c \cdot E_d \cdot \cos(\varphi) \cdot \eta_{opt, 0''} \cdot K(\varphi) \cdot F_e - P_{Q, \text{collector} \rightarrow \text{ambient}} \quad (42.37)$$

All the parameters used in Equation 42.37 have been explained in the earlier paragraphs, with the exception of the *soiling factor*,  $F_e$ , which is  $0 < F_e < 1$ , and takes into account the progressive soiling of mirrors and absorber tube glass after washing. This means that the reflectivity and transmissivity are usually lower than nominal, and the peak optical efficiency is also lowered. Usual values of  $F_e$  are around 0.97, which is equivalent to a mirror reflectivity of 0.90 for mirrors with a nominal reflectivity of 0.93.

#### 42.4.4 Industrial Applications for Parabolic-Trough Collectors

The large potential market existing for solar systems with PTCs can be clearly seen in the statistical data. The U.S. industry consumes about 40% of the total energy demand in that country. Of this, approximately half (about 20% of the total energy consumption) involves IPH suitable for solar applications with PTCs, which are internationally known as IPH applications. As an example of the situation in other countries with a good level of direct solar radiation, industry is also the biggest energy consumer in Spain (more than 50% of the total energy demand), and 35% of the industry demand is in the mid-temperature range (80°C–300°C) for which PTCs are very suitable.

Besides this large potential market for parabolic-trough systems, there is also an environmental benefit that is taken more and more into consideration: contrary to fossil fuels, solar energy does not contaminate, and it is independent of political or economic interruptions of supply (due to war, trade boycott, etc).

Since industrial process energy requirements in the mid-temperature range are primarily met by steam systems, representative configurations of solar steam generation systems are presented in this section with simple diagrams to facilitate their understanding.

Steam is the most common heat transport medium in industry for temperatures below 250°C where there is a great deal of experience with it. Compact steam generators have proven to be extremely reliable. Integration of a solar steam generation system for a given industrial process involves a simple plant interface to feed steam directly into the existing process, with no major facility changes. Medium-temperature steam can be supplied with PTCs in three different ways:

1. Using a high-temperature, low-vapor-pressure working fluid in the solar collectors and transferring the heat to an unfired boiler where steam is produced. Oil is widely used for this purpose.
2. Circulating pressurized hot water in the solar collectors and flashing it to steam in a flash tank. This method is suitable for temperatures that are not too high (below 200°C), because of the high pressure required in the absorber pipes and flash tank for higher temperatures.
3. Boiling water directly in the collectors (the so-called direct steam generation process).

A brief description of each of these methods follows.

#### 42.4.4.1 Unfired Boiler System

Figure 42.20 shows the schematic diagram for an unfired steam boiler system with PTCs. A heat transfer fluid (HTF) is circulated through the collector field, and steam is generated in an unfired boiler. A variation of the system shown in Figure 42.20 incorporates a preheater in the water makeup line, which not only increases the system cost, but also reduces the inlet temperature to the solar field. Water could be circulated in the collector loop, but the fluid generally selected is a low-vapor-pressure, nonfreezing hydrocarbon, or silicon oil. The use of oil overcomes the disadvantages associated with water (high vapor pressure and risk of freezing) and accommodates energy storage, but certain characteristics of these oils cause other problems. Generally, precautions must be taken to prevent the oil from leaking out of the system, which could cause fire. Oil is also expensive and has poorer heat transport properties than water. They are extremely viscous when cold, and a positive displacement pump is sometimes needed to start the system after it has cooled down. The use of a fluid to transfer thermal energy from the solar field to an unfired boiler where steam is produced is internationally known as HTF technology.

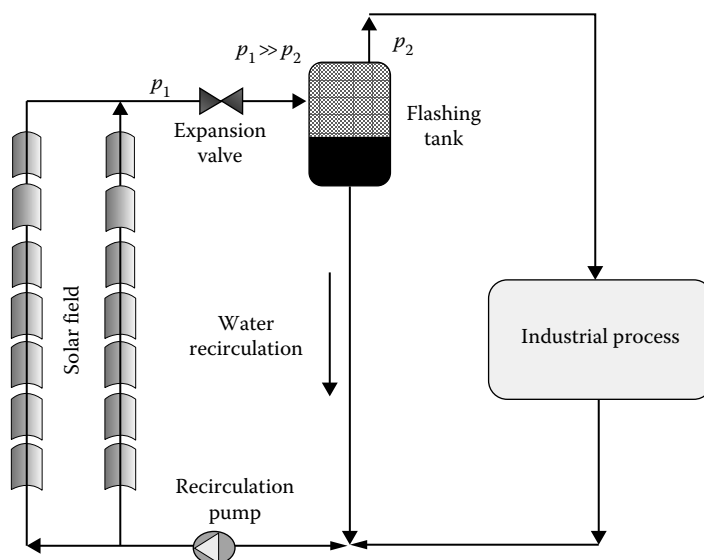

The unfired boiler itself is an expensive item requiring alloy tubes for corrosion protection, and it is an additional resistance to heat flow. As in the flash-steam system, the collectors must operate at a temperature some degrees (20°C approx.) above the steam delivery temperature. Because the process steam must be maintained at a certain temperature, the solar-generated steam is delivered at a variable flow rate depending on the solar radiation available at the aperture of the solar collectors. The collector outlet temperature can be held constant by varying the oil flow rate through the collectors as the collected solar energy varies due to cloud passage or any other reason.

#### 42.4.4.2 Flash-Steam Systems

A diagram of a flash-steam system is shown in Figure 42.21. Water at a high enough pressure to prevent boiling is circulated through the collector field and flashed to steam across a throttling valve into a separator. This constant-enthalpy process converts the sensible heat of the water into the latent heat of a two-phase mixture at the conditions prevailing in the separator. The maximum steam quality (i.e., the fraction of total flow that is converted

**FIGURE 42.20**  
Unfired-boiler steam-generating system.

**FIGURE 42.21**  
Flash-steam solar system.

into steam) is less than 10% due to thermodynamic constraints. The steam thus produced is fed into the industrial process, while the water remaining in the flash tank is recirculated to the solar field inlet. Feed-water makeup is injected from the flash tank into the pump suction to maintain the liquid level in the tank.

Using water as an HTF simplifies the construction of a flash-steam system. However, although water is an excellent heat transport medium, freezing problems can occur. Therefore, the freeze protection mechanism must be carefully designed and controlled to ensure that a minimum amount of heat is supplied to the water to prevent freezing due to low ambient temperature.

The disadvantages of the flash-steam system are associated with the steam generation mechanism. Collector temperatures must be significantly higher than the steam delivery temperature to obtain reasonable steam qualities downstream of the throttling valve and to limit the water recirculation rate. But higher temperatures reduce the collector's efficiency. In addition, the circulating pump must overcome the pressure drop across the flash valve, which can be important.

Moreover, the rapid rise in the water vapor pressure at temperatures above 175°C limits the steam pressure that can be achieved by this method to approximately 2 MPa (305 psig) at acceptable levels of electrical power required for pumping. For higher pressures, the electricity consumption of the feed-water pump would be excessive and would jeopardize the efficiency of the whole system.

#### 42.4.4.3 Direct Steam Generation

DSG in the absorber tubes of PTCs is an attractive concept because the average collector operating temperature would be near the steam delivery temperature and because the phase change reduces the required water flow through the circulating pump. The system diagram would be similar to that of the flash-steam system but without a flash valve. The disadvantages of this concept are associated with the thermo-hydraulic problems associated with the two-phase flow existing in the evaporating section of the solar

field. Nevertheless, experiments performed at the PSA in Spain have proven the technical feasibility of DSG with horizontal PTCs at 100 bar/400°C (Zarza et al., 2002).

#### 42.4.5 Sizing and Layout of Solar Fields with Parabolic-Trough Collectors

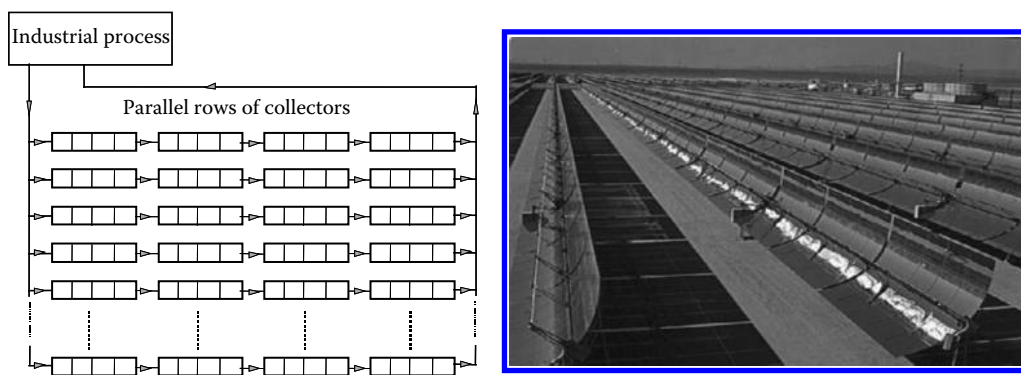

A typical parabolic-trough solar collector field (Figure 42.22) is composed of a number of parallel rows of several collectors connected in series so that the working fluid circulating through the absorber pipe is heated as it passes from the inlet to the outlet of each row.

The first step in the design of a parabolic-trough solar field is the definition of the so-called design point, which is composed of a set of parameters that determine solar field performance. Parameters to be defined for the *design point* are

- Collector orientation
- Date (month and day) and time of design point
- Direct solar irradiance and ambient air temperature for the selected date and time
- Geographical location of the plant site (latitude and longitude)
- Total thermal output power to be delivered by the solar field
- Solar collector soiling factor
- Solar field inlet/outlet temperatures
- Working fluid for the solar collectors
- Nominal fluid flow rate

If oil is used in the solar field to transfer the energy to an unfired boiler (HTF technology), the selected temperature of the fluid at the solar field outlet must be at least 10°C higher than the steam temperature demanded by the process to be fed. So, for example, if the industrial process to be fed by the solar system requires 300°C steam, the oil temperature at the solar field outlet must be about 315°C. This difference is necessary to compensate for thermal losses between the solar field outlet and the steam generator inlet and the boiler pinch point, which is on the order of (approx.) 5°C–7°C.

Once the design point has been defined, the number of collectors to be connected in series in each row can be calculated using the parameters of the selected PTC (peak optical efficiency, incidence angle modifier, heat loss coefficient, and aperture area) and fluid

**FIGURE 42.22**

A typical solar field with parabolic-trough collectors.

(density, heat capacity, and dynamic viscosity). The number of collectors in each row depends on the nominal temperature difference between solar field inlet and outlet,  $\Delta T$ , and the single collector temperature step,  $\Delta T_c$ . Thus, if a collector field is intended to supply thermal energy to an unfired boiler that requires a temperature step of 70°C between inlet and outlet, with a nominal inlet temperature of 220°C, the inlet and outlet temperatures in each row will be 220°C and 290°C, respectively, with a  $\Delta T = 70^\circ\text{C}$ . Once this  $\Delta T$  has been determined, the number of collectors required in each row,  $N$ , is given by the ratio

$$N = \frac{\Delta T}{\Delta T_c}$$

where

$N$  is the number of collectors to be connected in series in a row

$\Delta T$  is the required  $\Delta T$  by the industrial process

$\Delta T_c$  is the difference between the single collector nominal inlet and outlet working temperatures

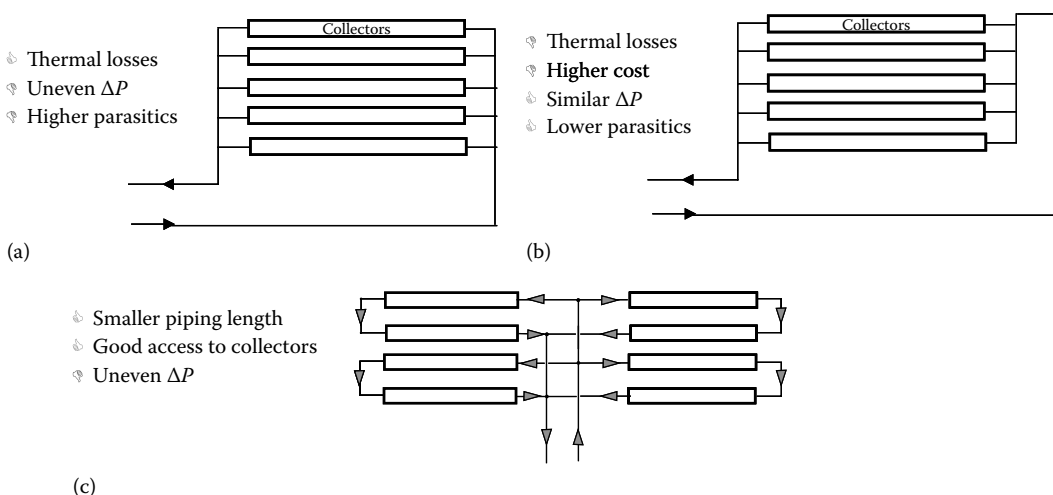

Once the number of collectors to be connected in series in each row has been calculated, the next step is to determine the number of rows to be connected in parallel. This number depends on the thermal power demanded by the industrial process. The procedure for determining the number of rows is very simple when there is no thermal storage system: the ratio between the thermal power demanded by the industrial process and the thermal power delivered by a single row of collectors at design point.

When thermal storage is available, the number of parallel rows is determined in a different way. In this case, the useful thermal energy delivered by a single row of collectors from sunrise to sunset during the design day must be calculated, as well as the thermal energy demanded during the complete day (i.e., 24 h period) by the process to be fed by the solar field. The number of parallel rows required is given by the ratio between the thermal energy demanded by the process and the thermal energy delivered by a single row of collectors.

After sizing the solar field, the designer has to lay out the piping. Three basic layouts are used in solar fields with PTCs. These layouts (direct return, reverse return, and center feed) are shown schematically in [Figure 42.23](#). In all three options, the hot outlet piping is shorter than the cold inlet piping to minimize thermal losses. The advantages and disadvantages in each of these three configurations are explained in following paragraphs.

The *direct-return* piping configuration is the simplest and probably the most extensively used in small solar fields. Its main disadvantage is that there is a much greater pressure difference between the inlets in parallel rows, so that balancing valves must be used to keep flow rates the same in each row. These valves cause a significant pressure drop at the beginning of the array, and thus their contribution to the total system pressure loss is also significant. The result is higher parasitic energy consumption than for the reverse-return layout, where the fluid enters the collector array at the opposite end. Pipe headers with different diameters are used in this configuration to balance array flow. The use of larger pipe headers also results in lower parasitic power requirements, but these could be offset by increases in initial investment costs and thermal energy losses.

The *reverse-return* layout has an inherently more balanced flow. While balancing valves may still be required, the additional system pressure loss is much lower than in a direct-return configuration. (Alternatively, header pipes can be stepped down in size on the inlet side and stepped up on the outlet side to keep flow rate in the headers constant, thereby

**FIGURE 42.23**

Solar field layouts for parabolic-trough collectors: (a) direct return, (b) inverse return, and (c) central feed.

providing uniform flow.) The extra length of piping at the solar field inlet is a disadvantage in the reverse-return configuration because of the additional heat loss, although this greatly depends on the solar field inlet temperature. If this temperature is low, additional heat loss is negligible. Adding to pipe length, however, results in higher piping, insulation, and fluid inventory costs.

The *center-feed* configuration is the most widely used layout for large solar fields. Like the direct-return design, pressure balancing valves may be required at the row inlets in very large solar fields, and pressure loss would be thus increased in the solar field. However, this configuration has two important advantages: (1) it minimizes the total amount of piping because there is no pipe running the length of the collector row, and (2) there is direct access to each collector row without buried pipes. This direct access is very important for repair works and solar field washing, which must be performed often in commercial plants to keep a high level of reflectivity, because vehicles have an easy access to each solar collector.

#### 42.4.6 Electricity Generation with Parabolic-Trough Collectors

The current PTC temperature range and their good solar-to-thermal efficiency up to 400°C make it possible to integrate a parabolic-trough solar field in a Rankine water–steam power cycle to produce electricity. The simplified scheme of a typical STP plant using parabolic troughs integrated in a Rankine cycle is shown in Figure 42.24. So far, all the STP plants with parabolic-trough collectors use the HTF technology because steam production by flashing is not suitable for 100-bar superheated-steam pressure, and commercial DSG has not yet been commercially proven for superheated steam at 100 bar.

A parabolic-trough power plant is basically composed of three elements: the solar system, the steam generator, and the power conversion system (PCS; see Figure 42.24). The solar system is composed of a parabolic-trough solar collector field and the oil circuit. The solar field collects the solar energy available in the form of direct solar radiation and converts it into thermal energy as the temperature of the oil circulating through the receiver tubes of the collectors increases.

**FIGURE 42.24**

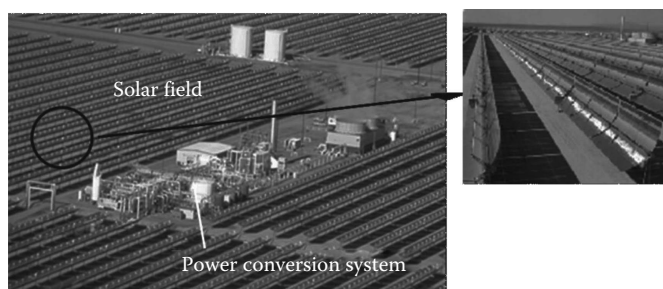

Simplified scheme of a solar thermal power plant with parabolic-trough collectors.

Once heated in the solar field, the oil goes to the steam generator, which is an oil–water heat exchanger where the oil transfers its thermal energy to the water that is used to generate the superheated steam required by the turbine. The steam generator is, therefore, the interface between the solar system (solar field + oil circuit) and the PCS itself. Normally, the steam generator used in these solar power plants consists of three stages:

1. *Preheater*: Where water is preheated to a temperature close to evaporation.
2. *Evaporator*: Where the preheated water is evaporated and converted into saturated steam.
3. *Superheater*: The saturated steam produced in the evaporator is heated in the superheater to the temperature required by the steam turbine.

The PCS transforms the thermal energy delivered by the solar field into electricity, using the superheated steam delivered by the steam generator. This PCS is similar to that of a conventional Rankine power plant, except for the main difference that heat supplied to the conventional Rankine cycle is from fossil fuels, while in the solar plant, the PTCs deliver the required thermal energy.

The superheated steam delivered by the steam generator is then expanded in a steam turbine that drives an electricity generator, which produces the electricity that is delivered to the distribution grid. The steam turbine is usually composed of two consecutive stages, for high- and low-pressure steam. Steam leaving the turbine high-pressure stage goes to a reheater where its temperature rises before entering the low-pressure turbine stage. After this stage, the steam is condensed, and the condensate goes to a water deaerator to remove oxygen and gases dissolved in the water. The steam leaving the turbine low-pressure stage can be condensed either in a wet cooling system (with cooling towers refrigerated by water) or in a dry cooling system (condenser refrigerated by air). The selection of the best cooling system is strongly influenced by the onsite availability of water resources. The main pump takes feed water for the steam generator from the deaerator, thus starting the Rankine thermodynamic cycle again.

**FIGURE 42.25**

Overall view of a solar power plant with parabolic-trough collectors.

Though parabolic-trough power plants usually have an auxiliary gas-fired heater to produce electricity when direct solar radiation is not available, the amount of electricity produced with natural gas is always limited to a reasonable level. This limit changes from one country to another: 25% in California (United States), 15% in Spain (until 2012, because this percentage was reduced to 0% in 2012), and no limit in Algeria. Figure 42.25 shows what an STP plant with PTCs looks like. The PCS is located at the center of the plant, surrounded by the solar field. The plant shown in Figure 42.25 is provided with a wet cooling system, and the steam leaving the cooling towers is clearly shown.

Parabolic-trough power plants can play an important role in achieving sustainable growth because they save about 2000 tons of CO<sub>2</sub> emissions per MW of installed power yearly. Typical solar-to-electric efficiencies of a large STP plant (>30 MW<sub>e</sub>) with PTCs are between 15% and 22%, with an average value of about 17%. The yearly average efficiency of the solar field is about 50%.

Though not included in Figure 42.24, a thermal energy storage system can be implemented in parabolic-trough power plants to allow operation of the PCS when direct solar radiation is not available. In this case, the solar field has to be oversized so that it can simultaneously feed the PCS and charge the storage system during sunlight hours. Thermal energy from the storage system is then used to keep the steam turbine running and producing electricity after sunset or during cloudy periods. Yearly hours of operation can be significantly increased, and plant amortization is thus enhanced when a storage system is implemented. However, the required total investment cost is also higher.

#### 42.4.7 Thermal Storage Systems for Parabolic-Trough Collectors

The main problem with using solar radiation is its discontinuity, because it is possible to collect only during sunlight hours. There is an additional limitation when dealing with concentrating solar systems as these systems can collect only the direct solar radiation, so they need clear sky conditions, because clouds block direct solar radiation. Thermal storage systems are implemented to solve these limitations.

When a solar system does not have to supply thermal energy during the night or during cloudy periods, a storage system is not necessary. On the other hand, if the industrial process has to be supplied during periods without direct solar radiation, a storage system has to be implemented to store part of the thermal energy supplied by the solar collectors during the sunlight hours to deliver it when the sun is not available.

Thermal storage systems have three main advantages:

1. Thermal energy can be supplied during hours when direct solar radiation is not available, so that solar energy collection and thermal energy supply do not have to be simultaneous.
2. The solar field inlet can be isolated from possible disturbances at the outlet, because the storage system behaves as a good thermal cushion and avoids feedback of the disturbances affecting the solar field outlet temperature.
3. A constant thermal power level can be supplied to the process if energy is taken from both solar field and thermal storage system, so that the energy taken from the thermal storage complements the energy delivered by the solar field. The variability of the beam solar radiation is thus compensated with thermal energy delivered by the thermal storage system.

The second advantage is very important because it enhances solar field operation on days with frequent cloud transients. No matter how effective solar field control is, the fluid temperature at the outlet is affected by cloud transients, and temperature fluctuations are likely. These fluctuations would immediately affect the working fluid temperature at the inlet if there were not a thermal storage system in between.

The hot water storage system used in low-temperature solar conversion systems (i.e., flat-plate collectors) is not suitable for parabolic-trough systems because the high pressure in the storage tank would make the system too expensive. For this reason, PTCs require the use of a different storage medium. Depending on the medium where the thermal energy is stored, there are two types of systems:

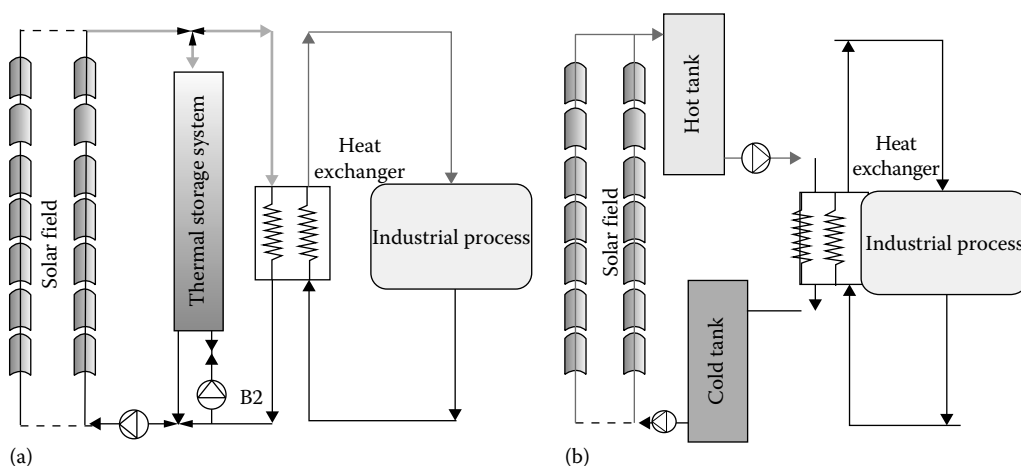

1. Single-medium storage systems
2. Dual-medium storage systems

#### **42.4.7.1 Single-Medium Storage Systems**

*Single-medium storage systems* are those in which the storage medium is the same fluid circulating through the collectors. The most common is thermal oil as both the working fluid and the storage medium. The efficiency of these systems is over 90%. Oil storage systems can be configured in two different ways:

##### **42.4.7.1.1 Systems with a Single Oil Tank**

For low-capacity storage systems, thermal energy can be stored in a single tank, in which the oil is stratified by temperature. Energy is stored as latent heat by increasing the temperature of the oil in the tank. Figure 42.26a shows this type of system configuration, in which the solar field can supply hot oil to the tank by means of three-way valves installed at the solar field inlet and outlet, so that all of it or only part of it enters. The density of the thermal oils commonly used as working fluids in these systems strongly varies with temperature. So, for instance, the density of Santotherm 55 oil at 90°C is 842.5 kg/m<sup>3</sup>, while at 300°C it is 701.4 kg/m<sup>3</sup>. Due to its lower density, the hot oil entering the storage tank through the top inlet manifold remains in the upper layers inside the tank, while the cold oil always remains at the bottom of the tank. As seen in Figure 42.26a, the boiler supplying the thermal energy demanded by the industrial process can be fed from either the storage tank or the solar field, depending on the position of the three-way valve. When discharging the storage system, the hot oil leaves the tank through the top outlet manifold and returns to the bottom after leaving the boiler. Pump “B2” is used

**FIGURE 42.26**

Thermal storage systems with (a) one and (b) two oil tanks.

exclusively to feed the boiler from the storage tank, when the solar field is not in operation. Cold oil leaves from the bottom of the storage tank and goes to the solar field during daylight hours to be heated and then returned to the top of the storage tank. The storage system is fully charged when all the oil stored in the tank is hot. As already mentioned, the use of a single oil storage tank is feasible only for small storage systems. For high-capacity systems, two oil tanks (i.e., one tank for cold oil and another for hot oil) are needed.

#### 42.4.7.1.2 Systems with Two Oil Tanks

There are two oil tanks in these systems (see Figure 42.26b), one hot tank and one cold tank. The boiler is always fed from the hot tank, and once the oil has transferred heat to the water in the unfired boiler, it goes to the cold tank. This tank supplies the solar field, which at the same time feeds the hot tank with the oil heated by the collectors.

One of the drawbacks of using oil as the storage medium is the need to keep the oil in the storage tank(s) pressurized and inert. Thermal oil has to be kept pressurized above the vapor pressure corresponding to the maximum temperature in the oil circuit to prevent the oil from changing into gas. Fortunately, the vapor pressure of the thermal oils used in these systems is usually low for the 100°C–400°C temperature range, and pressurization is easily maintained by injecting argon or nitrogen. This inert atmosphere also avoids the risk of explosion in the tank from pressurized mists, which are explosive in air.

Another disadvantage of oil systems is the need for appropriate fire-fighting systems, as well as a concrete oil sump to collect any leaks and avoid contamination. All this equipment increases the cost of the storage system. Thermal oil storage systems usually have two safety systems to avoid excessive overpressure inside the tank when temperature increases (the oil expands considerably with temperature):

1. A relief valve to discharge the inert gas into the atmosphere when the pressure inside the tank is over a predefined value. This valve usually works when the pressure inside the tank increases slowly (for instance, during charging).
2. Due to the small section of the relief valve, it cannot dissipate sudden overpressures. There is an additional security device for this purpose: a pressure-rated ceramic rupture disk. This system allows gases to be rapidly evacuated into the

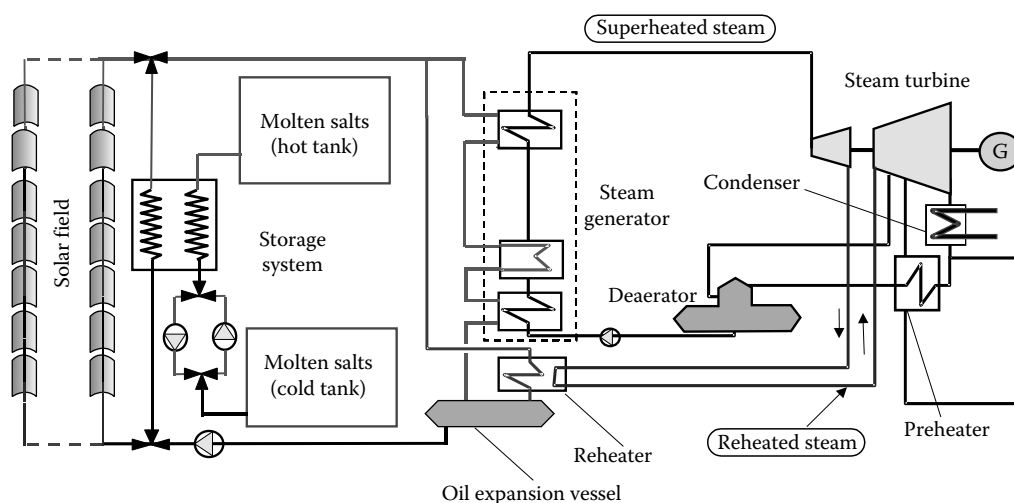

atmosphere. The rupture disk is destructive, because it consists of a ceramic membrane that breaks if the pressure in the tank is higher than calibrated. The rupture disk works only in case of an emergency when overpressure occurs so quickly that the relief valve cannot keep the pressure inside the tank below the limit value.

An additional auxiliary system required in thermal oil storage tanks is a small vessel where gas and volatile compounds produced by oil cracking are condensed and evacuated.

#### 42.4.7.2 Dual-Medium Storage Systems

*Dual-medium storage systems* are those in which the heat is stored in a medium other than the working fluid heated in the solar collectors. Iron plates, ceramic materials, molten salts, or concrete (Laing et al., 2008) can be used as the storage medium. In these systems, the oil is commonly used as the heat transfer medium between the solar field and the material where the thermal energy is stored in the form of sensible heat. In the case of thermal storage in iron plates, the oil circulates through channels between cast iron slabs placed inside a thermally insulated vessel, transferring thermal energy to them (charging process) or taking it from them (discharging process). When concrete is used as storage medium, the oil circulates through steel tubes installed inside big blocks of concrete.

Molten salts (a eutectic mixture of sodium and potassium nitrates) are nowadays used for dual-medium thermal storage systems in parabolic-trough solar plants. In this case, two tanks are needed: one for cold molten salt and another to store the hot molten salt. Obviously, the lowest temperature is always above the melting point of the salt (250°C, approx.). In this case, a heat exchanger is needed to transfer energy from the oil used in the solar field (heat transfer medium) to the molten salt used for energy storage (storage medium). Figure 42.27 shows the simplified scheme of a parabolic-trough power plant with a molten-salt thermal energy storage system. This type of thermal storage system is currently installed in many Spanish commercial plants, with a storage capacity of 1 GWh in each plant, and it is claimed to be the current most cost-effective option for large commercial solar power plants with large solar shares.

**FIGURE 42.27**

Scheme of a parabolic-trough power plant with molten-salt storage system.

Thermal storage systems using latent heat, also called phase change material (PCM) storage systems because they use a medium that changes phase during charging and discharging, are under development, and several prototypes have been experimentally tested (Bayón et al., 2010). The storage medium used in the first prototypes was a mixture of  $\text{NaNO}_3$  and  $\text{KNO}_3$ . The melting temperature of the mixture can be varied from  $220^\circ\text{C}$  to  $300^\circ\text{C}$  (approx.) changing the percentage of these two components, thus covering a wide range of steam pressures (i.e., 22–100 bar approx.). The main technical constraint of this type of storage systems is the low thermal conductivity of the salt mixture. Although the use of graphite foils to enhance heat transfer has been successfully evaluated, other options are under study and are ready for testing in the short term. However, latent-heat thermal storage systems are not expected to reach the market before 2020. PCM storage systems are required by STP plants with DSG, because the sensible heat storage systems used in HTF plants are not suitable to store the thermal energy released by the steam during its condensation.

#### 42.4.8 Direct Steam Generation

All solar power plants with PTCs implemented to date use thermal oil as the working fluid in the solar field, and they usually follow the general scheme in Figure 42.24, with only slight differences from one plant to another. The technology of these plants has been improved since the implementation of the first commercial plant in 1984 (Lotker, 1991; Price et al., 2002). However, though the collector design and connection between the solar system and the PCS have been improved, some further improvements could still be implemented to reduce costs and increase efficiency. The main limitation to improving their competitiveness is the technology itself: the use of oil as a heat carrier medium between the solar field and the PCS, which entails a high-pressure drop in the oil circuit, limitation of the maximum temperature of the Rankine cycle, and O&M costs of the oil-related equipment. If the superheated steam required to feed the steam turbine in the power block were produced directly in the receiver tubes of the PTCs (i.e., DSG), the oil would be no longer necessary, and temperature limitation and environmental risks associated with the oil would be avoided (Ajona and Zarza, 1994). Figure 42.28 shows the overall scheme of a parabolic-trough power plant with DSG in the solar field. Simplification of overall plant configuration is evident when comparing Figures 42.24 and 42.28.

**FIGURE 42.28**

Simplified scheme of a parabolic-trough power plant with direct steam generation.

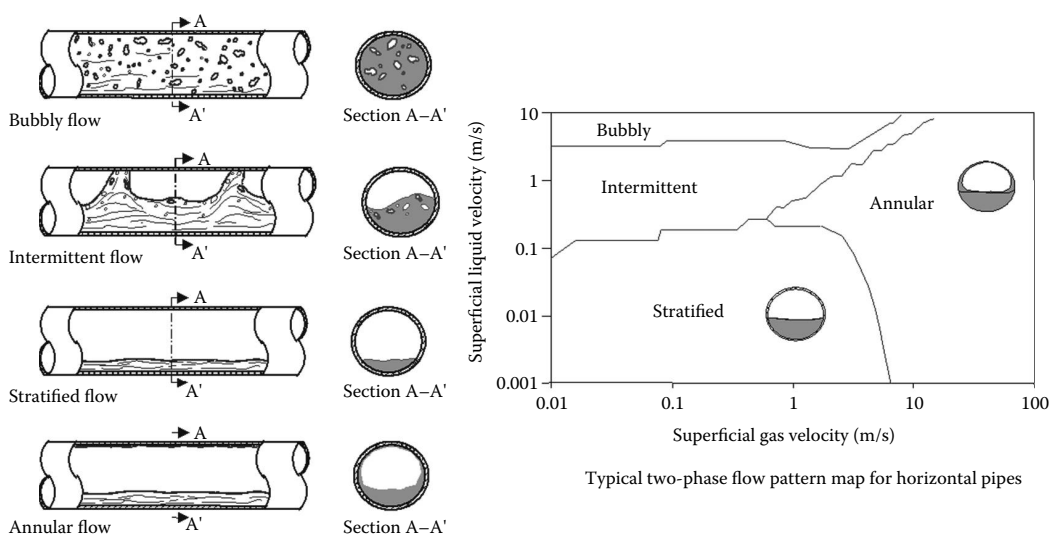

DSG has technical advantages that must be considered (Zarza et al., 1999):

- No danger of pollution or fire due to the use of thermal oil at temperatures of about 400°C
- Possibility of raising the maximum temperature of the Rankine cycle above 400°C, the limit imposed by the thermal oil currently used
- Reduction in the size of the solar field, thus reducing the investment cost
- Reduction in operation and maintenance-related costs, as thermal-oil-based systems require a certain amount of the oil inventory to be changed every year, as well as antifreeze protection when the air temperature is below 14°C

However, DSG presents certain challenges as a way to improve the current technology of parabolic-trough solar power plants, due to the two-phase flow (liquid water + steam) existing in the absorber tubes of the solar field evaporating section. The existence of this two-phase flow involves some uncertainties that must be clarified before a commercial plant making use of this technology can be built. Some of these uncertainties are

- Solar field control
- Process stability
- Stress in the receiver pipes
- Higher steam loss (leaks) than oil-based systems

Figure 42.29 shows the typical two-phase flow pattern in a horizontal pipe. As observed in Figure 42.29, four main flow patterns are possible, depending on the surface flow rates in the liquid and steam phases: bubbly, intermittent, stratified, and annular. The borders between adjacent flow patterns are not as well defined as they appear in Figure 42.29, but are rather separated by transition zones.

**FIGURE 42.29**

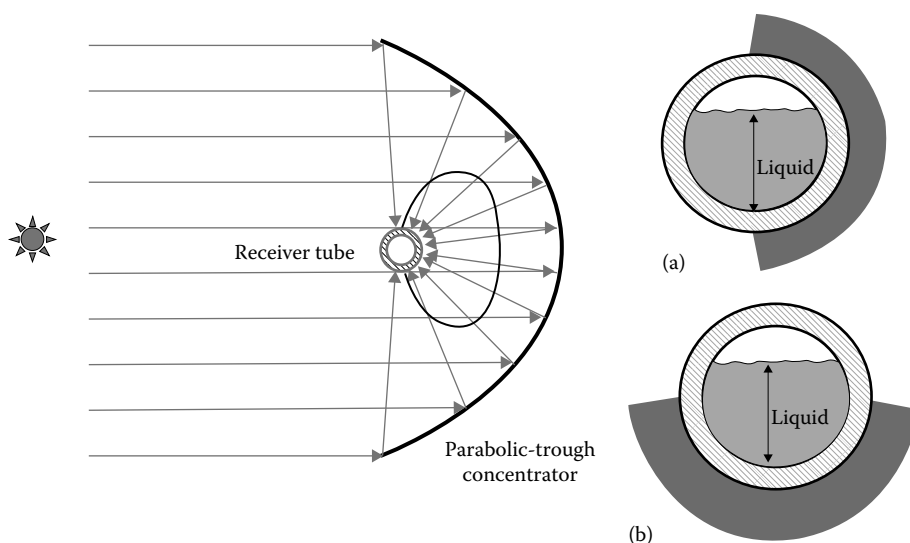

Two-phase flow configurations and typical flow pattern map for a horizontal receiver pipe.

In bubbly and intermittent flows, the steel absorber pipe inner wall is well wetted, thus avoiding dangerous temperature gradients between the bottom and the top of the pipe when it is heated from one side. The result is a good heat transfer coefficient all the way around the pipe because the liquid phase is not stratified.

In the stratified region (Goebel, 1997), the water is in the bottom of the absorber pipe, while the steam remains above the surface of the water. The result of this stratification is an uneven heat transfer coefficient around the pipe. Wetting of the bottom of the pipe is still very good and so is the heat transfer coefficient. But the cooling effect of the steam is poorer, and the heat transfer coefficient in the top section of the absorber pipe can be very low, resulting in a wide temperature difference of more than 100°C between the bottom and the top of the pipe in a given cross section when it is heated from one side. The thermal stress and bending from this steep temperature gradient can destroy the pipe. Figure 42.30 shows what happens in a cross section of the steel absorber pipe when it is heated underneath (Figure 42.30b, parabolic-trough concentrator looking upward) and from one side (Figure 42.30a, parabolic-trough concentrator looking at the horizon). The figure clearly shows how stratified flow can cause steep temperature gradients only when the vector normal to the aperture plane of the concentrator is almost horizontal (Figure 42.30a).

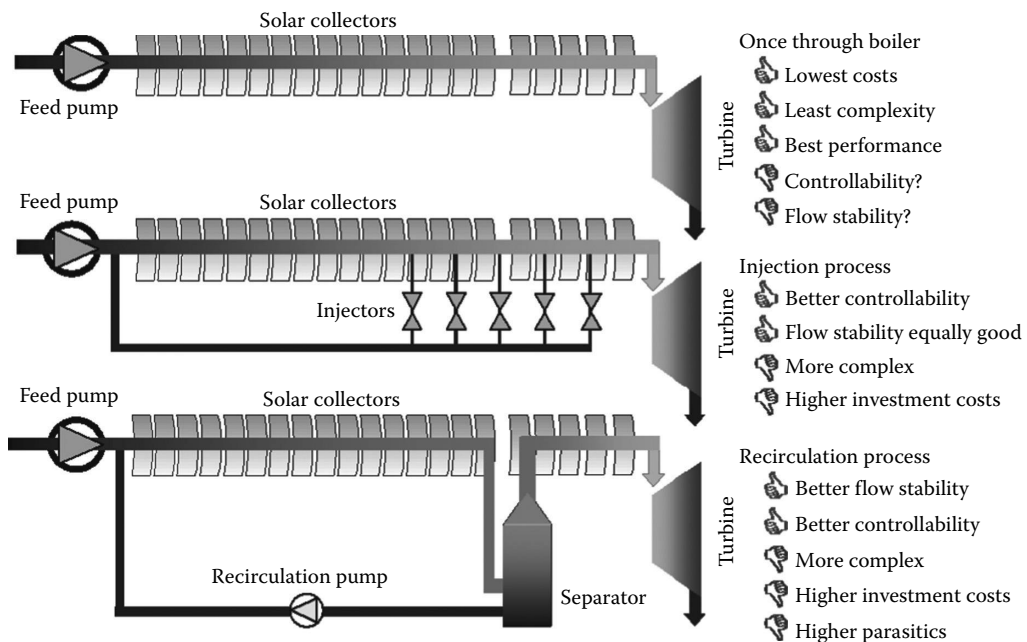

In the annular region, though there is partial stratification of water at the bottom of the pipe, there is a thin film of water wetting the upper part of the pipe. This film is enough to ensure a good heat transfer coefficient all the way around the pipe, thus avoiding dangerous thermal gradients that could destroy it. Typical absorber pipe cross sections in the stratified and annular regions are also shown in Figure 42.29.

Nevertheless, the technical problems due to water stratification inside the absorber pipes can be avoided if the feed-water mass flow is kept above a threshold level. There are three basic DSG processes, called once-through, injection, and recirculation. These three options require a solar field composed of long rows of PTCs connected in series to perform the

**FIGURE 42.30**

Liquid-phase stratification and concentrated incident solar flux onto the receiver pipe: (a) solar collector in vertical position; (b) solar collector in horizontal position (looking upward).

**FIGURE 42.31**  
The three basic DSG processes.

complete DSG process: water preheating, evaporation, and steam superheating. Figure 42.31 summarizes the advantages and disadvantages of the three basic DSG options.

First, in the once-through process, all the feed water is introduced at the collector row inlets and converted into superheated steam as it circulates through the collector rows.

Second, in the injection process, small fractions of feed water are injected along the collector row. The main advantage of this process is the good controllability of the superheated steam parameters at the field outlet. On the downside, this makes the system more complex and increases its cost.

The third option, the so-called recirculation process, is the most conservative one. In this case, a water–steam separator is placed at the end of the evaporating section of the collector row. Feed water enters the solar field inlet at a higher flow rate than the steam to be produced by the system. Only a fraction of this water is converted into steam as it circulates through the collectors of the preheating and evaporating sections. At the end of the evaporating section, the saturated steam is separated from the water by the separator, and the remaining water is recirculated to the solar field inlet by a recirculation pump. The excess water in the evaporating section guarantees good wetting of the receiver pipes and makes stratification of liquid water impossible. Good controllability is the main advantage of this DSG option, but the need for a recirculation pump and the excess water that has to be recirculated from the water–steam separator to the solar field inlet increase system parasitic loads, penalizing overall efficiency.

Figure 42.31 shows that, compared to each other, each of the three basic DSG options has advantages and disadvantages (Zarza et al., 1999), and only their evaluation under real solar conditions can show which option is the best. This is why in 1996 a European consortium launched an R&D project to investigate all the technical questions concerning the DSG process. The name of that project was DIrect Solar Steam (DISS), and it was

developed by partners belonging to all the sectors involved in this technology (i.e., electric utilities, industry, engineering companies, and research centers) in efficient collaboration with other European projects related to PTCs and STP plants (e.g., STEM, ARDISS, GUDE, EuroTrough, PRODISS).

The only DSG life-size test facility available in the world at the end of last century was designed and implemented at the PSA during the first phase of the DISS project to investigate the feasibility of DSG in PTCs under real solar conditions. DISS-phase I started in January 1996 and ended in November 1998, with the financial support of the European Commission. The second phase of the project, also partly funded by the European Commission, started in December 1998 and lasted 37 months.

Though the DISS solar field can be operated over a wide temperature/pressure range, the three main operating modes are as follows:

Solar Field Conditions	Inlet	Outlet
Mode 1	40 bar/210°C	30 bar/300°C
Mode 2	68 bar/270°C	60 bar/350°C
Mode 3	108 bar/300°C	100 bar/375°C

The DISS test facility accumulated more than 8000 h of operation until 2012. The experimental data gathered in the project and the simulation tools that were developed on the basis of test data provided enough information to evaluate and compare the three DSG basic operation modes (i.e., recirculation, injection, or once-through) or any combination of them. Water injectors at the inlet of the solar collectors and water pumps are provided with frequency converters for smooth, efficient speed control from 10% to 100%. This facility is still in operation and delivers very useful information for the short-term commercial deployment of DSG.

The PSA DISS test facility field was initially composed of a single row of 11 PTCs connected in series, with a total length of 550 m and 2700 m<sup>2</sup> of aperture surface. The collector row is connected to the balance of plant where the superheated steam delivered by the solar field is condensed and used as feed water for the solar field (closed-loop operation).

The DISS test facility implemented at the PSA in DISS-phase I was improved during the subsequent years, and it became a very flexible and powerful life-size test facility, suitable not only for investigating thermo-hydraulic aspects of DSG under real solar conditions, but also for evaluating optimized components and O&M procedures for commercial DSG solar plants. Figure 42.32 shows the present schematic diagram of the PSA DISS facility. A water–steam separator (marked TK-4 in Figure 42.32) connects the end of the evaporating section to the inlet of the steam superheating section when the facility is operated in recirculation mode. Two additional collectors were added to the first row in 2003, so it is currently 750 m long with an aperture area of 3822 m<sup>2</sup>, with a nominal thermal power of 1.8 MW<sub>th</sub> and a maximum 400°C/100 bar superheated steam production of 1 kg/s.

The DISS project results proved the feasibility of the DSG process in horizontal PTCs, and important know-how was acquired by the project partners regarding the thermo-hydraulic parameters of the liquid water–steam flow in DSG solar fields within a wide range of pressures (30–100 bar). Experimental results were evaluated and complemented with results from lab-scale experiments and simulation tools. So several models developed in the past to calculate the pressure drop in pipes with two-phase flow were compared with the project's experimental results, and the models with the most accurate simulation results were identified. The proposed Chisholms (1980) and Friedel models proved to be the best match (Zarza, 2004).

**FIGURE 42.32**

Schematic diagram of the PSA DISS test facility.

The good match between experimental data and simulation results obtained with finite-element models for the temperature profile in the DSG absorber pipes was another conclusion achieved in the DISS project. It was proven that the temperature gradients in the steel absorber pipes are within safe limits for a wide range of mass fluxes. Results concerning pressure drop and temperature gradients in the absorber pipes of the DISS collector row enabled accurate simulation and design tools for large DSG commercial solar fields to be developed (Eck et al., 2003) and was one of the major contributions of DISS to the development of the DSG technology.

Different possibilities (i.e., inner capillary structures and displacers) for enhancing heat transfer in the DSG absorber pipes were also investigated; however, experimental results showed that the absorber pipes do not need these devices to keep the temperature gradients within safe limits.

Several control schemes for once-through and recirculation operation modes were developed and evaluated with good results in the project. As initially expected, it was found that the temperature and pressure of the superheated steam produced by the solar field can be controlled more easily in recirculation mode, though an efficient control was achieved also for the once-through mode.

The influence of the inclination of the absorber pipes on the thermo-hydraulic parameters of the two-phase flow was investigated also. Tests at 30, 60, and 100 bar were performed in two positions, horizontal and tilted 4°. Though inclination of the absorber pipe reduced the stratified region, the test results obtained without inclination clearly showed that inclination of the absorber pipes is not required to guarantee sufficient cooling for the wide range of operating conditions investigated in the project.

Of the three DSG basic processes (i.e., injection, recirculation, and once-through), experimental results showed that recirculation is the most feasible option for financial, technical, and O&M-related parameters of commercial application. Test results showed good stability of the recirculation process even with a low recirculation ratio, thus making possible the use of small, cheap water-steam separators in the solar field.

The experience and know-how acquired in DISS was applied to the INDITEP project (2002–2005) in designing the first pre-commercial DSG solar power plant, in which the thermal energy delivered by a DSG solar field is used to feed a superheated-steam Rankine cycle (Zarza et al., 2004). The INDITEP project (Rueda et al., 2003) was the logical continuation of the DISS project, because the design and simulation tools developed in it for DSG solar fields were used in INDITEP, and most of the partners had also been involved in the previous project. INDITEP was promoted by a Spanish-German consortium of engineering companies, power equipment manufacturers, research centers, and businesses involved in the energy market: Iberdrola Ingeniería Consultoría (project Coordinator), CIEMAT, DLR, FLAGSOL GmbH, FRAMATONE, GAMESA Energía Servicios S.A., INITEC Tecnología S.A., Instalaciones Inabensa S.A., and ZSW. The European Commission also provided financial assistance.

Three basic requirements were defined for the design of this first pre-commercial DSG solar power plant:

1. The power block had to be robust and operable under flexible conditions in order to assure durability and reliability. Higher priority was therefore given to power block robustness and flexibility, while efficiency was considered less critical for this first DSG plant.
2. The plant must be small in order to limit the financial risk. Operating stability of a multi-row DSG solar field under uneven distribution of solar radiation and solar radiation transients must be proven.
3. The solar field must operate in recirculation mode because the DISS project demonstrated that the recirculation mode is the best option for commercial DSG solar fields (Eck and Zarza, 2002).

A 5.47 MW<sub>e</sub> power block was selected for this plant to meet the first two requirements. Though, due to its small size, this power block is not very highly efficient, its robustness was guaranteed by the manufacturer with references from facilities already in operation. Figure 42.33 shows a schematic diagram of the power block design and its main parameters (Table 42.4).

**FIGURE 42.33**

Schematic diagram of the power block designed for the DSG plant INDITEP.

TABLE 42.4

INDITEP Project 5 MW<sub>e</sub> DSG Solar Power Plant Power Block Parameters

Manufacturer	KKK
Gross power (kW <sub>e</sub> )	5,472
Net power (kW <sub>e</sub> )	5,175
Net heat rate (kJ/kWh)	14,460
Gross efficiency (%)	26.34
Net efficiency (%)	24.9

The DSG solar field design consists of 70 ET-100 PTCs developed by the European EuroTrough consortium with financial support from the European Commission. This collector was chosen over the LUZ company's LS-3 collector, which is in use at the most recent SEGS plants erected in California (United States), because of its improved optical efficiency and lighter steel structure (Luepfert et al., 2003).

The seven parallel rows of ET-100 PTC axes are oriented north–south to collect the largest amount of solar radiation per year, even though the differences in solar field thermal energy output in winter and summer are more significant than with east–west orientation. Figure 42.34 shows the schematic diagram of a typical solar field collector row at design point. Every row is made up of 10 collectors: 3 collectors for preheating water + 5 collectors for evaporating water + 2 collectors for superheating steam. The end of the boiling section and the inlet of the superheating steam section in every row are connected by a compact water–steam separator, which in turn drains into a larger shared vessel. Water from the separator in every row goes to the final vessel from which it is then recirculated to the solar field inlet by the recirculation pump.

The temperature of the superheated steam produced in each row of collectors would be controlled by means of a water injector placed at the inlet of the last collector. The amount of water injected at the inlet of the last collector in every row is increased or decreased by the control system to keep the superheated steam temperature at the outlet of the row as close as possible to the set point defined by the operator.

Due to the lack of public financial support, the DSG plant designed in INDITEP could not be implemented. However, the experience and know-how gained in the projects DISS and INDITEP were used to implement a first 5 MW<sub>e</sub> DSG STP plant in Kanchanaburi Province,

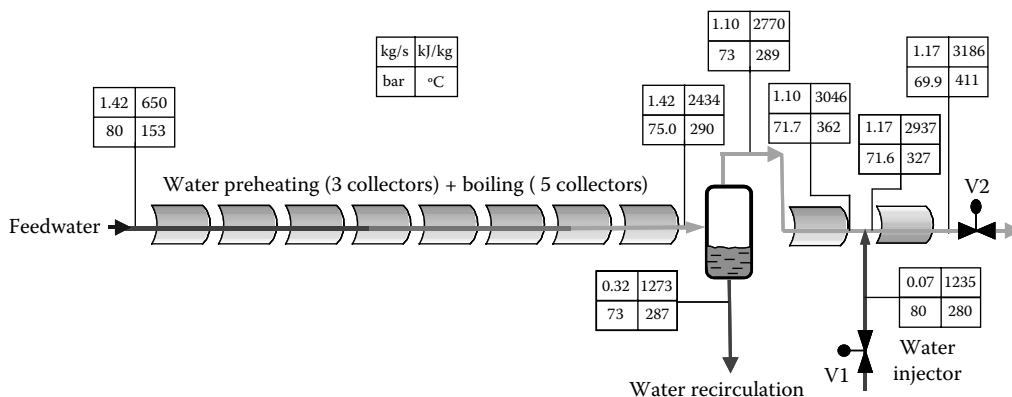

FIGURE 42.34

Scheme of a typical row of collectors in the DSG plant designed in INDITEP.

Thailand ([http://www.solarlite.de/en/project\\_kanchanaburi.cfm](http://www.solarlite.de/en/project_kanchanaburi.cfm)) by the German company Solarlite with the collaboration and scientific support of DLR. The name of this plant is TSE-1, and it has a collector area of 45,000 m<sup>2</sup>. The nominal solar field output steam temperature/pressure is 330°C/30 bar. This plant proved the commercial feasibility of the recirculation process for DSG in PTCs.

Keeping in mind the benefits of the once-through process when compared to the recirculation process, a German consortium composed of DLR and the company Solarlite launched in 2011 the project DUKE (Durchlaufkonzept – Entwicklung und Erprobung) with the financial support of the German government, the collaboration of PSA, and a duration of 3 years to study the commercial feasibility of the once-through process. The DISS test facility was improved in 2012–2013 within the framework of the project DUKE with the installation of three additional PTCs and new instrumentation. Experimental results delivered by DUKE will be essential for the commercial future of the DSG once-through process.

#### 42.4.9 SEGS Plants and State-of-the-Art of Solar Power Plants with Parabolic-Trough Collectors

From a commercial standpoint, PTCs are the most successful technology for generating electricity with solar thermal energy. More than 50 commercial STP plants with PTCs were in operation in 2012, with a total output power of more than 2.5 GW<sub>e</sub>. The first nine plants, called the SEGS (Solar Electricity Generating Systems) I–IX, which use thermal oil as the working fluid (HTF technology), were designed and implemented by the LUZ International Limited company from 1985 to 1990. All the SEGS plants are located in the Mojave Desert, northwest of Los Angeles, California. With their daily operation and over 2.2 million square meters of PTCs, SEGS plants are this technology's best example of commercial maturity and reliability. Their plant availability is over 98%, and their solar-to-electric annual efficiency is in the range of 14%–18%, with a peak efficiency of 22% (DeMeo and Galdo, 1997; Price et al., 2002). All SEGS plant configurations are similar to that shown in Figure 42.24, with only slight differences between one plant and another (Table 42.5).

The success of the SEGS plants was very important to get the support of bankers and investors for the commercial projects implemented in Spain and other countries later on. In fact, the configuration of the commercial STP plants implemented 20 years later than the SEGS plants was almost the same. The main difference between SEGS and more recent STP plants with parabolic troughs is the installation of a big thermal storage system using

**TABLE 42.5**

SEGS Plants Installed by LUZ International Limited

Plant	Net Capacity (MW <sub>e</sub> )	Location	Inauguration
SEGS I	14	Dagget, CA	1984
SEGS II	30	Dagget, CA	1985
SEGS III	30	Kramer Jn, CA	1986
SEGS IV	30	Kramer Jn, CA	1986
SEGS V	30	Kramer Jn, CA	1987
SEGS VI	30	Kramer Jn, CA	1988
SEGS VII	30	Kramer Jn, CA	1988
SEGS VIII	80	Harper Lake, CA	1989
SEGS IX	80	Harper Lake, CA	1990

a mixture of molten salts, thus improving the plant dispatchability. The SEGS plant configuration was modified by LUZ from one plant to another in order to achieve higher efficiencies and lower O&M costs, so the only plant with a thermal energy storage system was SEGS I, which had a two-tank oil storage system. LUZ came to the conclusion that the auxiliary gas heater had to be implemented in the oil circuit because plant operating procedures were more difficult with the auxiliary heater installed in the water–steam circuit. LUZ research and development in the design and improvement of the solar collector field components and integration of the power block achieved higher plant efficiencies and provided a technology for large solar power plants, leading to a reduction in the cost of the solar field per  $\text{m}^2$  to about 75% of the first SEGS plant, and solar system thermal efficiency was increased 8% (Harats and Kearney, 1989).

Figure 42.35 shows an aerial view of the SEGS III and IV plants. The layout chosen by LUZ for the solar fields is the so-called Central Feed, because it allows easy washing and maintenance access to all the collector rows. The power block (steam generator, steam turbine, electricity generator, condenser, etc.) building is located in the center of the collector field.

The SEGS IX plant, put into operation in 1990, was the last one installed by LUZ before its bankruptcy in 1991. Although LUZ had projects for another four plants to be erected in Harper Lake in a very advanced stage, they were cancelled due to the company's bankruptcy. LUZ had increased the net nominal power of the SEGS plants from 14  $\text{MW}_e$  (SEGS I) to 80  $\text{MW}_e$  (SEGS VIII and IX).

In SEGS plants VIII and IX (see [Figure 42.24](#)), there is no gas-fired steam reheater and the steam turbine has two stages working with steam at  $371^\circ\text{C}/104$  bar and  $371^\circ\text{C}/17$  bar, respectively. The thermal oil is heated in the solar collectors up to a temperature of approximately  $390^\circ\text{C}$ , and split into two parallel circuits, the steam generator and reheater. In the steam-generating circuit, the oil passes through a steam superheater, boiler, and preheater, generating steam at  $371^\circ\text{C}$  and 104 bar. This steam expands in the first stage of the turbine, passing to a reheater thermally fed by the other oil circuit, reheating steam to  $371^\circ\text{C}$  and 17 bar. During June, July, August, and September, the auxiliary gas boiler is put into operation to keep the turbine working at full load during peak-demand hours. For the rest of the time, the steam turbine is mainly driven by the solar system only ([Table 42.6](#)).

**FIGURE 42.35**

Aerial view of the SEGS III and IV plants.

**TABLE 42.6**

Basic Characteristics of the SEGS I-IX Plants

	SEGS I	SEGS II	SEGS III	SEGS IV	SEGS V	SEGS VI	SEGS VII	SEGS VIII	SEGS IX
Starting up	December 1984	December 1985	December 1986	December 1986	October 1987	December 1988	December 1988	December 1989	September 1990

LUZ Industries developed three generations of PTCs, called LS-1, LS-2, and LS-3. The LS-1 and LS-2 designs are conceptually very similar. The main differences are the overall dimensions. The parabolic reflectors are glass panels simply screwed to helicoidal steel tube frames that provide the assembly with the required integrity and structural stiffness.

The LS-3 collector is twice as long as the LS-2, with a parabola 14% wider, which reduces the number of flexible connections, local control units, temperature sensors, hydraulic drives, and similar equipment by more than half. However, the LS-3 design represents a change in collector philosophy, more than a change in scale. While the LS-2 model used a torque tube to provide the required stiffness, the LS-3 is made of a central steel space frame that is assembled on-site with precision jigs. The result of this innovation is a lighter and more resistant structure, with highly accurate operation in heavy winds (Table 42.7).

The electricity produced by the SEGS plants is sold to the local utility under individual 30-year contracts for every plant. To optimize the profitability of these plants, it is essential to produce the maximum possible energy during peak-demand hours, when the electricity price is the highest. The gas boilers can be operated for this, either to supplement the solar field or alone. Nevertheless, the total yearly electricity production using natural gas was limited at that time by the Federal Commission for Energy Regulation in the United States to 25% of the overall yearly production.

Peak-demand hours are when there is the most electricity consumption, and therefore, the tariff is the highest. Off-peak and super off-peak hours are when electricity consumption is low, and the electricity price is therefore also lower. At present, 16% of the SEGS plants' annual net production is generated during summer peak-demand hours, and the revenues from this are on the order of 55% of the annual total. These figures show how important electricity generated during peak-demand hours is for the profitability of these plants.

Thanks to the continuous improvements in the SEGS plants, the total SEGS I cost of \$0.22 per kWh<sub>e</sub> for electricity produced was reduced to \$0.16 per kWh<sub>e</sub> in the SEGS II and down to \$0.09 per kWh<sub>e</sub> in SEGS IX (Kearney and Cohen, 1997).

The other important contribution to the profitability of the SEGS plants was the favorable tax laws it took advantage of. The large tax rebate was a crucial factor in the economic feasibility of the SEGS plants. The eventual reduction in these tax exemptions was overcome by the considerable cost reduction from one plant to another achieved by LUZ. The significant reduction in both fossil fuel prices and tax exemptions made it impossible for the SEGS plants to maintain the profit margin they had had at the beginning, resulting in the bankruptcy of the company and the cancellation of the planned erection of more SEGS plants.

Another factor that led to the bankruptcy of LUZ was the short time in which one SEGS plant had to be fully implemented to obtain tax benefits. A plant had to be installed in less than 12 months. For the last 80 MW<sub>e</sub> plant (SEGS X), this short leeway required around-the-clock construction work, which rocketed the investment cost and made it impossible for a SEGS X to be financially successful, and its construction was therefore cancelled in the middle of 1991 as a consequence of LUZ's bankruptcy (Lotker, 1991).

Though LUZ achieved a significant cost reduction in the SEGS plants, the current cost of electricity produced by modern parabolic-trough solar power plants is higher, and it must still be further reduced before it can become competitive with conventional power plants and PV plants (Pitz-Paal et al., 2005). Without tax incentives or an adequate premium for electricity generated by this type of plants, they are not profitable, because current investment and O&M costs demand a public support strategy for commercial development. At present, the direct capital cost is about three times that of a fossil-fueled power plant, and the generating cost is about three times higher. Annual thermal efficiency (solar-to-useful thermal energy delivered) of commercial parabolic-trough solar fields is about 50%. This means a yearly savings of about 0.45 ton of CO<sub>2</sub> emissions and 0.1 ton of fossil fuel per square meter of PTC (Geyer, 2002).

In spite of their environmental benefits, there are some barriers to the commercial use of this technology. The main barriers at present are the high investment cost (\$3500–\$6000 per kW, depending on plant size and thermal storage capacity) and the minimum size of the power block required for high thermodynamic efficiency. However, these barriers are shared by all the STP technologies currently available (i.e., CRSs, Dish Stirling systems, and LF concentrator systems) (Romero et al., 2004). The high investment cost can be compensated with public incentives in the form of tax credits or favorable feed-in tariffs. The favorable feed-in tariff implemented in Spain in 2007 and the tax credits and loan guarantees in the United States for STP plants opened the door to many commercial projects, thus achieving a total installed power of more than 2.5 GW<sub>e</sub> with PTCs at the end of 2012.

Since the size limit imposed in Spain for STP plants (i.e., 50 MW<sub>e</sub>) had no technical reasoning behind, several commercial projects with unit powers higher than 100 MW<sub>e</sub> were promoted in other countries at the beginning of the second decade in this century. The SOLANA plant promoted by Abengoa, Arizona, with a unit power of 280 MW<sub>e</sub> and a 6 h thermal storage system with molten salts, is a good example of these large STP plants.

At the time of writing the technology commercially available for parabolic-trough power plants is the HTF technology, which uses oil as the heat carrier between the solar field and the power block, while thermal storage systems with molten salts in two tanks is the preferred option. The promotion of many commercial projects since 2007 has led to the development of many new collector designs (URSSATrough, SenerTrough, SkyTrough, etc.) with good mechanical and geometrical quality and lower and lower manufacture and assembly costs.

**FIGURE 42.36**

The UltimateTrough prototype installed in a commercial solar power plant in Southern California. (Courtesy of Flabeg.)

These new collector designs have been specially developed for large solar fields. Although most of the new collector designs developed in the period 2007–2013 had similar dimensions and features (150 m length, 5.76 m parabola width, 1.7 m focal distance), very innovative designs with much bigger aperture area have been developed keeping in mind the future installation of very large solar fields. The UltimateTrough design is the best example of new collectors with very large aperture area. With an aperture of 1689 m<sup>2</sup>, a parabola width of 7.5 m, and a length of 240 m, UltimateTrough was specially designed for STP plants with a unit power of 100 MW<sub>e</sub> or more, although it can be used for smaller plants also. Figure 42.36 shows the UltimateTrough collector prototype installed in an STP plant in Southern California for evaluation.

More than 2 GW<sub>e</sub> were installed in the period 2007–2013 with PTCs in Spain, the United States, and Mediterranean and North Africa region, and several countries (Morocco, South Africa, and others) had launched national programs to install STP plants and promote solar thermal electricity production.

Most of the commercial STP plants installed in the period 2007–2013 with PTCs have the configuration showed either in Figure 42.24 (plants without thermal storage) or Figure 42.27 (plants with molten-salt thermal storage systems), and only 3 plants had a parabolic-trough solar field integrated in the bottoming cycle of a combined-cycle gas-fired power plant. This configuration is called the integrated solar combined-cycle system (ISCCS) configuration. Though the contribution of the solar system to the overall plant power output is small (10%–15% approx.) in the ISCCS configuration, it seems to be a good approach to market penetration in some countries, which is why the World Bank is promoting ISCCS plants in developing countries (Geyer et al., 2003). Figure 42.37 shows the schematic diagram of a typical ISCCS plant.

The first commercial plant with PTCs in Europe was the ANDASOL-I plant (Aringhoff et al., 2002a,b), a SEGS-like plant with a 6 h molten-salt thermal storage system. Figure 42.38 is an aerial view of ANDASOL-I.

The financial crisis in 2011 made some countries change their mind concerning the promotion of STP plants. This was the case of Spain, where the legal framework implemented in 2007 was significantly modified in 2012 and 2013 to reduce the incomes of the STP plants owners, and the feed-in tariff was cancelled for new plants. Studies performed

**FIGURE 42.37**

in the second decade of this century have pointed out the possibility of achieving a significant midterm cost reduction in parabolic-trough technology (Enermodal, 1999; Sargent & Lundy, 2003; Kearney and ESTELA, 2010). Mass production and component improvement through R&D would lead to an electricity cost fully competitive with conventional power plants in 2025. It is therefore clear that parabolic-trough technology must seek ways to become more competitive with conventional power plants. The European Solar Thermal Electricity Association (ESTELA) issued a strategic research agenda in 2013 with the recommended R&D topics to speed up the cost reduction of electricity produced by STP plants. This document is available at [www.estelasolar.eu](http://www.estelasolar.eu). Within the potential improvements for cost reduction, DSG of high-pressure/high-temperature superheated steam in

the receiver pipes seems to be one of the promising ways to achieve this goal, because the thermal oil currently used in the HTF technology as the working fluid and the associated equipment (oil/water heat exchanger required to produce the superheated steam, oil circuit, expansion vessel, etc.) would be no longer needed. Improvement of thermal storage systems and development of receivers tubes for higher temperatures are two other important R&D topics.

Also in the United States, a national R&D program called *The SunShot Initiative* was launched in February 2011 to achieve a significant cost reduction in CSTP technologies. The SunShot Initiative is a collaborative national effort to make the United States a leader in the global clean energy race by fueling solar energy technology development. The vision of SunShot is to make the total cost of solar energy economically viable for everyday use. This initiative is aimed at reducing the total installed cost of solar energy systems by 75%.

The future of STP plants with PTCs strongly depends on the cost reduction achieved for future plants, because photovoltaic panels have significantly reduced their cost, and a similar cost reduction must be achieved by STP plants to compete with that technology, even taking into account the benefit of the STP plants' dispatchability.

---

## 42.5 Linear Fresnel Reflectors

LF reflectors are composed by an array of linear (or slightly bent) mirror strips that independently move and collectively focus on absorber lines suspended from elevated towers. Reflective segments are close to the ground and can be assembled in a compact way up to 1 ha/MW. This technology aims at achieving the performance of parabolic troughs with lower costs. They are characterized by a fixed linear focus where the absorber is static (Mills, 2004). However, optical efficiency is lower than that of parabolic troughs due to a higher impact of the incidence angle and the cosine factor. Consequently, operating temperature at the working fluid is usually lower, typically between 150°C and 350°C. By this reason, LF technology has been historically applied to generate saturated steam via direct in-tube steam generation and use into ISCCS or in regenerative Rankine cycles, though current R&D is aiming at higher temperatures above 400°C (Platzer, 2009).

LF reflectors typically make use of lower cost non-vacuum thermal absorbers where the stagnant air cavity provides significant thermal insulation, light reflector support structures close to the ground, low-cost flat float glass reflector, and low-cost manual cleaning, because the reflectors are at human height (Kalogirou, 2004). The LFs also have much better ground utilization, typically using 60%–70% of the ground area compared to about 33% for a trough system and lower O&M costs due to more accessible reflectors.

### 42.5.1 Historical Evolution of Linear Fresnel Reflector Systems

After some pioneering experiences (Francia, 1968; Di Canio et al., 1979), the first serious development undertaken on the compact LF reflector system was proposed at the University of Sydney in 1993. The concept is composed by a single field of reflectors together with multiple linear receivers (see [Figure 42.39](#)). Each reflector is able to change

**FIGURE 42.39**

Scheme of compact LF system with a multi-tower array and dynamic aiming strategy of mirror strips.

their focal point from one receiver to another during the day in order to minimize shading and shadow losses in the dense reflector field. This system covers about 71% of the ground compared with 33% for parabolic-trough systems (Mills and Morrison, 1999). In 2000, the company Solarmundo built a 2400 m<sup>2</sup> LF prototype collector field with such a technology at Liege, Belgium, but test results were not reported. Later the company moved to Germany and was renamed Solar Power Group (SPG). SPG signed an exclusivity cooperation agreement with DSD Industrieanlagen GmbH (renamed to MAN Ferrostaal Power Industry in 2005). A 800 kW LF pilot operating at 450°C has already been tested in the PSA, Spain (Bernhard et al., 2008; Hautmann et al., 2009).

Back in Australia, in early 2002, a new company, Solar Heat and Power Pty Ltd. (SHP), made extensive changes to the engineering design of the reflectors to lower cost and has become the first to commercialize LF technology. SHP initiated in 2003 for Macquarie Generation, Australia's largest electricity generator, a demonstration project of 103 MW<sub>th</sub> (approximately 39 MW<sub>e</sub>) plant with the aim of supplying preheat to the coal-fired Liddell power station. Phase 1 of the project, completed in 2004, resulted in a 1350 m<sup>2</sup> segment not connected to the coal-fired plant and was used to trial initial performance, and it first produced steam at 290°C in July 2004. The expansion to 9 MW<sub>th</sub> was completed by 2008. Activities of the company moved to the United States and were continued by Ausra, Palo Alto. Ausra established a factory of components, tubular absorbers, and mirrors in Las Vegas and built the Kimberlina 5 MW demonstration plant in Bakersfield at the end of 2008. In 2010, Ausra was purchased by AREVA, which is presently committed to the commercial deployment of this technology.

The third technology player after SPG/MAN and AREVA is the German company NOVATEC Solar, formerly NOVATEC Biosol. The technology of NOVATEC is based upon its collector Nova-1 aimed to produce saturated steam at 270°C. They have developed a serial production factory for prefabricated components, a 1.4 MW small commercial plant, PE-1, in Puerto Errado, Murcia, Spain, which has been grid connected since March 2009, and a second 30 MW commercial plant, PE-2 (with a mirror surface of 302,000 m<sup>2</sup>), also built in Murcia, Spain. NOVATEC is promoting 50 MW plants mixing PTC and LF fields, where LF provides preheating and evaporation and PTC field takes over superheating. The company claims that this hybridization results in 22% less land use and higher profitability. In March 2011, ABB acquired a 35% shareholding in Novatec Solar. In September 2011, Novatec Solar claimed that its technology has successfully generated superheated steam at temperatures above 500°C at its 1.4 MW demonstration plant in Murcia, Spain, by implementing a receiver containing vacuum absorber (Selig, 2011).

In last few years, new companies have explored the application of Fresnel technologies for electricity generation. SkyFuel Inc., Albuquerque, New Mexico, is developing the Linear Power Tower™, a Fresnel based on concept designed to use a high-temperature molten-salt HTE, and it incorporates thermal energy storage. In Europe, the French company CNIM is developing its own technology for the boiler part of the plant focusing on direct superheated steam generation and LF principle. A first prototype (800 m<sup>2</sup>) has been built, commissioned, and pretested in 2010 (Lehaut, 2010).

#### 42.5.2 Future Technology Development and Performance Trends

Even though some solid commercial programs are underway on LF, still it is early to have consolidated performance data with respect to electricity production. The final optimization would integrate components development to increment temperature of operation and possible hybridization with other STP systems like parabolic troughs.

There are many possible types of receivers, including evacuated tube and PV modules, but the most cost-effective system seems to be an inverted cavity receiver. In the case of SHP technology, the absorber is a simple parallel array of steam pipes at the top of a linear cavity, with no additional redirection of the incoming light from the heliostats to minimize optical losses and the use of hot reflectors. In the case of SPG technology, the absorber is a single tube surmounted by a hot nonimaging reflector made of glass, which must be carefully manufactured to avoid thermal stress under heating and exhibit some optical loss. Both systems can produce saturated steam or pressurized water. At present, AREVA and NOVATEC are looking for new absorbers able to work at temperatures above 450°C. By 2015, according to developers, LF can be expected to be operating with superheated steam at 500°C yielding an efficiency improvement of up to 18.1% relative to current saturated steam operation at 270°C (Kearney and ESTELA, 2010).

For reflectors, automation is a key issue that has been demonstrated by NOVATEC. Additional effort should be given to the optimized demonstration of multitower arrays to maximize ground coverage ratios. However, it is the lack of reliable information regarding annual performance and daily evolution of steam production that should be targeted as a first priority. Still some concerns remain regarding the ability to control steam production, because of the pronounced effect of cosine factor in this kind of plants. This dynamic performance would also affect the potential integration with other STE systems such as PTC or CRS. Until now, most comparative assessments vis-à-vis parabolic troughs are not economically conclusive, revealing the need to use much larger fields to compensate lower efficiencies. In order to achieve break-even costs for electricity with current LF technology, the cost target for the Fresnel solar power plants needs to be about 55% of the specific costs of parabolic-trough systems (Dersch et al., 2009).

---

### 42.6 Central-Receiver Solar Thermal Power Plants

CRSs with large heliostat fields and solar receivers located on top of a tower are deploying the first generation of grid-connected commercial plants from 2007. The CRS power plant technology can be considered as sufficiently mature after the pioneering experience of several 0.5–10 MW pilot plants in the early 1980s and the subsequent improvement of such key components as heliostats and solar receivers in many later projects merging

international collaboration during the past 20 years. Solar-only plants like Gemasolar and PS10 and hybrid configurations like SOLGAS, CONSOLAR, or SOLGATE have provided a portfolio of alternatives that have led to the first scaled-up plants for the period 2007–2014. The first small 10–20 MW projects, still non-optimized, already reveal a dramatic cost reduction over previous estimates and provide a path for a realistic LEC milestone of \$0.08 per kWh by 2030.

In power towers, incident sunrays are tracked by large mirrored collectors (heliostats), which concentrate the energy flux onto radiative/convective heat exchangers called solar receivers, where energy is transferred to a thermal fluid. After energy collection by the solar subsystem, the thermal energy conversion to electricity is quite similar to fossil-fueled thermal power plants and the earlier-described parabolic-trough system power block.

Reflective solar concentrators are employed to reach the temperatures required for thermodynamic cycles (Mancini et al., 1997). In power towers or CRSs, the solar receiver is mounted on top of a tower, and sunlight is concentrated by means of a large paraboloid that is discretized into a field of heliostats (Figure 42.40). CRSs have a high potential for midterm cost reduction of electricity produced since there are many intermediate steps between their integration in a conventional Rankine cycle up to the higher exergy cycles using gas turbines at temperatures above 1300°C, leading to higher efficiencies and throughputs.

The typical optical concentration factor ranges from 200 to 1000. Because of economy of scale, 10–100 MW plant sizes are chosen, even though advanced integration schemes are claiming the economics of smaller units as well (Romero et al., 2000a,b). The high solar flux incident on the receiver (averaging between 300 and 1000 kW/m<sup>2</sup>) enables operation at relatively high temperatures of up to 1000°C and integration of thermal energy into more efficient cycles in a step-by-step approach. CRS can be easily integrated in fossil plants for hybrid operation in a wide variety of options and has the potential for generating electricity with high annual capacity factors through the use of thermal storage. With storage, CRS plants are able to operate over 4500 h/year at nominal power (Kolb, 1998).

**FIGURE 42.40**

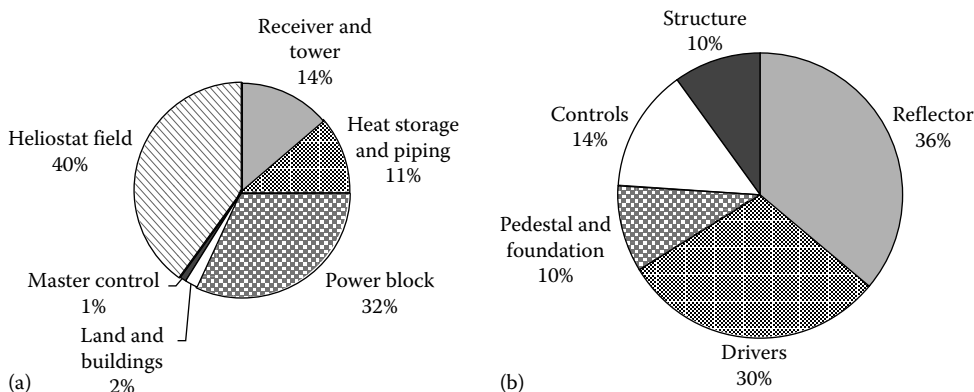

Aerial view of the first commercial solar towers in the world. PS20 with 20 MW at the front and the PS10 with 11 MW at upper left. Heliostat field layout is formed by hundreds of tracking mirrors focusing concentrated light onto the receiver aperture. PS20 and PS10 have been developed by Abengoa Solar and are located in Sanlúcar la Mayor, Spain. (Courtesy of Abengoa Solar, Sanlúcar la Mayor, Spain.)

### 42.6.1 Technology Description

A solar power tower, or CRS, plant may be described in terms of the following subsystems:

- Collector system, or heliostat field, created with a large number of two-axis tracking units distributed in rows.
- Solar receiver, where the concentrated flux is absorbed. It is the key element of the plant and serves as the interface between the solar portion of the plant and the more conventional power block.
- Heat exchanger system, where an HTF may be used to carry the thermal energy from the receiver to the turbine.
- Heat storage system, with which system dispatchability is ensured during events like cloud passages and can adapt to demand curves.
- Fossil fuel backup for hybrid systems with a more stable output.
- Power block, including steam generator and turbine alternator.
- Master control, UPS, and heat rejection systems.

A detailed description and historical perspective of all the subsystems would be excessive, given the large number of configurations and components tested to date. Because of their higher temperatures, CRSs have been able to make use of a diversity of thermal fluids, such as air, water–steam, molten nitrate salt, and liquid sodium. In general, the components that impact the most on investment cost are the heliostat field, the tower receiver system, and the power block. The heliostat field and solar receiver systems distinguish solar thermal tower power plants from other CSP plants and are therefore given more attention in the following. In particular, the heliostat field is the single factor with the most impact on plant investment, as seen in Figure 42.41. Collector field and power block together represent about 72% of the typical solar-only plant (without fossil backup) investment, of which heliostats represent 60% of the solar share. Even though the solar receiver impacts the capital investment much less (about 14%), it can be considered the most critical subsystem

**FIGURE 42.41**

(a) Investment costs breakdown for a CRS plant, only solar. As it can be observed, the heliostat field and the power block are the most impacting subsystems on plant investment. (b) Breakdown of production cost for a single heliostat distributed among its main components. Reflector and tracking mechanism are in this case the most capital intensive components.

in terms of performance, since it centralizes the entire energy flux exchange. The largest heliostat investment is the drive mechanism and reflecting surface, which alone are almost 70% of the total.

#### 42.6.1.1 Heliostat and Collector Field Technology

The collector field consists of a large number of tracking mirrors, called heliostats, and a tracking control system to continuously focus direct solar radiation onto the receiver aperture area. During cloud passages and transients, the control system must defocus the field and react to prevent damage to the receiver and tower structure.

Heliostats fields are characterized by their off-axis optics. Since the solar receiver is located in a fixed position, the entire collector field must track the sun in such a way that each and every heliostat individually places its surface normal to the bisection of the angle subtended by sun and the solar receiver. Figure 42.42 shows the variability of elevation angles in a heliostat field and identifies the elevation angle. The geometrical definition of the inclination angle  $n$  of a single heliostat is a function of the tower height, its distance from the tower, and the incidence angle of the sun. Assuming  $z_S$  is the heliostat vertical dimension and  $z_T$  is the geometrical tower height above ground, the so-called optical tower height may be defined as the elevation of the center of the receiver aperture area above the pivot point of the heliostat ( $z_T - z_S/2$ ).

$$\psi = h + n - 90^\circ \quad (^\circ) \quad (42.38)$$

$$90^\circ - n = \arctan \left[ \frac{(z_T - (z_S/2))}{x} \right] + \psi \quad (^\circ) \quad (42.39)$$

$$n = \frac{180^\circ - h - \arctan[(z_T - (z_S/2))/x]}{2} \quad (^\circ) \quad (42.40)$$

Heliostat field performance is defined in terms of the optical efficiency, which is equal to the ratio of the net power intercepted by the receiver to the product of the direct insolation and the total mirror area. The optical efficiency includes the cosine effect, shadowing, blocking, mirror reflectivity, atmospheric attenuation, and receiver spillage (Falcone, 1986).

**FIGURE 42.42**

(a) Visualization of the off-axis optics of heliostats representing different inclination angles of mirrors located in a heliostat field. (b) Geometrical definition of elevation angle  $n$ .

Because of the large area of land required, complex optimization algorithms are used to optimize the annual energy produced by unit of land, and heliostats must be packed as close as possible so the receiver can be small and concentration high. However, the heliostats are individual tracking reflective Fresnel segments subject to complex performance factors, which must be optimized over the hours of daylight in the year, by minimizing the cosine effect, shadowing and blocking, and receiver spillage. Since the reflective surface of the heliostat is not normal to the incident rays, its effective area is reduced by the cosine of the angle of incidence  $\psi$ ; the annual average  $\cos \psi$  varies from about 0.9 at two tower heights north of the tower to about 0.7 at two tower heights south of the tower. Of course, annual average cosine is highly dependent on site latitude. Consequently, in places close to the equator, a surround field would be the best option to make best use of the land and reduce the tower height. North fields improve performance as latitude increases (south fields in the Southern Hemisphere), in which case, all the heliostats are arranged on the north side of the tower. Representative surround and north collector field configurations are depicted in Figure 42.43.

**FIGURE 42.43**

Representation of optimized fields for a latitude of  $36^\circ$  with surround field (top) and north field (bottom) configurations.

Another point to be considered in the layout is the heliostat dimensions. If the heliostats are spaced too close together, their corners could collide, so mechanical limits preclude pedestal spacing closer than the maximum dimension of the heliostat (i.e., the diagonal or diameter of the heliostat,  $D_m$ ). This causes a significant disadvantage when the aspect ratio (height/width) differs greatly from 1.

Blocking of reflected rays is also an important limitation on spacing heliostats. Blocking is produced by neighboring heliostats. To avoid blocking losses, the distance  $\Delta x$  between the heliostat rows must be calculated according to the following equation:

$$\Delta x = x \frac{z_s}{z_T} \quad (42.41)$$

Shading produced by neighboring heliostats also has to be taken into account. This occurs mostly at low sun angles and in the middle of the field where blocking conditions would allow close spacing. The shadows move during the day and year, as does the heliostat orientation, so there is no simple rule. In addition, the tower or other objects may also cast a shadow over part of the heliostat field. Usually shadowing in the field is calculated by projecting the outlines of the heliostats aligned, the tower, and anything else that casts a shadow onto a plane perpendicular to the center sunray. Shadowed portions of any heliostat appear in the overlapping areas in this projection. Classical computer codes like HELIOS provide this calculation (Biggs and Vittitoe, 1979).

Not all the sunlight that clears the heliostats reaches the vicinity of the receiver. Some of the energy is scattered and absorbed by the atmosphere. This effect is referred to as the attenuation loss (Falcone, 1986). This factor increases when water vapor or aerosol content in the atmosphere is high and is typically anywhere between 5% and 15% in a solar field. Atmospheric attenuation is usually expressed as a function or experimental correlation depending on the range of heliostat inclination.

The size of the image formed by each heliostat depends on mirror focusing and canting and on the size of the heliostat and errors, as expressed by its beam quality. Because of that, there is an intercept factor for a given receiver aperture area. Some of the energy spills over around the receiver. While spillage can be eliminated by increasing the size of the receiver, at some point, increased size becomes counterproductive because of the resulting increased receiver losses and receiver costs.

The combination of all these factors influencing the performance of the heliostat field should be optimized to determine an efficient layout. There are many optimization approaches to establish the radial and azimuthal spacing of heliostats and rows. One of the most classic, effective, and widespread procedures is the *radial staggered* pattern, as shown in Figure 42.44, originally proposed by the University of Houston in the 1970s (Lips and Vant-Hull, 1978). Typical radially staggered field spacing at 35° latitude using square low-cost heliostats can be expressed by

$$\frac{\Delta R}{\Delta D_m} = \frac{1.009}{\Theta} - 0.063 + 0.4803\Theta \quad (42.42)$$

$$\frac{\Delta Z}{\Delta D_m} = 2.170 - 0.6589\Theta + 1.247\Theta^2 \quad (42.43)$$

**FIGURE 42.44**

Radial staggered field layout, where  $\Delta Z$  represents the azimuthal spacing and  $\Delta R$  represents the radial spacing.

where  $\Theta$  represents the receiver elevation angle in radians:

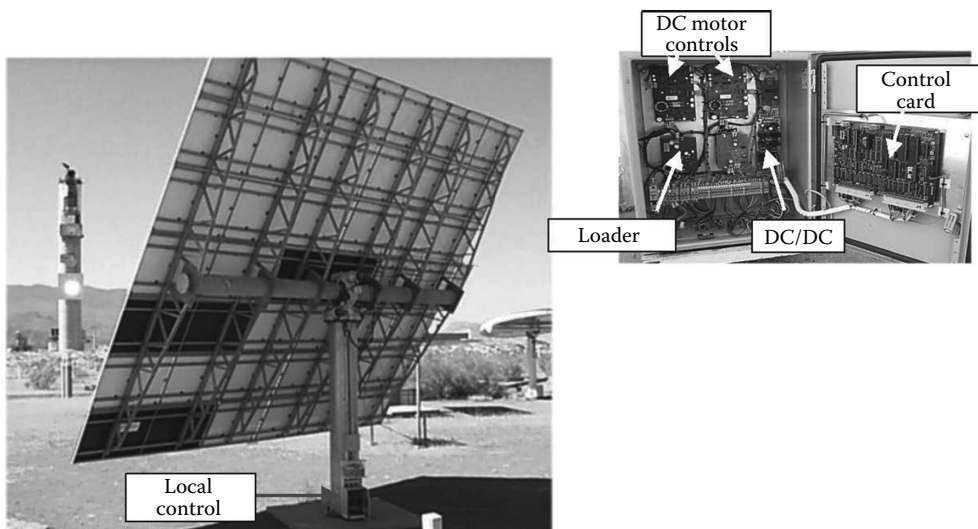

$$\Theta = \arctan \left[ \frac{(z_T - (z_S/2))}{x} \right]$$

Integral optimization of the heliostat field is decided by a trade-off between cost and performance parameters. Heliostats, land, and cabling network must be correlated with costs. Cost and performance also often have reverse trends, so that when heliostats are packed closer together, blocking and shadowing penalties increase, but related costs for land and wiring decrease. A classical code in use since the 1980s for optimization of central receiver subsystems is DELSOL3 (Kistler, 1986). In DELSOL3, heliostat field layout is optimized for tower height and solar receiver geometry. Figure 42.45 shows a breakdown of efficiency maps for the different performance factors in a typical one-sided north heliostat field. It may be deduced that the heliostat density is greatest at the inner boundary and decreases with increasing radial distance from the tower. The average land coverage ratio is typically 0.20–0.25.

The radially staggered distribution clearly creates *prearranged* grids based on the tower height versus row-to-radius ratio. This geometrical procedure provides a smart solution to the problem with good optimization of computing resources. However, with today's computers, it is possible to calculate the yearly energy available at any point in a site for a given tower height, the *yearly normalized energy surface* (YNES). Yearly efficiency maps can be generated based on the cosine factor, the spillage factor, and the site atmospheric attenuation coefficient using real direct normal irradiance (DNI) data, within a reasonable computing time. It is therefore easy to find the place where the yearly energy available is the highest for location of the first heliostat. It is also possible to calculate the effect of shadowing and blocking by this heliostat on the YNES, so YNES can be recalculated, and the best position for the next heliostat can be found. Although this iterative method is time consuming, it is worthwhile if either the efficiency of the solar plant can be increased or the capital cost can be reduced. This YNES-based layout method enables better flexibility than predetermined gridding strategies (Sánchez and Romero, 2006).

**FIGURE 42.45**

Mapping of total optical efficiency of a north-field area of heliostats and its breakdown into cosine factor, shadowing and blocking, air transmittance, and receiver spillage.

**FIGURE 42.46**

Rear view of the heliostat COLON SOLAR of 70 m<sup>2</sup> with typical T-shape structure and torque tube. The control box is located at the bottom of the pedestal. The reflected image is shown at the Lambertian target located on the tower.

Mature low-cost heliostats consist of a reflecting surface, a support structure, a two-axis tracking mechanism, pedestal, foundation, and control system (Figure 42.46). The development of heliostats shows a clear trend from the early first-generation prototypes, with a heavy, rigid structure, second-surface mirrors, and reflecting surfaces of around 40 m<sup>2</sup> (Mavis, 1989), to the current commercial designs with large 100–120 m<sup>2</sup> reflecting surfaces, lighter structures, and lower-cost materials (Romero et al., 1991).

Since the first-generation units, heliostats have demonstrated beam qualities below 2.5 mrad that are good enough for practical applications in solar towers, so the main focus of development is directed at cost reduction. Two basic approaches are being pursued to reduce per m<sup>2</sup> installed cost.

The first approach is devoted to increasing the reflective area by employing curved surfaces made up of several mirror facets. Each facet surface typically goes from 3 to 6 m<sup>2</sup>. This increment in optical surface results in a cost reduction, since some components, like the drive mechanism, pedestal, and control, do not increase linearly. However, there is a limit to this advantage, since the larger the area, the higher the optical errors and washing problems are also.

The second line of development is the use of new light-reflective materials like polymer reflectors and composites in the supporting structure, such as in the stretched-membrane heliostats. The stretched-membrane drum consists of a metal ring to which prestressed 0.4 mm stainless-steel membranes are welded. One of the membranes is glued to a polymer reflector or thin mirrors. A vacuum is created inside the plenum with a controlled blower to ensure curvature.

In Spain, some developments worthy of mention are the 70 m<sup>2</sup> COLON SOLAR prototype (Osuna et al., 1999), the 105 m<sup>2</sup> GM-100 (Monterreal et al., 1997), and more recently, the 90 and 120 m<sup>2</sup> Sanlúcar heliostats (Osuna et al., 2004). In the United States, a similar development in glass/metal technology was the 150 m<sup>2</sup> ATS heliostat (Alpert and Houser, 1990). The stretched-membrane milestone is the 150 m<sup>2</sup> Steinmuller heliostat ASM-150 with an excellent beam quality of 2 mrad (Weinrebe et al., 1997). In spite of the good quality achieved by stretched membranes, projected costs are higher than the more mature glass/metal units.

Eventually, 120 m<sup>2</sup> heliostats were adopted for the first commercial tower power plants PS10 and PS20 promoted by the company Abengoa Solar (Osuna et al., 2004). The company SENER has developed a similar 115 m<sup>2</sup> heliostat for its Gemasolar plant. Estimated production costs of large-area glass/metal heliostats for sustainable market scenarios are around \$130–\$200 per m<sup>2</sup>. Large-area glass/metal units make use of glass mirrors supported by metallic frame facets.

Recently, some developers are introducing substantial changes in the conception of heliostat design. A number of projects based upon the paradigm of maximum modularity and mass production of components are claiming small-size heliostats as a competitive low-cost option. Companies like BrightSource, eSolar, Aora, or Cloncurry are introducing heliostat units of only a few m<sup>2</sup>. The small heliostats have better optical efficiency, and even they can be flat mirrors compared to curved and canted facets in the large heliostats. This advantage and the easier transportation to the site with minimal installation works can lead to a further decrease in the heliostats costs. BrightSource with an ambitious program of large projects is making use of single-facet 7.3 m<sup>2</sup> heliostats (Silberstein et al., 2009), and the company eSolar with a multitower plant configuration presents a highly innovative field with ganged heliostats of extremely small size (1.14 m<sup>2</sup> each) that implies the large number of 12,180 units for a single 2.5 MW tower (Schell, 2009). If such small heliostats may reach installed costs below \$200 per m<sup>2</sup>, it can be understood only under aggressive mass production plans and preassembly during manufacturing process by reducing on-site mounting works. Annual performance and availability of those highly populated fields are still under testing.

The drive mechanism is in charge of independent azimuthal and elevation movement, in such a way that the specular surface follows the sun position and reflects the beam onto the focal point. The ratio between the angle of incidence and the reflected ray leads

to angular errors doubling at the target. It is therefore crucial for a tracking system to be highly accurate. Heliostat drives should have the following characteristics:

- Sufficiently robust to support their own weight, the movable structure, and wind loads, and be rigid enough to avoid low-frequency vibrations.
- Able to generate extremely slow movement, with high reduction ratios (up to 40,000:1).
- Highly accurate positioning (use of encoders) and no free movement.
- Able to ensure relatively fast return to stow position in case of high winds or other dangerous weather conditions, and other events.
- Resistance to outdoor exposure.
- Easy maintenance.
- Low-cost manufacture and operation.

The most common drive mechanism configuration makes use of worm-gear systems for both elevation and azimuth axes (Figure 42.47). Both gears are essentially analogous in terms of tooth shape and reduction ratio. In many cases, there is a first planetary reduction step and then a second worm-gear reduction step at the outlet. The advantage of the

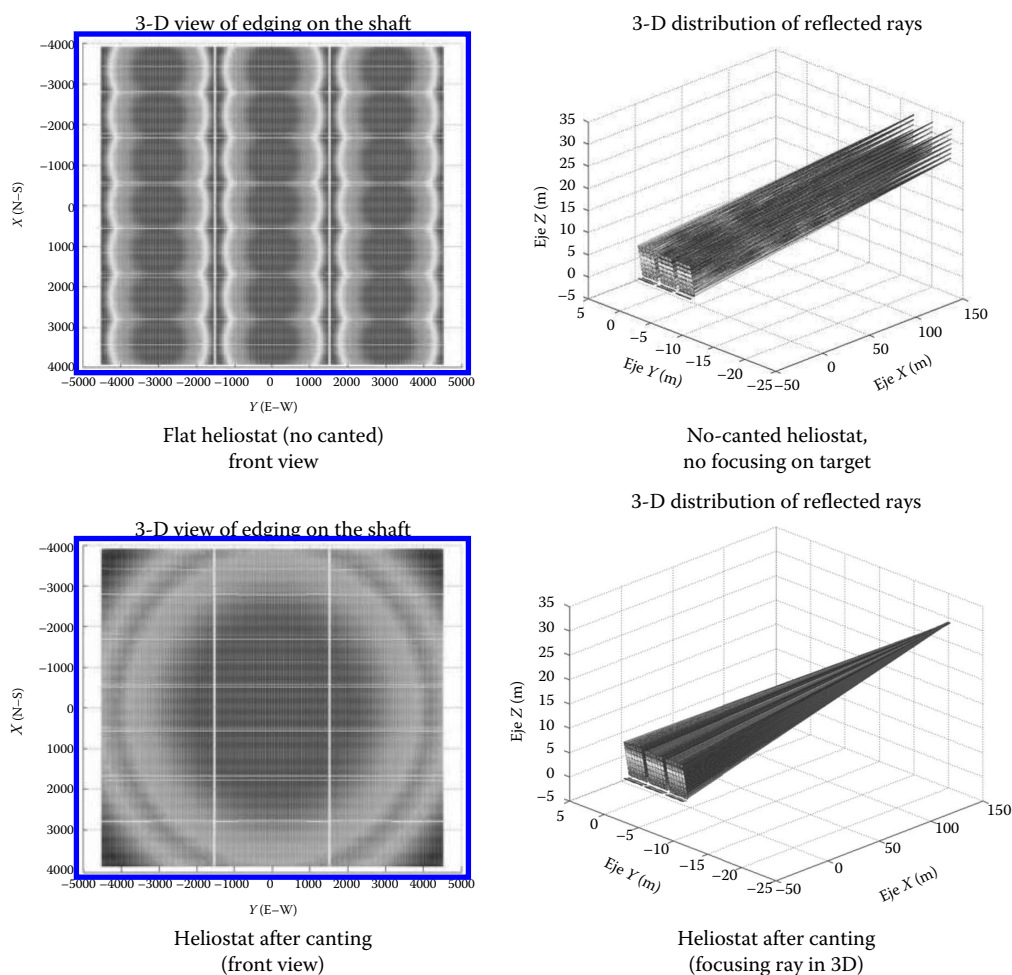

**FIGURE 42.47**

Detail of a typical worm-gear drive mechanism. At the bottom, the azimuthal actuator located on top of the pedestal is shown. The upper worm actuates against the gear connected to the torque tube.

planetary system is the high ratio of reduction in a limited space. The worm gear provides high reduction ratios at high momentums. However, worm gears are less efficient because of the stress of high friction. This stress has a positive reaction, since the self-locking worm comes to a halt whenever the angle of friction between the worm thread and the gear teeth is higher than the nominal design angle.

Mature glass/metal faceted heliostats report availabilities over 95% and beam qualities of 2.4–2.8 mrad. Yearly average reflectivity of a heliostat field reaches 85%–92%. Faceted heliostats with curved mirrors require canting of the facets to form a large paraboloid. In Figure 42.48, the effect of canting facets can be seen.

Control of CRSs is more complicated than other types of STP plants since optics are off-axis, and each and every heliostat individually tracks the sun. The control system in a CRS is naturally separated into the heliostat field control system (HFCS) and the receiver and power system control system (RPSCS) (Yebra et al., 2004). The main purpose of the HFCS is to keep each heliostat positioned at the desired coordinates at all times, depending on power system

**FIGURE 42.48**

Effect of canting facets in a glass metal heliostat. In the upper part, it can be observed that a flat heliostat with curved facets is not focusing in a single image. In the lower part, a canted heliostat is depicted.

demand. The general purpose of the HFCS is to generate a uniform time–spatial distribution of the temperature on the volumetric receiver by controlling the timed insertion of an associated group of heliostats at predefined aiming points on the receiver by modifying the aiming-point coordinates and changing from one heliostat group to another during operation. This is accomplished by an HFCS aiming-point strategy (Garcia-Martín et al., 1999). The current trend in control systems is a distributed control, with a hard real-time operating system, integrating heterogeneous hardware and software platforms in real time, that guarantees a deterministic response to external (physical environment) and internal (operator interface) events. The RPSCS regulates the pressure and temperature of the HTF, and steam generator.

The heliostat local control is responsible for all the emergency and security maneuvers and sun-tracking calculations, as well as communication with the control room. The current trend is to increase the heliostat intelligence and autonomy. In addition, some drive mechanism options consider the use of wireless communications and PV-power supply, eliminating the need for cabling and trenching. This is the case of the stand-alone heliostat developed at the PSA in Spain, where a field of 92 such heliostats is in operation (García et al., 2004).

#### 42.6.2 Solar Receiver

In a solar power tower plant, the receiver is the heat exchanger where the concentrated sunlight is intercepted and transformed into thermal energy useful in thermodynamic cycles. Radiant flux and temperature are substantially higher than in parabolic troughs, and therefore, high technology is involved in the design, and high-performance materials should be chosen. The solar receiver should mimic a blackbody by minimizing radiation losses. To do so cavities, black-painted tube panels or porous absorbers able to trap incident photons are used. In most designs, the solar receiver is a single unit that centralizes all the energy collected by the large mirror field, and therefore high availabilities and durability are a must. Just as cost reduction is the priority for further development in the collector field, in solar receivers, the priorities are thermal efficiency and durability. Typical receiver absorber operating temperatures are between 500°C and 1200°C, and incident flux covers a wide range between 300 and over 1000 kW/m<sup>2</sup>. The picture in [Figure 42.49](#) clearly shows the high flux to be withstood by the receiver.

Thermal and optical losses are the key parameters for quantifying the efficiency of a solar receiver.

$$\eta_{rec} = (\alpha\tau_w) + (\alpha\varepsilon_w) \frac{\sigma T_w^4}{C \cdot \phi} - (\varepsilon\bar{\rho}) \frac{\sigma T^4}{C \cdot \phi} - U \frac{(T - T_a)}{C \cdot \phi} \quad (42.44)$$

This equation is the result of the energy balance of gains and losses in the receiver, with an absorber surface at temperature  $T$ . In some cases, the receiver has a transparent window that absorbs part of the incident radiation at a temperature,  $T_w$ , higher than the ambient,  $T_a$ . The concentrated solar irradiance ( $C \cdot \phi$ ) is absorbed with an efficiency of ( $\alpha\tau_w$ ). The radiation must often go through a transparent window, where it is partially absorbed, before reaching the absorber surface, reflected and transmitted onto the absorber. These not-so-simple effects are represented by the apparent window transmittance,  $\tau_w$ . Likewise, the second term in Equation 42.44 expresses the energy emitted of temperature  $T_w$  from the hot window toward the absorber. Therefore, this second term adds gains to the first. The loss terms are of two different types. The most important in a central receiver represents energy thermally radiated by the absorber through the receiver aperture. These radiation

**FIGURE 42.49**

Lateral view of the 80 m concrete tower of the CESA-1 facility located at the Plataforma Solar de Almería in Spain. The concentrated flux is aiming a standby position previous to start operation.

losses depend on the emissivity of the absorber and on thermal radiation reflectivity  $\rho_w$  of the window. In the product  $(\epsilon\bar{\rho})$ ,  $\bar{\rho}$  indicates  $(1 - \rho_w)$  or  $(\alpha_w + \tau_w)$ .

The absorber convective, or conductive, loss to the ambient is determined by the heat loss coefficient  $U$ , which depends on the temperature and the forced convection due to wind. In good central receiver designs,  $U$  can be sufficiently reduced by thermal insulation and decreased aperture area; therefore,  $U$  is basically expressed as a convective loss heat transfer coefficient. Generally, this coefficient is obtained from the dimensionless Nusselt number and subsequently as a function of numbers like Reynolds (Re), Prandtl (Pr), and Grashof (Gr). Forced convection is determined by combinations of the Re and Pr numbers, while natural convection is characterized by Pr and Gr numbers.

In the solar tower, the convective heat loss is calculated differently depending on whether the receiver is a cavity or a cylindrical external receiver. A typical simple mixed convection coefficient for an external receiver can be obtained calculated (Siebers and Kraabel, 1984) as

$$U_{mix} = \left( h_{forced}^{3.2} + h_{nat}^{3.2} \right)^{1/3.2} \quad (42.45)$$

where

$h_{nat} = 9.09 \text{ (W/m}^2 \text{ }^\circ\text{C)}$  for an average absorber temperature of  $480^\circ\text{C}$

$h_{forced}$  is separated into three cases depending on the receiver diameter (Kistler, 1986)

In all cases, the Reynolds number is  $Re = (1.751 \times 10^5)D$ .

---

Case 1: $D \leq 4.0$ m	$h_{forced} = \left(\frac{1}{D}\right) \cdot \left(0.3 + 0.488 \cdot Re^{0.5} \cdot \left(1.0 + \left(\frac{Re}{282000}\right)^{0.625}\right)^{0.8}\right) \cdot 0.04199$
Case 2: $4.0 < D \leq 125.0$	$h_{forced} = 14.0$
Case 3: $D > 125.0$ m	$h_{forced} = 33.75 \cdot D^{-0.19}$

---

For a cavity receiver, the convective heat loss can be directly calculated as (Kistler, 1986) follows:

$$Q_{conv} = Q_{forced} + Q_{nat} \text{ (W)} \quad (42.46)$$

$$Q_{forced} = 7631 \frac{A}{W_{ap}^{0.2}} \quad (42.47)$$

$$Q_{nat} = 5077 \cdot A_{cav} \quad (42.48)$$

where

$A$  is the aperture area ( $m^2$ )

$W_{ap}$  is the aperture width (m)

$A_{cav}$  is the approximation to total area inside cavity ( $m^2$ )

For more detailed correlations applicable to convection losses in different kinds of solar receivers, Becker and Vant-Hull (1991) is recommended.

There are different solar receiver classification criteria depending on the construction solution, the use of intermediate absorber materials, the kind of thermal fluid used, or heat transfer mechanisms. According to the geometrical configuration, there are basically two design options, external and cavity-type receivers. In a cavity receiver, the radiation reflected from the heliostats passes through an aperture into a box-like structure before impinging on the heat transfer surface. Cavities are constrained angularly and subsequently used in north-field (or south-field) layouts. External receivers can be designed with a flat plate tubular panel or in a cylindrical shape. Cylindrical external receivers are the typical solution adopted for surround heliostat fields. Figure 42.50 shows examples of cylindrical external, billboard external, and cavity receivers.

Receivers can be directly or indirectly irradiated depending on the absorber materials used to transfer the energy to the working fluid (Becker and Vant-Hull, 1991). Directly irradiated receivers make use of fluids or particle streams able to efficiently absorb the concentrated flux. Particle receiver designs make use of falling curtains or fluidized beds. Darkened liquid fluids can use falling films. In many applications, and to avoid leaks to the atmosphere, direct receivers should have a transparent window. Windowed receivers are excellent solutions for chemical applications as well, but they are strongly limited by the size of a single window, and therefore clusters of receivers are necessary.

The key design element in indirectly heated receivers is the radiative/convective heat exchange surface or mechanism. Basically, two heat transfer options are used, tubular panels and volumetric surfaces. In tubular panels, the cooling thermal fluid flows inside the tube and removes the heat collected by the external black panel surface by convection. It is therefore operating as a recuperative heat exchanger. Depending on the HTF

**FIGURE 42.50**

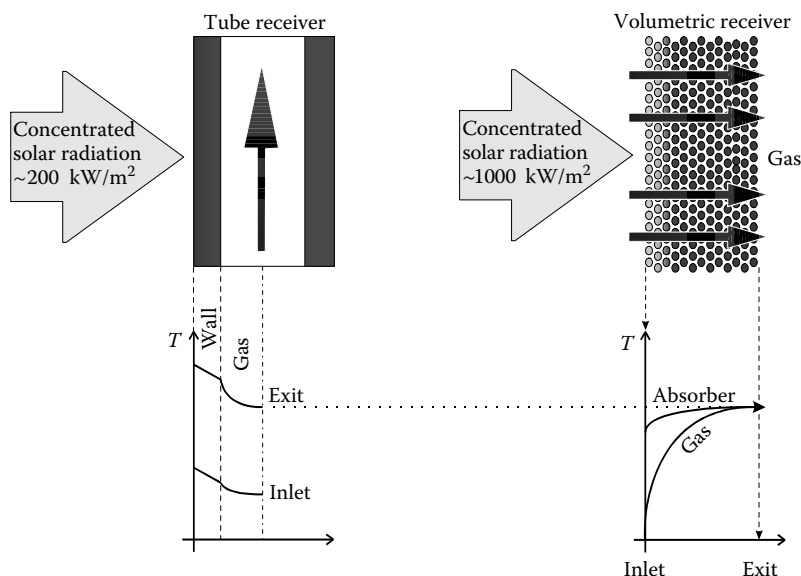

Different configurations of solar receivers. From left to right and top to bottom: (a) external tubular cylindrical, (b) cavity tubular, (c) billboard tubular, and (d) volumetric.

properties and incident solar flux, the tube might undergo thermo-mechanical stress. Since heat transfer is through the tube surface, it is difficult to operate at an incident flux above  $600 \text{ kW/m}^2$  (peak). Table 42.8 shows how only with high thermal conductivity liquids like sodium, it is possible to reach operating fluxes above  $1 \text{ MW/m}^2$ . Air-cooled receivers have difficulties working with tubular receivers because of the lower heat transfer coefficients, as already found in the German-Spanish GAST project where two tubular receivers, one metal and one ceramic, were tested at the PSA in Spain (Becker and Boehmer, 1989). To improve the contact surface, a different approach based on wire, foam, or appropriately shaped materials within a volume is used. In volumetric receivers, highly porous structures operating as convective heat exchangers absorb the concentrated solar radiation. The solar radiation is not absorbed on an outer surface, but

**TABLE 42.8**

Operating Temperature and Flux Ranges of Solar Tower Receivers

Fluid	Water–Steam	Liquid Sodium	Molten Salt (Nitrates)	Volumetric Air
<i>Flux (MW/m<sup>2</sup>)</i>				
Average	0.1–0.3	0.4–0.5	0.4–0.5	0.5–0.6
Peak	0.4–0.6	1.4–2.5	0.7–0.8	0.8–1.0
Fluid outlet temperature (°C)	490–525	540	540–565	700–800 (>800)

**FIGURE 42.51**

Heat transfer principles in tubular and volumetric receivers.

inside the structure *volume*. The heat transfer medium (mostly air) is forced through the porous structure and is heated by convective heat transfer. Figure 42.51 shows a comparison of the two absorber principles. Volumetric absorbers are usually made of thin heat-resistant wires (in knitted or layered grids) or either metal or ceramic (reticulated foams, etc.) open-cell matrix structures. Good volumetric absorbers are very porous, allowing the radiation to penetrate deeply into the structure. Thin substructures (wires, walls, or struts) ensure good convective heat transfer. A good volumetric absorber produces the so-called volumetric effect, which means that the irradiated side of the absorber is at a lower temperature than the medium leaving the absorber. Under specific operating conditions, volumetric absorbers tend to have an unstable mass flow distribution. Receiver arrangements with mass flow adaptation elements (e.g., perforated plates) located behind the absorber can reduce this tendency, as well as appropriate selection of the operating conditions and the absorber material.

Selection of a particular receiver technology is a complex task, since operating temperature, heat storage system, and thermodynamic cycle influence the design. In general, tubular technologies allow either high temperatures (up to 1000°C) or high pressures (up to 120 bar), but not both (Kribus, 1999). Directly irradiated or volumetric receivers allow even higher temperatures but limit pressures to below 15 bar.

### 42.6.2.1 Tubular Receivers

The most common systems used in the past have been tubular receivers where concentrated radiation is transferred to the cooling fluid through a metal or ceramic wall. Conventional panels with darkened metal tubes have been used with steam, sodium, and molten salts for temperatures up to 500°C–600°C. Much less experience is available on tubular receivers with gas, though temperatures in the range of 800°C–900°C are possible. Cavity receivers have been tested in France (Themis) and Spain (IEA-SSPS-CRS project and CESA-1 plant). External tubular receivers were used in Solar One (United States), IEA-SSPS-CRS (Spain), and Solar Two (United States) (Grasse et al., 1991; Pacheco and Gilbert, 1999). Other experimental systems using water–steam and tubular receivers were Nio in Japan, Eurelios in Italy, and SES-5 in the former Soviet Union.

Solar One in Barstow, California, used a once-through superheated water–steam receiver. It operated from 1984 to 1988 and was the largest central receiver in the world for two decades. It was an external cylindrical receiver made up of twenty-four 1 m wide by 14 m long rectangular panels (Figure 42.52). The six panels on the south side were feed-water preheat units. Preheated water was then transferred to once-through boilers and superheaters on the north side. The tubes in each panel were welded throughout their length and painted black with Pyromark® paint. The design specifications were for steam at 516°C and a pressure of 100 bar. Up to 42 MW<sub>th</sub> could be absorbed by the receiver. The initial thermal efficiency was 77% for an absorbed power of 34 MW<sub>th</sub>. After painting it black and curing the surface, it increased to 82% with  $\alpha = 0.97$ . Almost constant thermal losses have been verified (4.5–5 MW<sub>th</sub>) for this kind of receiver, due basically to radiation losses and

**FIGURE 42.52**

External cylindrical tubular receiver used in Solar One power plant, Barstow, California.

operating the receiver at constant temperature by regulating the mass flow rate. One of the main problems found during testing was overheating and deformation in the superheating section because of solar transients and poor heat transfer (Radosevich and Skinrood, 1989). Cracking and leaking were observed at the top of the boiler tubes after 18 months of operation. The temperature gradient between the edges and the center of the tubes can go up to 111°C during start-ups and shutdowns.

CESA-1, which operated 1631 h between 1983 and 1986 in Almería, Spain, was a north-facing water–steam cavity receiver. The 3.4 m square aperture was tilted 20° to the heliostat field. The receiver panel configuration and position of the steam drum are shown in Figure 42.53. The boiler consisted of three panels of A-106 Gr B carbon steel tubes, with an effective surface of 48.6 m<sup>2</sup>, and a superheater made of X-20 Cr Mo V 121 steel. The 6.7 MW maximum incident power on the receiver produced superheated steam at 110 kg/cm<sup>2</sup> and 525°C. As in Solar One, operating problems and noticeable deformations were found in the superheating zone, requiring it to be operated with lower flux. Also because of that, operation had to proceed slowly during start-up and transients, penalizing efficiency. More than 45 min were required to reach nominal conditions (Sánchez, 1986).

Molten-salt tubular receivers are represented by the Themis system (cavity) and Solar Two (cylindrical external), and subsequently applied to the commercial project Gemasolar. In a molten-salt system, cold salt at about 290°C is pumped from a tank at ground level to the receiver mounted atop a tower where it is heated by concentrated sunlight to 565°C. Using molten salts as receiver coolant provides a number

**FIGURE 42.53**

Inner view of tubular panels and drum of the water–steam cavity receiver used in the CESA-1 project in Spain.

of benefits because there is no phase change, and it is possible to heat up to 565°C without the problems associated in tubes with superheating sections. Mixtures of 60% sodium nitrate and 40% potassium nitrate have been extensively tested with satisfactory results in France and the United States. Molten nitrates provide good thermal conductivity (0.52 W/m K) and heat capacity (1.6 kJ/kg K) at relatively low prices. Molten nitrate salt, though an excellent thermal storage medium, can be a troublesome fluid to deal with because of its relatively high freezing point (220°C). To keep the salt molten, a fairly complex heat trace system must be employed. (Heat tracing is composed of electric wires attached to the outside surface of pipes. Pipes are kept warm by way of resistance heating.) Problems were experienced during the start-up of Solar Two due to the improper installation of the heat trace. Though this problem has been addressed and corrected, research is needed to reduce the reliance on heat tracing in these plants. Also, valves can be troublesome in molten-salt service. Special packings must be used, oftentimes with extended bonnets, and leaks are not uncommon. Furthermore, freezing in the valve or packing can prevent it from operating correctly. While today's valve technology is adequate for molten-salt power towers, design improvements and standardization would reduce risk and ultimately reduce O&M costs (De Meo and Galdo, 1997).

Solar Two, tested between 1996 and 1999 (Pacheco et al., 2000), is still the technical reference for molten-salt tubular receivers. The 42 MW absorber consisted of a 6.2 m-high and 5.1 m-diameter cylinder, with 768 2 cm-diameter tubes. Reported efficiency with no wind was 88% for 34 MW absorbed (86% with wind under 8 km/h). Peak concentrated solar flux was 800 kW/m<sup>2</sup> and average 400 kW/m<sup>2</sup>. Though reported efficiency was close to nominal, during the 3 years of operation, there were many incidents, and modifications and repairs to avoid freezing and obstructions in tubes, downcomers, manifolds, valves, and pipelines. The consequence was a very limited experience in long-term testing. Some attempts were made in the early 1990s to simplify molten-salt receivers by removing the salt-in-tube heat exchanger and introducing open-air falling-film flat plates (Romero et al., 1995). Table 42.9 summarizes typical operating temperatures, incident flux, pressures, and efficiencies in tubular water-steam and molten-salt receivers.

#### 42.6.2.2 Volumetric Receivers

As already mentioned, volumetric receivers use highly porous structures for the absorption of the concentrated solar radiation deep inside (in the *volume*) the structure. Volumetric receivers can work open to the ambient or enclosed by a transparent window. With metal absorbers, it is possible to achieve air outlet temperatures up to 850°C, and with ceramic fibers, foams, or monoliths (SiC), the temperature can surpass 1000°C (Avila-Marin, 2011).

**TABLE 42.9**

Summary of Operational Range for Tubular Water–Steam and Molten-Salt Receivers

Receivers Water–Steam	Molten-Salt Receivers
Temperature fluid outlet 250°C/525°C	Temperature outlet 566°C
Incident flux 350 kW/m <sup>2</sup>	Incident flux 550 kW/m <sup>2</sup>
Peak flux 700 kW/m <sup>2</sup>	Peak flux 800 kW/m <sup>2</sup>
Pressure 100–135 bar	
Efficiency 80%–93%	Efficiency 85%–90%

The main advantages of an air-cooled volumetric receiver are as follows:

- The air is free and fully available at the site.
- No risk of freezing.
- Higher temperatures are possible, and therefore the integration of solar thermal energy into more efficient thermodynamic cycle looks achievable.
- No phase change.
- Simple system.
- Fast response to transients or changes in incident flux.
- No special safety requisites.
- No environmental impact.

Open volumetric receivers have made dramatic progress since the pioneering experiences of the late 1970s (Sanders, 1979) and early 1980s (Fricker et al., 1988). More than 20 absorbers and prototypes in the 200–300 kW<sub>th</sub> range have been tested in the Sulzer test bed at the PSA (Becker et al., 1989, 1992; Hoffschmidt et al., 2001). Wire mesh, knitted-wire, foam, metal, and ceramic monolith volumetric absorbers have been developed worldwide. The relatively large number of volumetric prototypes tested has demonstrated the feasibility of producing hot air at temperatures of 1000°C and upward and with aperture areas similar to those used in molten-salt or water–steam receivers. Average flux of 400 kW/m<sup>2</sup> and peaks of 1000 kW/m<sup>2</sup> have been proven, and their low-inertia and quick sun-following dispatchability are excellent. Comparative assessments have demonstrated that wire mesh has the lowest thermal losses (Table 42.10). This can mainly be explained by the very high porosity of the absorber, which permits a large portion of the irradiation to penetrate deep into its volume. The choice of ceramics as the absorber material makes higher gas outlet temperatures possible. In particular, siliconized SiC has been revealed as a good option because of its high thermal conductivity. Even though ceramic absorbers have lower efficiencies at 680°C (this is the reference temperature for applications where hot air is used as the HTF to produce superheated

**TABLE 42.10**

Properties and Efficiencies Reported for Several Absorber Materials Tested at the Plataforma Solar de Almería ( $D_{m,p}$  = Mean Pore Diameter)

Type of Receiver	Designed by	Absorber Structure	Porosity ( $V_p/V_{tot}$ )	$D_{m,p}$ (mm)	Absorber Thickness (mm)	Material	Thermal Conductivity (500°C) (W/m K)	Efficiency (680°C) (%)

steam in a heat exchanger), they have demonstrated efficiencies about 80% at temperatures of 800°C. With higher solar flux and temperatures, more compact designs and smaller receivers can be developed.

A milestone in the experimental scale-up of open volumetric receivers was the Technology Program Solar Air Receiver (TSA) project, under the leadership of the German Steinmüller company. A 2.5 MW<sub>th</sub> air-cooled receiver was tested on top of the PSA CESA-1 tower late in 1991. The TSA experimental setup was a small-scale PHOEBUS-type receiver (Schmitz-Goeb and Keintzel, 1997), in which atmospheric air is heated up through a wire mesh receiver to temperatures on the order of 700°C to produce steam at 480°C–540°C and 35–140 bar, in a heat recovery steam generator with a separate superheater, reheater, evaporator, and economizer feeding a Rankine turbine-generator system. All the hardware, including receiver, steam generator, and heat storage, was located atop the CESA-1 tower. Average solar flux at the receiver aperture was 0.3 MW/m<sup>2</sup>. The HFCS was implemented with heuristic algorithms to obtain an automatic aiming strategy able to maintain stationary flux and air outlet temperature (Garcia-Martin et al., 1999). One of two blowers controlled the air mass flow rate through the receiver and the other the air through the steam generator. The 1000 kWh capacity thermocline storage system (alumina pellets) was enough to allow 30 min of nominal off-sun operation. Depending on the load, it could be charged, bypassed, or discharged. The 3 m-diameter absorber was made of hexagonal wire mesh modules (Figure 42.54). The TSA receiver was successfully operated by DLR and CIEMAT for a total of nearly 400 h between April and December 1993 (Haeger, 1994), and for shorter periods in 1994 and 1999, demonstrating that a receiver outlet temperature of 700°C could easily be achieved within 20 min of plant start-up and receiver thermal efficiencies up to 75% were obtained as shown in Figure 42.55.

A significant number of volumetric prototypes have been reported unable to reach nominal design conditions because of local cracks and structural damages. Those failures were, in many cases, caused by thermal shock, material defects, or improper operation. In the middle 1980s, some projects promoted by the German Aerospace Center (DLR) studied the fluid dynamics and thermal mechanisms inherent in volumetric absorbers (Hoffschmidt et al., 2001). One of the conclusions of these studies was that in highly porous absorber materials, the air flow through the absorber structure is unstable under high solar flux, which leads to the destruction (cracks or melting) of the absorber structure by local overheating (Pitz-Paal et al., 1996). As a consequence of this analysis, a new approach

**FIGURE 42.54**

Front view of the TSA volumetric receivers. The absorber was composed of hexagonal pieces of wire mesh. The outer ring includes the air return system.

**FIGURE 42.55**

TSA receiver efficiency at different temperatures and incident powers during test campaign carried out in 1993.

developed monolithic ceramic absorbers able to work at high temperatures and fluxes due to their high thermal conductivity and geometric modularity, which were put to use first in the German-Spanish HiTRec project (Hoffschmidt et al., 1999) and afterward in the European SOLAIR project (Hoffschmidt et al., 2002).

The HiTRec–SOLAIR receiver principle is shown in Figure 42.56. A stainless steel support structure on the back of a set of ceramic absorber modules forms the base of the receiver. Similar to ceramic burner tubes, the absorber modules are separated from the back and allowed to expand both axially and radially with thermal expansion of the modules or movement of the stainless steel construction behind them during start-up or shut-down. The absorber modules are spaced to avoid touching adjacent modules. The support structure is a double-sheet membrane, which may be cooled by either ambient or returned air. Tubes attached to the absorber cups pass through holes in the front sheet and are

**FIGURE 42.56**

Principle of volumetric receivers used in HiTRec and SOLAIR projects.

welded to the rear sheet. The cooling air circulates between the two sheets and, as it leaves through the sides of the segments, also cools the support structure. The air reaches the absorber aperture through the spaces between the segments. Outgoing air and ambient air are mixed and sucked back into the segments. As they penetrate the absorber structure, the air is heated up by convection. On leaving the absorber structure, the hot air is ducted to the bottom of the cup. There an orifice, previously sized according to solar flux simulations, adjusts the air mass flow rate to compensate the expected solar flux profile over the aperture and to provide homogeneous outlet air temperatures from the cups. Then, the air passes through the tubes hosting the cups and across the holes in the rear sheet of the membrane.

A first milestone in the development of this type of receiver was the qualification of the 200 kW HiTRec-II receiver (Hoffschmidt et al., 2003). Testing lasted from November 2000 through May 2001. During the course of the test program, the HiTRec-II receiver was operated over a period of 38 days, accumulating a total of 155 operating hours with a thermal efficiency of up to  $76\% \pm 7\%$  at  $700^\circ\text{C}$ . Eventually, a SOLAIR 3 MW prototype was developed, installed, and tested in the TSA test bed in the PSA and therefore connected to the heat storage thermocline, the steam generator, and the air circuit. The receiver was designed as a real modular absorber, which was assembled from 270 ceramic modules measuring  $140\text{ mm}^2$ . Each module consisted of a square absorber structure glued to a SiSiC cup. The cups were square at the aperture, but round at the back. The honeycomb absorber structure was made of recrystallized SiC with a normal open porosity of 49.5%. The SOLAIR-3000 receiver had a total aperture surface of  $5.67\text{ m}^2$ . During testing, the incident solar radiation is reflected by the heliostat field and concentrated on the ceramic volumetric absorber with an average flux density of  $0.5\text{ MW/m}^2$ . The air leaves the absorber outlet at  $700^\circ\text{C}$ – $750^\circ\text{C}$ . The system was evaluated during 2003 and 2004 presenting an air return ratio (ARR) of 0.5, efficiency of  $(72 \pm 9)\%$  at a temperature of  $750^\circ\text{C}$ , and efficiency of  $(74 \pm 9)\%$  at  $700^\circ\text{C}$ . Efficiencies were estimated at over 85% (and up to 89%) for outlet air temperatures in the range of  $590^\circ\text{C}$ – $630^\circ\text{C}$  and mean incident solar fluxes of  $310$ – $370\text{ kW/m}^2$  (Agrafiotis et al., 2007).

Though simplicity and operating results are satisfactory, it is obvious that open volumetric receiver thermal efficiencies must be improved to achieve cost-effective plant designs able to replace tubular receivers (Palero et al., 2008). In addition, there have not yet been any long-term endurance tests, radiation losses must be further reduced, and the ARR should be improved in open receiver designs. Plant performance analysis leads to the conclusion that ARR in a PHOEBUS-type receiver should be close to 70% to keep air-cooled solar plants in the same efficiency range as other power tower plants cooled with molten-salt or water–steam (Marcos et al., 2004).

The future use of open volumetric receivers in more efficient thermodynamic cycles, with air return temperatures up to  $500^\circ\text{C}$ , and more, may lead to even more stringent requirements for the ARR. Assuming a target air-mixing efficiency of at least 0.93 or higher, it means that for air return temperatures of  $200^\circ\text{C}$ , ARR should be over 0.8 and for temperatures above  $400^\circ\text{C}$ , the ARR should be raised to 0.9.

Another option for working with closed-loop air circuits is the use of windowed volumetric receivers. One attractive application is based upon solar receivers as the preheating chamber of a gas turbine (Romero et al., 2002). In 1996, the German Aerospace Center (DLR) initiated a specific development program called REFOS for the purpose of producing an optimum 350 kW windowed-module design able to work at temperatures up to  $1000^\circ\text{C}$  and with pressures up to 15 bar. The aim of the REFOS project was to develop, build, and test modular pressurized volumetric receivers under representative operating conditions

**FIGURE 42.57**  
Example of 350 kW REFOS module.

for coupling to gas turbines. Emphasis was on testing solar preheating of air, accompanied by basic materials research. The REFOS receiver consists of a cylindrical vessel containing a curved knitted absorber. A quartz dome is used to pressurize the air cycle. A hexagonal secondary concentrator with a 1.2 m inner diameter is used to increment the flux density and protect the window flange. The hexagonal shape was selected to optimize the layout of cluster packing in such a way that the REFOS modules can be used in either small or large power plants (Figure 42.57). Typical REFOS module specifications are as follows:

- Absorbed thermal power (design point): 350 kW per unit
- Absolute pressure (operation): 15 bar
- Air outlet temperature: 800°C for metal absorber and up to 1000°C for ceramics
- Temperature increment per module: 150°C
- Receiver efficiency (including secondary): 80% at design point

Several modules have been tested at the PSA under cooperation agreements between DLR and CIEMAT. In the most extensive tests performed in 1999, the design conditions were demonstrated with a single module operating at air outlet temperatures of 800°C at 15 bar, at power levels up to 400 kW<sub>th</sub>. More than 247 h of testing proved the feasibility of the receiver, which reached a maximum temperature of 1050°C without incurring damage (Buck et al., 2002). Thermal efficiencies were between 63% and 75%.

### 42.6.3 Experience in Central Receiver Systems

Although there have been a large number of STP tower projects, only a few have culminated in the construction of an entire experimental system. Table 42.11 lists the experimental systems that have been tested all over the world before commercial projects started in 2006. In general terms, as observed, they are characterized as being small demonstration systems between 0.5 and 10 MW, and most of them were operated in the 1980s (Entropie, 1982; Falcone, 1986; Grasse et al., 1991). The thermal fluids used in the receiver have been liquid sodium, saturated or superheated steam, nitrate-based molten salts, and air. All of

**TABLE 42.11**

Experimental CRS Facilities in the World

Project	Country	Power (MW <sub>e</sub> )	Heat Transfer Fluid	Storage Media	Beginning Operation

<sup>a</sup> Thermal.

them can easily be represented by flow charts, where the main variables are determined by working fluids, with the interface between power block and the solar share.

The set of experiences referred to has served to demonstrate the technical feasibility of the CRS power plants, whose technology is sufficiently mature. The most extensive experience has been collected by several European projects located in Spain at the premises of the PSA (Grasse et al., 1991), and the 10 MW Solar One (Radosevich and Skinrood, 1989) and Solar Two plants (Pacheco and Gilbert, 1999) in the United States. Since the early 1990s, most proposals for the first generation of commercial plants have focused on nitrate salt and air as the receiver HTFs, since a joint U.S./German study identified their potential and economics in power tower plants (Chavez et al., 1993), though in Spain, parallel initiatives have developed saturated steam designs (Silva et al., 1999). Several penetration strategies have been proposed since then, and many more may be developed in the future, since solar towers have the great advantage of admitting very open integration designs depending on the dispatching scenarios, annual capacity factors, and hybridization schemes. At present, water-steam and molten salts are the HTFs being selected for the first generation of commercial plants.

#### 42.6.3.1 Water-Steam Plants: The PS10 Project

Production of superheated steam in the solar receiver has been demonstrated in several plants, such as Solar One, Eurelios, and CESA-1, but operating experience showed critical problems related to the control of zones with dissimilar heat transfer coefficients like boilers and superheaters (Grasse et al., 1991). Better results regarding absorber panel life-time and controllability have been reported for saturated steam receivers. In particular, the Solar Thermal Enhanced Oil Recovery pilot plant, which proved to be highly reliable for oil extraction using direct injection of steam, was successfully operated in Kern County, California, for 345 days in 1983 (Blake et al., 1985). The good performance of saturated steam receivers was also qualified at the 2 MW Weizmann receiver that produced steam at 15 bar for 500 h in 1989 (Epstein et al., 1991). Even though technical risks are reduced by saturated steam receivers, the outlet temperatures are significantly lower than those of superheated steam, making applications where heat storage is replaced by fossil fuel backup necessary.

At present, estimated costs of electricity production from the solar share of hybrid systems are \$0.08–\$0.15 per kWh, whereas expected costs for solar-only plants are in the range of \$0.15–\$0.20 per kWh. The implementation of hybridized systems is one of the paths leading to a breakthrough in the financial barriers to the deployment of solar electricity technologies as it reduces the initial investment (Kolb, 1998). The use of hybrid plants with the low technological risk of a CRS with saturated steam as the working fluid is the starting point. Two projects subsidized by the European Commission, the SOLGAS project promoted by SODEAN and the COLON SOLAR project promoted by the Spanish utility, SEVILLANA (Ruiz et al., 1999), established the strategy of market penetration on the basis of the integration of saturated steam receivers in cogeneration systems and repowering of combined cycles. The size of the cavity receiver was optimized to supply 21.8 MW<sub>th</sub> to the fluid at 135 bar and 332.8°C outlet temperature. The collector subsystem consisted of 489 heliostats (each with a 70 m<sup>2</sup> reflective surface) and a 109 m tower. As observed in Table 42.12, the use of low-temperature receivers and phase-change saturated steam yields a much higher thermal efficiency of up to 92% at nominal load. The table shows a theoretical comparison between a typical volumetric air-cooled receiver working at 700°C air outlet temperature and saturated steam receiver at 250°C thermal outlet. Both are cavity receivers with an incident power of 45 MW (Osuna et al., 2004).

Integrating power towers into existing combined-cycle plants can create issues with respect to heliostat field layout, since the solar field is forced to make use of sites near gas pipelines and industrial areas. Land becomes a nonnegligible share of plant cost, and site constraints lead to layout optimization and subsequent optical performance problems. This was the case of the COLON heliostat field, which represented a real design challenge, because of the significant restrictions imposed by the available site (Romero et al., 1999). The hybrid solar-gas scheme predicts solar production costs below \$0.11 per kWh and annual solar shares in the range of 8%–15%. The lack of public support schemes for hybrid STP plants in Spain at that time led to project abortion, and the plant was never built.

The follow-up of the COLON SOLAR project was finally a solar-only saturated steam plant called PS10 (Planta Solar 10 MW). PS10 came about as a consequence of the Spanish legal framework for a special regime of feed-in tariffs for renewable electricity, issued in March 2004. PS10 is located on the Casa Quemada estate (37.2° latitude), 15 km west of the city of Seville (Spain). The 11 MW plant was designed to achieve an annual electricity production of 23 GWh at an investment cost of less than \$4000 per kW. The project made use of available, well-proven technologies like the glass-metal heliostats developed by the Spanish Inabensa company and the saturated steam cavity receiver developed by the TECNICAL company to produce steam at 40 bar and 250°C (Osuna et al., 2004). The plant is a solar-only system with saturated steam heat storage

**TABLE 42.12**

Comparison of Thermal Losses and Efficiency in Air Volumetric and Saturated Steam Receivers for the PS10 Project

Losses	Air (%)	Steam (%)
Reflection	7.9	2.0
Radiation	8.6	0.8
Convection	0.0	2.6
Spillage	5.0	2.1
Air return	3.7	0.0
Total efficiency	74.8	92.4

**FIGURE 42.58**

Basic scheme of PS10 solar thermal power plant with saturated steam as thermal fluid.

able to supply 50 min of plant operation at 50% load. The system makes use of 624,121 m<sup>2</sup> heliostats, distributed in a north-field configuration, a 90 m-high tower, a 15 MWh heat storage system, and a cavity receiver with four 4.8 × 12 m tubular panels. The basic flow diagram selected for PS10 is shown in Figure 42.58. Though the system makes use of a saturated steam turbine working at extremely low temperature, the nominal efficiency of 30.7% is relatively good. This efficiency is the result of optimized management of waste heat in the thermodynamic cycle. At the turbo-generator exit, the steam is sent to a water-cooled condenser, working at 0.06 bar. The condenser outlet is preheated with 0.8 and 16-bar steam bled from the turbine. The output of the first preheater is sent to the deaerator, which is fed with steam again bled from the turbine. A humidity separator is installed between the high- and low-pressure sections of the turbine to increase steam quality in the last stages of expansion. A third and last preheater fed with steam from the receiver increases water temperature to 245°C. When mixed with water returned from the drum, 247°C receiver feed water is obtained. As summarized in Table 42.13, the combination of optical, receiver, and power block efficiencies leads to

**TABLE 42.13**

Annual Energy Balance for the PS10 Plant at Nominal Conditions and Annual Basis

#### Nominal Rate Operation

Optical efficiency	77.0%	67.5 → 51.9 MW
Receiver and heat handling efficiency	92.0%	51.9 → 47.7 MW
Thermal power to storage		11.9 MW
Thermal power to turbine		35.8 MW
Thermal power/electric power efficiency	30.7%	35.8 → 11.0 MW
Total efficiency at nominal rate	21.7%	

#### Energetic Balance in Annual Basis

Mean annual optical efficiency	64.0%	148.63 → 95.12 GWh
Mean annual receiver and heat-handling efficiency	90.2%	95.12 → 85.80 GWh
Operational efficiency (start-up/stop)	92.0%	85.80 → 78.94 GWh
Operational efficiency (breakages, O&M)	95.0%	78.94 → 75.00 GWh
Mean annual thermal energy/electricity efficiency	30.6%	75.00 → 23.0 GWh
Total annual efficiency	15.4%	

a total nominal efficiency at design point of 21.7%. Total annual efficiency decreases to 15.4%, including operational losses and outages. PS10 is a milestone in the CRS deployment process, since it is the first solar power tower plant developed for commercial exploitation. Commercial operation started on June 21, 2007. Since then, the plant is performing as specified. The construction of PS20, a 20 MW<sub>e</sub> plant with the same technology as PS10, followed. PS20 started operation in May 2009. With 1255 heliostats (120 m<sup>2</sup> each) spread over 90 ha and with a tower of 165 m high, the plant is designed to produce 48.9 GWh/year (Figure 42.40).

Saturated steam plants are considered a temporary step to the more efficient superheated steam systems. Considering the problems found in the 1980s with superheated steam receivers, the current trend is to develop dual receivers with independent absorbers, one of them for the preheating and evaporation, and another one for the superheating step. The experience accumulated with heuristic algorithms in central control systems applied to aiming point strategies at heliostat fields allows achieving a flexible operation with multi-aperture receivers. The company Abengoa Solar, developer of PS10 and PS20, has already designed a superheated steam receiver for a new generation of water–steam plants to be implemented in the first CRS project in South Africa (Fernandez-Quero et al., 2005). The most advanced strategy is the program initiated by the BrightSource PLT. BrightSource has already built a demonstration plant of 6 MW<sub>th</sub> located at the Negev desert in June 2008 (Silberstein et al., 2009). The final objective of BrightSource is to promote plants producing superheated steam at 160 bar and temperature of 565°C (named DPT550). With those characteristics, they expect up to 40% conversion efficiency at the power block for unit sizes between 100 and 200 MW. The receiver is cylindrical, dual, and with a drum. The first commercial project producing superheated steam is Ivanpah Solar in California of 380 MW, with three towers. The plant is expected to connect to the grid in 2014.

The combination of recent initiatives on small heliostats, compact modular multitower fields, and production of superheated steam may be clearly visualized in the development program of the company eSolar. This company proposes a high degree of modularity with power units of 46 MW covering 64 ha, consisting of 16 towers and their corresponding heliostat fields sharing a single central power block. With replication, modularity sizes up to 500 MW and upward may be obtained (Tyner and Pacheco, 2009). Two modules of 2.5 MW each were installed in 2009 by eSolar in Lancaster, California. Each receiver had two independent cavities, and the heliostat layout consisted of identical arrays to maximize replication and modularity. Each tower is associated with 12,180 flat heliostats of 1.14 m<sup>2</sup> each (Schell, 2009). The receivers are dual-cavity, natural-circulation boilers. Inside the cavity, the feed water is preheated with economizer panels before entering the steam drum. A downcomer supplies water to evaporator panels where it is boiled. The saturated water/vapor mixture returns to the drum where the steam is separated, enters superheater panels, and reaches 440°C at 6.0 MPa. Each receiver absorbs a full-load power of 8.8 MW<sub>th</sub>.

A comparative analysis of system integration schemes for megawatt-range DSG central receiver STP plants reveals that the differences between superheated steam and saturated steam schemes may be minimized in some extent given the fact that dual receivers involve two apertures and worse thermal efficiencies (Sanz-Bermejo et al., 2014). Superheated steam systems at 550°C and pressure between 60 and 80 bar obtain the best results. However, the increment of efficiency versus saturated solar plant at 69 bar is just 2.3% in the best case, and if the 69-bar saturated system integrates an intermediate reheat process, it can even achieve the same performance level of superheated

systems. It is also relevant to mention that saturated conditions at 40 bar provide similar performance than superheated system operating at 500°C.

#### 42.6.3.2 Molten-Salt Systems: Solar Two and Gemasolar

The Solar One Pilot Plant successfully demonstrated operation of a utility-scale power tower plant. The Solar One receiver heated subcooled water to superheated steam, which drove a turbine. The superheated steam was also used to charge an oil-rock thermocline storage system. Solar One operated for 6 years from 1982 to 1988, the last three of which were devoted to power production (Radosevich and Skinrood, 1989). Although Solar One successfully demonstrated the feasibility of the power tower concept, the thermal storage system was inadequate for operating the turbine at peak efficiency, because the storage system operated only between 220°C and 305°C, whereas the receiver outlet (and design turbine inlet) temperature was 510°C. The primary mode of operation was directly from receiver outlet to turbine input, bypassing the thermal storage system, and storage provided auxiliary steam during offline periods.

For high annual capacity factors, solar-only power plants must have an integrated cost-effective thermal storage system. One such thermal storage system employs molten nitrate salt as the receiver HTF and thermal storage media. To be usable, the operating range of the molten nitrate salt, a mixture of 60% sodium nitrate and 40% potassium nitrate, must match the operating temperatures of modern Rankine cycle turbines. In a molten-salt power tower plant, cold salt at 290°C is pumped from a tank at ground level to the receiver mounted atop a tower where it is heated by concentrated sunlight to 565°C. The salt flows back to ground level into another tank. To generate electricity, hot salt is pumped from the hot tank through a steam generator to make superheated steam. The superheated steam powers a Rankine cycle turbine. A diagram of a molten-salt power tower is shown in Figure 42.59. The collector field can be sized

FIGURE 42.59

Schematic of a molten-salt central receiver system with cylindrical tubular receiver.

**FIGURE 42.60**

Comparison of volume energy storage capacity for several chemical, thermal, and mechanical media.

to collect more power than is demanded by the steam generator system, and the excess salt is accumulated in the hot storage tank. With this type of storage system, solar power tower plants can be built with annual capacity factors up to 70%. As molten salt has a high energy storage capacity per volume (500–700 kWh/m<sup>3</sup>), as shown in Figure 42.60, they are excellent candidates for STP plants with large capacity factors. Even though nitrate salt has a lower specific heat capacity per volume than carbonates, they still store 250 kWh/m<sup>3</sup>. The average heat conductivity of nitrates is 0.52 W/m K, and their heat capacity is about 1.6 kJ/kg K. Nitrates are a cheap solution for large storage systems. The cost of the material is \$0.70 per kg or \$5.20 per kWh<sub>th</sub>. Estimates for large systems including vessels are in the range of \$13 per kWh<sub>th</sub>.

Several molten-salt development and demonstration experiments have been conducted over the past two and half decades in the United States and Europe to test entire systems and develop components. The largest demonstration of a molten-salt power tower was the Solar Two project, a 10 MW power tower located near Barstow, California.

The purpose of the Solar Two project was to validate the technical characteristics of the molten-salt receiver, thermal storage, and steam generator technologies; improve the accuracy of economic projections for commercial projects by increasing the capital, operating, and maintenance cost database; and distribute information to utilities and the solar industry to foster a wider interest in the first commercial plants. The Solar Two plant was built at the same site as the Solar One pilot plant and reused much of the hardware including the heliostat collector field, tower structure, 10 MW turbine, and balance of plant. A new, 110 MWh<sub>th</sub> two-tank molten-salt thermal storage system was installed, as well as a new 42 MWh<sub>th</sub> receiver, a 35 MWh<sub>th</sub> steam generator system (535°C, 100 bar), and master control system (Kelly and Singh, 1995).

The plant began operating in June 1996. The project successfully demonstrated the potential of nitrate-salt technology. Some of the key results were the following: receiver efficiency was measured at 88%, the thermal storage system had a measured round-trip efficiency of over 97%, and the gross Rankine-turbine cycle efficiency was 34%, all of

which matched performance projections. The collector field performance was less than predicted, primarily due to the low availability of the heliostats (85%–95% versus 98% expected), the degradation of the mirrored surfaces, and poor heliostat canting. Most of the heliostat problems were attributed to the fact that the heliostat field had sat idle and unmaintained for 6 years between Solar One shutdown and Solar Two start-up. The overall peak-conversion efficiency of the plant was measured at 13.5%. The plant successfully demonstrated its ability to dispatch electricity independently from solar collection. On one occasion, the plant operated around the clock for 154 h straight (Pacheco et al., 2000). The plant met daily performance projections when the actual heliostat availability was accounted for. Although there were some plant start-up issues, and it did not run long enough to establish annual performance or refine operating and maintenance procedures, the project identified several areas where the technology could be simplified and its reliability improved. On April 8, 1999, testing and evaluation of this demonstration project was completed, and it was shut down.

To reduce the risks associated with scaling-up hardware, the first commercial molten-salt power tower should be approximately three times the size of Solar Two (Zavoico et al., 2001). One attempt to prove scaled-up molten-salt technology is the Gemasolar project (Figure 42.61) promoted, built, and operated by Torresol Energy, a joint venture between the Spanish SENER and MASDAR initiative from Abu Dhabi (Ortega et al., 2006). Table 42.14 summarizes the main technical specifications of Gemasolar project. With only 17 MW<sub>e</sub>, the plant that connected to the grid in summer 2011 is designed to produce 112 GWh<sub>e</sub>/year. A large heliostat field of 304,750 m<sup>2</sup> (115 m<sup>2</sup> each heliostat) is oversized to supply 15 h equivalent heat storage capacity. The plant is designed to operate around the clock in summertime, leading to an annual capacity factor of 74%. Fossil backup corresponding to 15% of annual production is added. The levelized energy costs are estimated to be approximately \$0.16 per kWh. Gemasolar represents a breakthrough for solar technology in terms of time-dispatch management (Burgaleta et al., 2009; García and Calvo, 2012).

**FIGURE 42.61**

**TABLE 42.14**

Technical Specifications and Design Performance of the Gemasolar Project

**Technical Specifications**

Heliostat field reflectant surface	304,750 m <sup>2</sup>
Number heliostats	2,650
Land area of solar field	142 ha
Receiver thermal power	120 MW <sub>th</sub>
Tower height	145 m
Heat storage capacity	15 h
Power at turbine	17 MW <sub>e</sub>
Power NG burner	16 MW <sub>th</sub>

**Operation**

Annual electricity production	112 MWh <sub>e</sub>
Production from natural gas (annual)	15%
Capacity factor	74%

## 42.7 Dish–Stirling Systems

STP plants can also be applied to distributed generation through parabolic dishes in which a power conversion unit (PCU) is attached by an arm directly to the concentrator. Although there have been other modular PCU system initiatives in the past, like the dish/Brayton tested by Cummins and DLR (Buck et al., 1996) or the use of dish farms to produce superheated steam designed to feed a centralized Rankine cycle in Georgia (Alvis, 1984), it is the dish–Stirling system that has demonstrated from the earliest prototypes high peak conversion efficiencies of above 30% solar-to-electric and a daily average of up to 25%. Dish–Stirling systems are considered as efficient technology to convert solar energy into electricity. This high conversion efficiency is due to their high concentration ratios (up to 3000×) and high working temperatures of above 750°C (Stine and Diver, 1994).

### 42.7.1 System Description

Dish–Stirling systems track the sun and focus solar energy onto a cavity receiver, where it is absorbed and transferred to a heat engine/generator. An electrical generator, directly connected to the crankshaft of the engine, converts the mechanical energy into electricity (AC). To constantly keep the reflected radiation at the focal point during the day, a sun-tracking system continuously rotates the solar concentrator on two axes following the daily path of the sun. With current technologies, a 5 kW<sub>e</sub> dish–Stirling system would require 5.5 m diameter concentrator, and for 25 kW<sub>e</sub>, the diameter would have to increase up to 10 m. Stirling engines are preferred for these systems because of their high efficiencies (40% thermal to mechanical), high power density (40–70 kW/L), and potential for long-term, low-maintenance operation. Dish–Stirling systems are modular, that is, each system is a self-contained power generator, allowing their assembly in plants ranging in size from a few kilowatts to tens of megawatts (Mancini et al., 2003).

Global efficiency of the system can be defined as

$$\eta = \eta_C * \eta_R * \eta_{Stir} * \eta_{Gen} = \frac{P}{A_C * I} \quad (42.49)$$

where

- $\eta_C$  is the concentrator efficiency
- $\eta_R$  is the receiver efficiency
- $\eta_{Stir}$  is the Stirling engine efficiency
- $\eta_{Gen}$  is the generator efficiency
- $P$  is the gross power generated
- $A_C$  is the projected concentrator area
- $I$  is the direct normal irradiance

#### 42.7.1.1 Concentrator

The concentrator is a key element of any dish–Stirling system. The curved reflective surface can be manufactured by attached segments, by individual facets, or by a stretched membrane shaped by a continuous plenum. In all cases, the curved surface should be coated or covered by aluminum or silver reflectors. Second-surface glass mirrors, front surface thin-glass mirrors, or polymer films have been used in various different prototypes.

First-generation parabolic dishes developed in the 1980s were shaped with multiple, spherical mirrors supported by a trussed structure (Lopez and Stone, 1992). Though extremely efficient, this structure concept was costly and heavy. The introduction of automotive industry concepts and manufacturing processes has led to optimized commercial versions like the 25 kW SunCatcher system developed by the company Stirling Energy Systems (SES), which has peak efficiency rating of 31.25%, for converting solar energy-to-grid quality electricity. Large monolithic reflective surfaces can be obtained by using stretched membranes in which a thin reflective membrane is stretched across a rim or hoop. A second membrane is used to close off the space behind forming a partially evacuated plenum between them, giving the reflective membrane an approximately spherical shape. This concept was developed by the German SBP company in the 1990s, and several prototypes have been tested at the PSA in Spain (Schiel et al., 1994). An alternative to the single stretched membrane in large units is a composition of a number of small circular rings, each with their corresponding membrane (Beninga et al., 1997).

Another example of concentrator developments in dish–Stirling systems is the Eurodish prototype (Figure 42.62). The concentrator consists of 12 single segments made of fiber glass resin. When mounted, the segments form an 8.5 m–diameter parabolic shell. The shell rim is stiffened by a ring truss to which bearings and the Stirling support structure are later attached. Thin 0.8 mm–thick glass mirrors are glued onto the front of the segments for durable, high reflectivity of around 94% (Keck et al., 2003).

Solar tracking is usually done by two different methods (Adkins, 1987):

1. Azimuth-elevation tracking by an orientation sensor or by calculated coordinates of the sun performed by the local control.
2. Polar tracking, where the concentrator rotates about an axis parallel to the earth's axis rotation. The rate of rotation is constant and equal to 15° per h. Declination angle movement is only  $\pm 23.5^\circ$  per year (0.016° per h) and therefore adjusted from time to time.

**FIGURE 42.62**

Example of segmented parabolic concentrators. Rear and front views of two Eurodish prototype tested at the Plataforma Solar de Almería, Spain.

#### 42.7.1.2 Receiver

As in central receivers and parabolic-trough absorbers, the receiver absorbs the light and transfers the energy as heat to the engine's working gas, usually helium or hydrogen. Thermal fluid working temperatures are between 650°C and 750°C. This temperature strongly influences the efficiency of the engine. Because of the high operating temperatures, radiation losses strongly penalize the efficiency of the receiver; therefore, a cavity design is the optimum solution for this kind of system.

Two different heat transfer methods are commonly used in parabolic dish receivers (Diver, 1987). In directly illuminated receivers, the same fluid used inside the engine is externally heated in the receiver through a pipe bundle. Although this is the most conventional method, a good high-pressure, high-velocity, heat-transfer gas like helium or hydrogen must be used. In indirect receivers, an intermediate fluid is used to decouple solar flux and working temperature from the engine fluid. One such method is heat pipes, which employ a metal capillary wick impregnated with a liquid metal heated up through the receiver plate and vaporized. The vapor then moves across the receiver and condenses in a cooler section, transferring the heat to the engine. The phase change guarantees good temperature control, providing uniform heating of the Stirling engine (Moreno et al., 2001).

#### 42.7.1.3 Stirling Engine

Stirling engines solarized for parabolic dishes are externally heated gas-phase engines in which the working gas is alternately heated and cooled in constant-temperature, constant-volume processes (Figure 42.63b). This possibility of integrating additional external heat in the engine is what makes it an ideal candidate for solar applications. Since the Stirling cycle is very similar to the Carnot cycle, the theoretical efficiency is high. High reversibility is achieved since work is supplied to and extracted from the engine at isothermal conditions. The clever use of a regenerator that collects the heat during constant-volume cooling and heating substantially enhances the final system efficiency. For most engine designs, power is extracted kinematically by rotating a crankshaft connected to the pistons by a connecting rod. An example of a kinematic Stirling engine is shown in Figure 42.63a. Though, theoretically, Stirling engines may have a high life-cycle projection, the actual

**FIGURE 42.63**

(a) Representation of the ideal Stirling cycle. (b) Kinematic Stirling engine V-160 of 10 kW<sub>e</sub> manufactured by Solo Kleinmotoren with pistons situated in V and connected to a tubular array heat exchanger.

fact is that today their availability is still not satisfactory, as an important percentage of operating failures and outages are caused by pistons and moving mechanical components. Availability is therefore one of the key issues, since it must operate for more than 40,000 h in 20-year lifetime, or 10 times more than an automobile engine. One option to improve availability is the use of free-piston designs. Free-piston engines make use of gas or a mechanical spring so that mechanical connections are not required to move reciprocating pistons. Apparently, they are better than kinematic engines in terms of availability and reliability. The most relevant program in developing dishes with free-piston technology was promoted by Cummins in the United States in 1991. Unfortunately, there were technical problems with the PCU and the project was cancelled (Bean and Diver, 1995). The last 10 years, the company Infinia Solar has developed several prototypes and test fields for 3 kW free piston systems derived from satellite applications, though still extended operation is needed. Due to the flexibility of the heat source, a Stirling engine can also be operated with a solar/fossil or solar/biomass hybrid receiver (Laing and Trabling, 1997), making the system available during cloudy periods and at night.

#### 42.7.2 Dish–Stirling Developments

Like the other CSP technologies, practical dish–Stirling development started in the early 1980s. Most development has concentrated in the United States and Germany, and though developed for commercial markets, they have been tested in a small number of units (Stine and Diver, 1994).

The first generation of dishes was a facet-type concentrator with second-surface mirrors that already established concentration records ( $C = 3000$ ) and had excellent performances, though their estimated costs for mass production were above \$300 per m<sup>2</sup>. Their robust structures were extremely heavy, weighing in at 100 kg/m<sup>2</sup> (Grasse et al., 1991). The 25 kW Vanguard-1 prototype built by Advanco was operated at Rancho Mirage, California, in the Mojave Desert in production mode for 18 months (February 1984 to June 1985), and results were published by EPRI (Droher and Squier, 1986).

This system was 10.7 m in diameter with a reflecting surface of 86.7 m<sup>2</sup> and a 25 kW PCU made by United Stirling AB model 4-95 Mark II. This engine had four cylinders with a 95 cm<sup>3</sup> cylinder displacement. Cylinders were distributed in parallel and assembled in a square. They were connected to the regenerator and cooler and had double-acting pistons. The working gas was hydrogen at a maximum pressure of 20 MPa and temperature of 720°C.

Engine power was controlled by varying the working-gas pressure (Schiel, 1999). The Advanco/Vanguard system, with a net conversion efficiency (including ancillary systems) of more than 30%, still holds the world's conversion record.

McDonnell Douglas later developed another somewhat improved dish system making use of the same technology and the same engine. The dish was 10.5 m and 25 kW. The 88 m<sup>2</sup> parabolic dish consisted of 82 spherically curved glass facets. Six of these units were produced and installed at sites around the United States for testing in operation. Southern California Edison continued to evaluate the system later. Reported performances and efficiencies were similar to those of Advanco/Vanguard (Lopez and Stone, 1992). The project was frozen for several years until in 1996, SES acquired the intellectual and technology rights to the concentrator and the U.S. manufacturing rights to what is now called the Kockums, 4-95 Stirling engine-based PCU (Mancini et al., 2003). Under a DOE-industry cost-sharing project to commercialize the dish–Stirling system for emerging markets, SES started testing and improvement of several units in different locations in the United States and South Africa. More than 100,000 h of operation accumulated for all the systems have been reported (Stone et al., 2001; Mancini et al., 2003). Daily efficiency has been found to be 24%–27% and the annual average 24%, and what is even more important, they have claimed availabilities of 94% at irradiances of just over 300 W/m<sup>2</sup>. The redesigned 25 kW<sub>e</sub> system named SunCatcher has been qualified in a commercial basis at the Maricopa Solar Plant in Arizona. The plant totalized 1.5 MW with 60 dishes and started operation in January 2010. This plant did not achieve the expected performance obtained at previous prototypes testing, and it was dismantled in 2012 after 1 year of operation.

Since the pioneering Vanguard dish records, with the exception of SES, most of the design options have been directed at the development of lowering costs by such strategies as less demanding temperatures, thereby penalizing efficiency, and introducing lighter and less expensive reflectors made of polymers or thin glass glued onto resin-based structures. These dishes, which have a lower optical performance, were first used in non-Stirling applications, with lower operating temperatures, such as the Shenandoah (Solar Kinetics) and Solar Plant 1 in Warner Springs (LaJet) (Grasse et al., 1991). Typical concentrations were in the range of 600–1000, and working temperatures were in the range of 650°C. Several prototypes were developed by Acurex, LaJet, GE, SKI, and SBP. These developments were followed up in the United States by SAIC (Mayette et al., 2001) and WGA (Diver et al., 2001) under the DOE-industry R&D program, Dish Engine Critical Components (Mancini et al., 2003).

The most extensive testing of this light material concept has been done with the stretched-membrane concentrator developed in Germany by Schlaich, Bergermann und Partner (SBP). More than 50,000 h of testing have been accumulated in the six-prototype field, promoted by SBP and Steinmüller, and evaluated at the PSA in Spain (Schiel et al., 1994). The concentrator is a single 7.5 m–diameter facet made of a single 0.23 mm thick preformed stainless-steel stretched membrane. Thin-glass mirrors are bonded to the stainless-steel membrane. The membrane is pre-stretched beyond its elastic limit using a combination of the weight of water on the front and vacuum on the back, to form a nearly ideal paraboloid. Then, a slight active vacuum within the membrane drum preserves the optical shape. The V-160 engine, originally produced by Stirling Power Systems, is at present manufactured by the German company Solo Kleinmotoren (Figure 42.63). The engine sweeps 160 cm<sup>3</sup> of helium with two pistons. The engine has an efficiency of 30% and reported overall conversion efficiency of 20.3% (Figure 42.64). The figure demonstrates the high dispatchability of dish–Stirling systems at part loads.

**FIGURE 42.64**

Input/output parameters and performance measured for a 9 kW SBP stretched membrane dish–Stirling system tested in Almería, Spain.

Though stretched membranes had excellent optical results, the economics revealed production costs higher than expected. The successor of the SBP membrane dishes is the EuroDish system. The EuroDish project is a joint venture undertaken by the European Community, German/Spanish Industry (SBP, MERO, Klein + Stekl, Inabensa), and research institutions DLR and CIEMAT. The new design replaces the stretched-membrane concentrator with a glass-fiber composite shell onto which glass mirrors are bonded with an adhesive. The engine used in the EuroDish is the next-generation SOLO Kleinmotoren 161. Two new 10 kW EuroDish units, shown in Figure 42.62, were installed at the Plataforma Solar de Almería, Spain, early in 2001 for testing and demonstration. In a follow-up project called EnviroDish, additional units were deployed in France, India, Italy, and Spain to accumulate operating experience at different sites. The peak solar-to-net-electric energy conversion efficiency of the system is expected to be 21%–22%, based on the experience of former projects with the same engine. The peak system efficiency was first measured at 20%. The estimated annual production of a EuroDish system operating in Albuquerque, New Mexico, is 20,252 kWh of electricity with 90% availability and an annual efficiency of 15.7% (Mancini et al., 2003). SBP and the associated EuroDish industry have performed cost estimates for a yearly production rate of 500 units/year (5 MW/year) and 5000 units/year, which corresponds to 50 MW/year. The actual cost of the 10 kW unit without transportation and installation cost and excluding foundations is approximately U.S. \$10,000 per kW. The cost projections at production rates of 500 and 5000 units/year are U.S. \$2500 per kW and U.S. \$1500 per kW, respectively.

## 42.8 Conclusions and Outlook

From the 1970s to the 1990s, the development of solar thermal electricity technologies remained restricted to a few countries, and only a few, though important, research institutions and industries were involved. The situation has dramatically changed since 2006 with the approval of specific feed-in-tariffs or power purchase agreements in Spain and

the United States. Both countries, with more than 3 GW of projects by the end 2013, are leading the commercialization of STP. Other countries such as India, China, South Africa, Chile, Australia, Morocco, Algeria, and Saudi Arabia adopted the STP technology in their portfolios. Subsequently, a number and variety of engineering and construction companies, consultants, technologists, and developers committed to STP are rapidly growing and moving to global markets. A clear indicator of the globalization of STE commercial deployment for the future energy scenario has been elaborated by the International Energy Agency (IEA). This considers STP to play a significant role among the necessary mix of energy technologies for halving global energy-related CO<sub>2</sub> emissions by 2050 (IEA, 2010b). This scenario would require capacity addition of about 14 GW/year (55 new STP plants of 250 MW each). However, this new opportunity is introducing an important stress to the developers of STP. In a period of less than 5 years, in different parts of the world, these developers of STP are forced to move from strategies oriented to early commercialization markets based upon special tariffs, to strategies oriented to a massive production of components and the development of large amounts of projects with less profitable tariffs. This situation is speeding up the implementation of second-generation technologies, like DSG or molten-salt systems, even though in some cases, still some innovations are under assessment in early commercialization plants or demonstration projects.

Parabolic trough is the technology widely used nowadays in commercial projects, though other technologies like LF reflectors and CRSs are developing the first grid-connected projects and reveal promising impacts on cost reduction (Romero and Gonzalez-Aguilar, 2011). The projected evolution of levelized electricity costs (LECs) of different CSP technologies is depicted in Figure 42.65. LEC reduction is expected from mass production, scaling-up, and R&D. A technology roadmap promoted by the European Industry Association ESTELA (Kearney and ESTELA, 2010) states that by 2015, when most of the improvements currently under development are expected to be implemented in new plants, energy production boosts greater than 10% and cost decreases up to 20% are expected to be achieved. Furthermore, economies of scale resulting from plant size increase will also contribute

**FIGURE 42.65**

Evolution of levelized electricity cost for STP technologies based upon technology roadmaps and industry.

to reduce plants' CAPEX per MW installed up to 30%. STP deployment in locations with very high solar radiation further contributes to the achievement of cost competitiveness of this technology by reducing costs of electricity up to 25%. All these factors can lead to electricity generation cost savings up to 30% by 2015 and up to 50% by 2025, reaching competitive levels with conventional sources (e.g., coal/gas with stabilized electricity costs <€10 cents/kWh). Similar projections are published in another recent roadmap issued by the IEA (2010) and IRENA (2012).

The first generation of commercial SPT projects adopted technologies and concepts that have matured in the last 30 years. They were based on conservative designs and schemes that do not necessarily exploit the enormous potential of concentrated solar energy. Figure 42.66 illustrates the situation. Current technologies are based on solar receivers

**FIGURE 42.66**

Evolution of STP. Current technologies are based on solar receivers that operate with thermal oil or water–steam at working temperatures usually below 500°C, coupled to steam-based Rankine cycles. Next generation of technologies allows surpassing 1000°C and enable higher efficiencies via Brayton and combined cycles, as well as the thermochemical production of solar fuels.

operating at moderate solar concentration ratios with thermal oil or water–steam at working temperatures usually below 500°C, which are coupled to steam-based Rankine cycles. As a consequence, solar-to-electricity conversion efficiencies are below 20%, the application of energy storage is limited, the water consumption and land use are relatively high, the power block integration is rather inefficient, and the thermochemical routes to produce solar fuels are beyond reach. Next generations of STP plants should allow surpassing 1000°C and enable higher efficiencies via Brayton and combined cycles as well as better integration of thermal storage (Romero and Steinfeld, 2012). Novel receiver concepts based on volumetric absorption of directly irradiated porous structures and particles, with alternative thermal fluids (e.g., air), operate at higher solar concentration ratios and promise more efficient solar energy capture and conversions. Moreover, these advance concepts open the door to the thermochemical production of solar fuels. The solar concentrating technologies better adapted for these high-temperature applications are solar towers (CRS), whose current development mainly for power generation is paving the ground for future high-flux/high-temperature thermochemical applications.

Challenges and key general topics for the medium- to long-term R&D are improved designs of materials and components, increased system efficiency through higher operating temperatures, high reliability during unattended operation, hybrid solar/fossil fuel plants with small solar share, and solar share increase through integration of storage. R&D is multidisciplinary, involving optics, materials science, thermal engineering, and control and measurement techniques. Specifically, for PTC and LF systems, R&D is aimed at lighter and lower-cost structural designs including front surface mirrors with high solar-weighted reflectivity of about 95%; high-absorptance (>96%) coatings for tube receivers able to operate at above 500°C; medium-temperature thermal energy storage systems based on PCMs, molten salts, concrete, and packed bed of rocks suitable for solar-only systems; improvement in overall system O&M, including mirror cleaning, integral automation, and unattended control; system cost reductions and efficiency improvements by DSG; and alternative HTFs such as air. For CRS systems, R&D is aimed at improvements in the heliostat field as a result of superior optical properties, lower cost structures, and better control; development of water/superheated steam and advanced air-cooled volumetric receivers using wire mesh absorbers or ceramic monoliths and foams; advanced thermocline storage systems based on packed bed of ceramic materials (especially suitable for solar air receivers) and high-temperature thermochemical storage; and distributed control architectures, system integration, and hybridization in high-efficiency electricity production schemes. For DE, R&D is aimed at volumetric receivers coupled to Stirling and Brayton engines; improvements in mirrors and support structures; and improvements in system integration and control for fully automation, parasitic loads reduction, start-up optimization, and hybrid Stirling–Brayton operation.

### 43.1 Introduction

Wind power supplied about 2.6% of the world electricity demand in 2013 (up from 0.6% in 2005), and the size of that contribution is growing rapidly. Wind energy is the most rapidly expanding source of energy in the world today; over the past 10 years, the worldwide installed capacity of wind energy has grown at an average rate of nearly 25% per year, leading to an installed nameplate capacity at the end of 2012 of about 286,000 MW [1]. As of January 2013, China was the world leader in cumulative installed wind power capacity, with about 75,400 MW installed, followed by the United States with 60,200, Germany with 31,500, Spain with 22,500, India with 18,600, the United Kingdom with 9,100, Italy with 8,000, France with 7,600, Canada with 6,200, and Portugal with 4,400. This 60,000 MW of wind power capacity in the United States reflects a 5-year average annual growth rate of over 29%; it is sufficient to power approximately 15.2 million American households, providing 3.5% of the U.S. electricity consumption in 2012. Over 43% of U.S. electricity providers had wind in their generation mix in 2012, and 42% of new U.S. generating capacity added in 2012 was wind. On April 15, 2012, wind provided a peak of 56.7% of Xcel Energy's generated electricity in Colorado [2].

The cost to generate wind energy decreased dramatically from more than 30 cents (U.S.) per kilowatt-hour ( $\text{¢/kW h}$ ) in the early 1980s to under 4 $\text{¢/kW h}$  (at the best sites) in 2004. The cost has since increased somewhat, in spite of continuing technology improvements, as a result of worldwide increases in steel, concrete, and transportation costs that have led to increases in the prices of wind turbines. The large increases in the cost of natural gas and other fossil fuels prior to 2010 made wind-generated electricity a lower-cost option than natural gas for many utilities adding generating capacity, but recent drilling technology advances have led to significant increases in the U.S. natural gas supply and decreases in its cost. The long-term impacts of these technology advances on the price of natural gas and on how well wind can compete for new generating capacity remain to be seen.

There is considerable anecdotal evidence that the first wind machines may have been built over 2000 years ago, perhaps in China, but there is no firm evidence to support this conjecture. However, there is considerable written evidence that the windmill was in use in Persia by AD 900, perhaps as early as AD 640. [Figure 43.1](#) illustrates the main features of this type of mill. The center vertical shaft was attached to a millstone, and horizontal beams or arms were attached to the shaft above the millstone. Bundles of reeds attached vertically to the outer end of the arms acted as sails, turning the shaft when the wind blew. The surrounding structure was oriented so that the prevailing wind entered the open portion of the structure and pushed the sails downwind. The closed portion of the structure sheltered the sails from the wind on the upwind pass. The primary applications of these machines were to grind or mill grain and to pump water; they became generally known as *windmills*. The wind machines of today may look much different from those first machines, but the basic idea remains the same—use the power in the wind to generate useful energy. Modern wind machines, called *wind turbines*, tend to have a small number of airfoil-shaped blades, in contrast to the older windmills that usually had several flat or slightly curved blades (such as the American multiblade water pumper shown in [Figure 43.2](#)). The reasons for this difference in blade number will be examined a little later.

Although there are many different configurations of wind turbines, most of them can be classified as either horizontal-axis wind turbines (HAWTs), which have blades that rotate about a horizontal axis parallel to the wind, or vertical-axis wind turbines (VAWTs), which have blades that rotate about a vertical axis perpendicular to the wind.

**FIGURE 43.1**  
Illustration of ancient Persian wind mill.

**FIGURE 43.2**  
Typical American multiblade windmill. (Courtesy of Nolan Clark, U.S. Department of Agriculture.)

Figure 43.3 illustrates the main features of these configurations; they both contain the same major components, but the details of those components differ significantly.

According to Shepherd [3], the terms *horizontal* and *vertical* associated with these classifications are a potential source of confusion. Although they now refer to the driving shaft on which the rotor is mounted, in the past, the terms referred to the plane in which the rotor turned. Thus, the ubiquitous multibladed water-pumper type of windmill shown in Figure 43.2, now referred to as a *horizontal-axis machine*, had a rotor that turned in a vertical

**FIGURE 43.3**

Schematic of basic wind turbine configurations: (a) horizontal-axis wind turbine (HAWT) and (b) vertical-axis wind turbine (VAWT).

plane, so it was, at one point, known as a *vertical* mill. Likewise, the earliest windmills, such as the one illustrated in Figure 43.1, had rotors that turned in a horizontal plane and were known as *horizontal* windmills.

As shown in Figure 43.3, HAWTs and VAWTs have very different configurations. Each configuration has its own set of strengths and weaknesses. HAWTs usually have all of their drive train (the transmission, generator, and any shaft brake) equipment located in a nacelle or enclosure mounted on a tower as shown; their blades are subjected to cyclic stresses due to gravity as they rotate, and their rotors must be oriented (yawed) so the blades are properly aligned with respect to the wind. HAWTs may readily be placed on tall towers to access the stronger winds typically found at greater heights. The most common type of modern HAWT is the propeller-type machine, and these machines are generally classified according to the rotor orientation (upwind or downwind of the tower), blade attachment to the main shaft (rigid or hinged), maximum power control method in high winds (full or partial-span collective or individual blade pitch or blade stall), and the number of blades (generally two or three blades).

VAWTs, on the other hand, usually have most of their drive train on the ground, their blades do not experience cyclic gravitational stresses, and their rotors do not require orientation with respect to the wind. However, VAWT blades are subject to severe alternating aerodynamic loading due to rotation of the blades upwind and downwind during each revolution of the rotor, and VAWTs cannot readily be placed on tall towers to exploit the stronger winds at greater heights. The most common types of modern VAWTs are the Darrieus turbines, with curved, fixed-pitch blades, and the “H” or “box” turbines with straight fixed-pitch blades. Virtually all of these turbines rely on blade stall (loss of lift and increase in drag as the blade angle of attack increases at high wind speeds) for maximum power control in high winds. Although there are still a few manufacturers of VAWTs today, the overwhelming majority of wind turbine manufacturers devote their efforts to developing better (and usually larger) HAWTs.

While the fuel for wind turbines is free, the initial cost of a wind turbine is a very large contributor to the cost of energy (COE) for that turbine. In order to minimize that COE, wind turbine designs must be optimized for the particular site or wind environment in which they will operate. Trial and error methods were very commonly used to develop early, small turbines, but these methods become very expensive and time-consuming when used to design and/or optimize larger turbines. A large optimized wind turbine can be developed at a reasonable cost only if the designers can accurately predict the performance of conceptual machines and use modeling to investigate the effects of design alternatives. The following discussion describes the basic phenomena that enable a machine to convert wind to mechanical energy and then presents several of the models that have been developed to predict the aerodynamic, hydrodynamic, and structural dynamic performance of wind turbines.

### 43.2 Wind Turbine Aerodynamics

Items exposed to the wind are subjected to forces in both the drag direction (parallel to the air flow) and the lift direction (perpendicular to the air flow). The earliest wind machines, known as *windmills*, used the drag on the blades to produce power, but many windmill designs over the last few centuries did make limited use of lift to increase their performance. For predominantly drag machines, such as those illustrated in Figures 43.1 and 43.2, larger numbers of blades result in higher drag and, thus, produce more power; therefore, these machines tend to have many blades. The old Dutch windmills, such as the one shown in Figure 43.4, utilized lift as well as drag, and since lift devices must be widely separated to generate the maximum possible amount of power, those machines evolved with a relatively small number of blades. The high-lift, low-drag shapes that were developed for airplane wings and propellers in the early part of the twentieth century (commonly referred to as *airfoils*) were quickly incorporated into wind machines to produce the first modern wind machines, usually known as *wind turbines*. An example of a typical modern wind turbine is shown in Figure 43.5. Modern wind turbines use the lift generated by the blades to produce power, and since the blades must be widely separated to generate the maximum amount of lift, wind turbines have a small number of blades. The following paragraphs contrast the characteristics of the drag- and lift-type machines.

Figure 43.6 illustrates the flow field about a moving drag device. The drag results from the relative velocity between the wind and the device, and the power that is generated by the device (the product of the drag force and the translation or blade velocity) may be expressed as

$$P = Dlv = \left[ 0.5\rho(U - v)^2 \right] C_D clv \quad (43.1)$$

where

$P$  is the power extracted from the wind

$D$  is the drag force per unit length in the span direction (perpendicular to the page)

$l$  is the length of device in the span direction (perpendicular to the page)

$v$  is the translation (or blade) velocity

$\rho$  is the air density

$U$  is the steady free-stream wind velocity

$C_D$  is the drag coefficient ( $= (\text{Drag}) / ((1/2)\rho clU^2)$ ), a function of device geometry

$c$  is the device width (perpendicular to the wind, in the plane of the page)

**FIGURE 43.4**  
Example of Dutch windmill. (Courtesy of Richard A. Neiser, Jr.)

**FIGURE 43.5**  
G.E. 1.5 MW wind turbines near Lamar, Colorado.

**FIGURE 43.6**  
Schematic of translating drag device.

The translation (or blade) velocity of the device must always be less than the wind velocity, or no drag is generated and no power is produced. The power extraction efficiency of the device may be expressed as the ratio of the power extracted by the device to the power available in the wind passing through the area occupied by the device (the projected area of the device), a ratio known as the *power coefficient*,  $C_p$ . From Equation 37.17, the available power is

$$P_A = \frac{1}{2} \rho U^3 A = \frac{1}{2} \rho U^3 cl \quad (43.2)$$

where  $A (=cl)$  is the area of the device projected perpendicular to the wind.

For a drag machine,  $C_p$ , using Equations 43.1 and 43.2, is

$$C_p = \frac{P}{(1/2)\rho U^3 cl} = \frac{v}{U} \left[ 1 - \frac{v}{U} \right]^2 C_D \quad (43.3)$$

Now consider a device that utilizes lift to extract power from the wind, that is, an airfoil. Figure 43.7 depicts an airfoil that is moving at some angle relative to the wind and is

**FIGURE 43.7**  
Schematic of translating lift device.

subject to both lift and drag forces. The relative wind across the airfoil is the vector sum of the wind velocity,  $U$ , and the blade velocity,  $v$ . The angle between the direction of the relative wind and the airfoil chord (the straight line from the leading edge to the trailing edge of the airfoil) is termed the angle of attack,  $\alpha$ . The power extracted by this device may be expressed as

$$P = \frac{1}{2} \rho U^3 c l \left[ C_L - C_D \frac{v}{U} \right] \sqrt{1 + \left( \frac{v}{U} \right)^2} \quad (43.4)$$

where

$c$  is the chord length

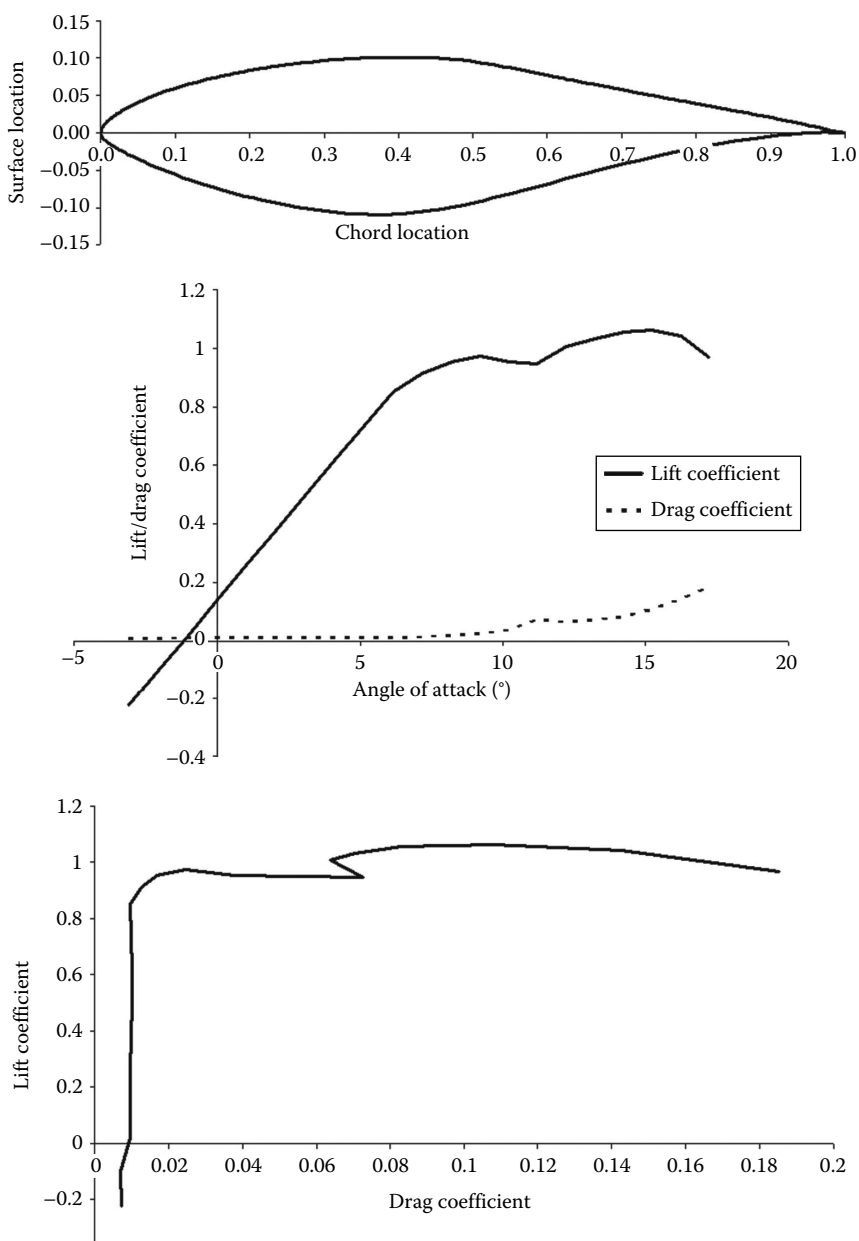

$C_L$  is the lift coefficient ( $= \text{Lift} / ((1/2) \rho c l U^2)$ , a function of airfoil shape and  $\alpha$ )

The other quantities are as defined for Equation 43.1, but  $C_D$  is now a function of airfoil shape and  $\alpha$ . Lift and drag coefficients for some common airfoils may be found in Refs. [4–9]. In this case, the projected area of the device is  $cl$ , and the power coefficient, using Equations 43.3 and 43.4, is

$$C_P = \frac{v}{U} \left[ C_L - C_D \frac{v}{U} \right] \sqrt{1 + \left( \frac{v}{U} \right)^2} \quad (43.5)$$

Keep in mind that Equations 43.3 and 43.5 express the performance coefficients of these devices in terms of the *projected area* of the individual device. Figure 43.8 presents experimental lift and drag coefficient values for the S-809 airfoil, an airfoil designed by the National Renewable Energy Laboratory (NREL) for use on small HAWTs [10]. As the angle of attack increases beyond approximately  $9^\circ$ , the lift levels off and then drops slightly, and the drag begins to rise fairly rapidly. This is due to separation of the flow from the upper surface of the airfoil, a flow condition referred to as *stall*. Figure 43.9 compares Equations 43.3 and 43.5 using  $C_L = 1.0$  and  $C_D = 0.10$  for the airfoil (conservative values for modern airfoils, as seen from Figure 43.8), and a drag coefficient of 2.0 (the maximum possible) for the drag device. The airfoil has a maximum power coefficient of about 15, compared with 0.3 for the drag device; that is, it extracts 50 times more power per unit of device surface area. Of course, the airfoil must be translated across the wind to produce power, but this is easily achieved with rotating machines such as wind turbines.

As mentioned earlier, lift-type machines tend to have only a few blades, while drag-type machines tend to have many blades. Thus, the difference in the turbine performance coefficient (now based on the rotor frontal area rather than the blade or bucket frontal area) of actual wind machines is much less than that might be expected from the analysis presented earlier—a well-designed lift-type machine may achieve a peak power coefficient (based on the area covered by the rotating turbine blades) of 0.5–0.59, while a pure drag-type machine will achieve a peak power coefficient of no more than 0.2. Some of the multibladed drag-type windmills actually utilize a blade shape that creates some lift, and they may achieve power coefficients of 0.3 or a little higher. The drag machines rotate slowly (the blade translation velocity cannot exceed the effective wind speed) and produce high torque, while the lift machines rotate quickly (to achieve a high translation velocity) and produce low torque. The slow rotating, high-torque drag machines are very well suited for

**FIGURE 43.8**  
Profile and performance characteristics of the S-809 airfoil.

mechanical power applications such as milling grain and pumping water. On the other hand, extensive experience has shown that fast-rotating, lift-type machines are much easier to adapt to electrical generators and can produce electricity at a significantly lower COE than can the drag-type machines.

Because of their superior performance in electrical generation applications, only lift-type machines will be considered in the remainder of this discussion.

**FIGURE 43.9**

Comparison of power coefficients for drag-type and lift-type devices.

### 43.2.1 Aerodynamic Models

The aerodynamic analysis of a wind turbine has two primary objectives: (1) to predict the aerodynamic performance or power production of the turbine, and (2) to predict the detailed time-varying distribution of aerodynamic loads acting on the turbine rotor blades. In general, the same models are used to accomplish both objectives. Accurate prediction of turbine aerodynamic performance does not guarantee accurate prediction of the loading distribution—the performance predictions result from the integration of time-averaged aerodynamic lift and drag over the entire turbine, and significant errors may be present in the detailed lift and drag predictions but balance out in the performance predictions. While there is a considerable body of data showing good agreement of predicted performance with measured performance, especially for codes that have been tailored to give good results for the particular configuration of interest, there are very few data available against which to compare detailed load-distribution predictions.

The aerodynamics of wind turbines are far too complex to model with simple formulas that can be solved with handheld calculators; computer-based models ranging from very simplistic to very complex are required. Several commonly used aerodynamic models are described in the following paragraphs.

#### 43.2.1.1 Momentum Models

The simplest aerodynamic model of an HAWT is the actuator disk or momentum model in which the turbine rotor is modeled as a single porous disk. This analysis was originally adapted for wind turbine use by Betz [11] from the propeller theory developed by Froude [12] and Lanchester [13]. To develop the equations for this model, the axial force acting on the rotor is equated to the time rate of change of the momentum of the air stream passing through the rotor. The mass of air that passes through the rotor disk is assumed to remain

**FIGURE 43.10**

Schematic of stream-tube for horizontal-axis wind turbines.

separate from the surrounding air and only the air passing through the disk slows down. That mass of air with a boundary surface of circular cross section, extended upstream and downstream of the rotor disk, is shown in Figure 43.10. No air flows across the lateral boundary of this *stream-tube*, so the mass flow rate of air at any position along the stream-tube will be the same. Because the air is incompressible, the decrease in the velocity of the air passing through the disk must be accompanied by an increase in the cross-sectional area of the stream-tube to maintain the same mass flow. The presence of the turbine causes the air approaching from the upstream to gradually slow down; thus, the velocity of the air arriving at the rotor disk is already lower than the free-stream wind speed. As mentioned earlier, this causes the stream-tube to expand. In addition, the static pressure of the air rises to compensate for the decrease in kinetic energy.

As the air passes through the rotor disk, there is a drop in static pressure; the air immediately downstream of the disk is below the atmospheric pressure level, but there is no instantaneous change in velocity. As the air continues downstream, the static pressure gradually increases until it again comes into equilibrium with the surrounding atmosphere, and the velocity drops accordingly. This region of the flow is referred to as the *wake*. Thus, the difference in flow conditions between the far upstream and the far wake is a decrease in kinetic energy, but no change in static pressure.

Utilizing conservation of mass, conservation of axial momentum, the Bernoulli equation, and the first law of thermodynamics, and assuming isothermal flow, the power produced by the turbine (the product of the axial force and the air velocity at the rotor) may be readily derived. From the conservation of axial momentum, the thrust on the rotor,  $T$ , may be expressed as

$$T = \dot{m}(U - v_w) = \rho A v (U - v_w) \quad (43.6)$$

where

$\dot{m}$  is the mass flow rate of air ( $=\rho A v$ )

$v$  is the wind velocity at the rotor disk

$v_w$  is the wind velocity far downstream of the rotor disk (in the wake)

$U$  is the wind velocity far upstream of the disk

$A$  is the area of the rotor disk

The thrust may also be expressed in terms of the pressure drop caused by the rotor

$$T = A(p_u - p_d) \quad (43.7)$$

where

$p_u$  is the pressure just upwind of the rotor disk

$p_d$  is the pressure just downwind of the rotor disk

The Bernoulli equation, applied just upwind of the rotor and just downwind of the rotor, yields

$$p_\infty + \frac{1}{2}\rho U^2 = p_u + \frac{1}{2}\rho v_u^2 \quad (43.8)$$

$$p_d + \frac{1}{2}\rho v_d^2 = p_w + \frac{1}{2}\rho v_w^2 \quad (43.9)$$

where the subscripts  $\infty$ ,  $u$ ,  $d$ , and  $w$  denote far upwind of the rotor, immediately upwind of the rotor, immediately downwind of the rotor, and far downwind of the rotor, respectively.

The pressures are equal far upwind of the rotor and far downwind of the rotor ( $p_\infty = p_w$ ), and the velocity is the same just upwind and just downwind of the rotor ( $v_u = v_d$ ). Substituting Equations 43.8 and 43.9 into Equation 43.7 yields

$$T = A \left[ \left( \frac{1}{2}\rho U^2 - \frac{1}{2}\rho v_u^2 \right) - \left( \frac{1}{2}\rho v_d^2 - \frac{1}{2}\rho v_w^2 \right) \right] = \frac{1}{2}\rho A (U^2 - v_w^2) \quad (43.10)$$

Equating 43.6 and 43.10 then yields

$$v = \frac{1}{2}(U + v_w) \quad (43.11)$$

That is, the velocity at the rotor disk is equal to the mean of the free-stream and wake velocities; thus, the velocity change between the free-stream and the wake is twice the change between the free-stream and the disk.

The power produced at the rotor, assuming isothermal flow and ambient pressure in the wake, is the product of the thrust and the velocity at the rotor:

$$\begin{aligned} P = Tv &= \frac{1}{2}\rho A (U^2 - v_w^2) v = \frac{1}{2}\rho A (U - v_w)(U + v_w)v \\ &= \frac{1}{2}\rho A [2(U - v)]2vv = 2\rho A (U - v)v^2 \end{aligned} \quad (43.12)$$

Now, define

$$a = \frac{(U - v)}{U} \quad (43.13)$$

which is commonly known as the *axial interference factor*. Using this in Equation 43.12 and rearranging yields

$$P = 2\rho A(aU)(1-a)^2U^2 = 2\rho AU^3a(1-a)^2 \quad (43.14)$$

The power coefficient for the turbine, then, is (utilizing Equations 43.2 and 43.14)

$$C_P = \frac{P}{P_A} = \frac{2\rho AU^3a(1-a)^2}{(1/2)\rho AU^3} = 4a(1-a)^2 \quad (43.15)$$

This is maximized for  $a = 1/3$ , yielding  $C_{P,\max} = 16/27 = 0.593$  as the maximum possible performance coefficient for a lift-type machine, a maximum often referred to as the *Betz limit*. Expressed in slightly different terms, this equation shows that a lift-type HAWT turbine can extract no more than 59.3% of the energy available in the wind passing through the rotor!

The typical performance of various types of wind machines is compared to the Betz limit in Figure 43.11, where the variations of the turbine power coefficients with the *tip-speed ratio* (the ratio of the speed of the blade tip to the free-stream wind speed) are presented. Even though the maximum performance of modern HAWTs and VAWTs is well above that of the older, drag-type machines such as the Dutch windmill and the American multiblade windmill, it is still somewhat below the Betz limit. Some HAWTs have demonstrated peak performance coefficients approaching 52%.

**FIGURE 43.11**

Typical performance of various types of wind turbines.

For HAWTs, the momentum model can be expanded to the widely used blade element momentum (BEM or BEMT) model in which the blades are divided into small radial elements, and local flow conditions at each element are used to determine blade forces and loads on those elements. To obtain accurate predictions, these models typically incorporate numerous modifications to account for blade and turbine wake effects, the three-dimensional flow near blade tips, the thick blade sections near the root, blade stall at high wind speeds, and unsteady effects associated with blade stall. Additional information on these models may be found in Hansen and Butterfield [14], Wilson [15], and Snel [16].

A very similar derivation yields a momentum model for the VAWT. This model may be expanded into the multiple stream-tube (the turbine rotor is modeled as multiple actuator disks, rather than just one) and the double-multiple stream-tube models (multiple actuator disks, with separate ones modeling the upwind and downwind passes of the rotor blades) that are the VAWT equivalent of the HAWT blade element model. Additional information on these models may be found in Touryan et al. [17], Wilson [15], and Paraschivoiu [18]. A recent paper by Simão Ferreira and Scheurich [19] shows that, although these models may predict turbine power production fairly accurately, they are not accurate when it comes to prediction of blade loads; more physically realistic models such as vortex codes or CFD codes must be used to accurately predict VAWT blade loads.

Momentum-based models are extremely popular with wind turbine designers because they are simple, fast, and fairly accurate for performance prediction, especially after they are tuned for a particular configuration. However, they are approximate because they are based upon the assumptions of flow conditions that are fixed in time and space, while the flow conditions around a wind turbine are constantly changing. These models cannot predict the effects of yawed flow, unsteady aerodynamics, and other complex flows that are present on wind turbines, all of which can have large impacts on turbine performance and loads. In some cases, specialized codes based on experimental results are used to approximate some of these effects, but these codes are limited to specific turbine sizes and geometries. In other cases, more realistic models such as vortex-based models, full computational fluid dynamics (CFD) models, and hybrid models are used to estimate these effects.

#### 43.2.1.2 Vortex Models

Vortex models are usually more properly referred to as lifting line or lifting surface models, depending on whether a lifting line or a lifting surface formulation is used to model the blades. In the lifting line method, each rotor blade is modeled as a series of segmented *bound line vortices* located at the blade 1/4-chord line, as illustrated in Figure 43.12a. Line vortex strengths, defined by the blade lift at each radial location, are associated with the vortex line segments. The lifting surface method represents the blade in more detail, as a distribution of vortex line segments over the blade surface, as illustrated in Figure 43.12b. Either of these models will generate both trailing vorticity (perpendicular to the span of the blade) due to the differences in vortex strength along the blade span and shed vorticity (parallel to the span of the blade) due to time-dependent changes in vortex strength that are shed into the wake as the turbine rotates. These vortex methods lend themselves to the modeling of unsteady problems, as the shed vorticity models the time-dependent changes in the blade bound vortex strength. Solutions are achieved by impulsively starting the turbine in a uniform flow field and allowing the computational flow field to develop until it reaches a steady-state or periodic condition.

The manner in which the transport of the vorticity in the turbine wake is modeled depends on whether a free-wake or a fixed (or prescribed) wake model is used. In the

**FIGURE 43.12**

Schematic of lifting line and lifting surface models of turbine blades: (a) lifting line model and (b) lifting surface model (Note: Each of the surface panels [15 shown here] is represented by a vortex system such as the three sketched here).

free-wake model, the vorticity is allowed to convect, stretch, and rotate as it is transported through the wake. However, the movement of each line vortex is influenced by the presence of all of the other line vortices, including those on the blade. As the computation progresses in time, the number of vortices that must be followed and the time required to calculate the vortex interactions both grow very quickly. In order to minimize the need for large computer resources, the fixed or prescribed wake models have been developed. In these models, the geometry of the wake is modeled as either fixed or described by only a few parameters, and the vortex interactions in the wake are no longer directly calculated. The result is a much faster execution time, but the accuracy of the predicted power generation and blade loads depends very heavily upon the fidelity with which the specified wake approximates the actual physical wake. The three-dimensional, lifting-surface, free-wake formulation is the most physically realistic of the vortex models, but a computer program implementing such a model will require a large amount of computer resources and time. Experience has shown that the dramatic increase in computer resources required by such a model does not yield significantly more accurate predictions than what can be obtained with a three-dimensional, lifting-line, fixed-wake model. A major problem with vortex codes is finding a good balance between model simplification (and the associated limitations on fidelity), computation time, and desired accuracy. The improved physical fidelity of the vortex models relative to the momentum models results in more accurate solutions, assuming the turbine is represented in adequate detail and the solution time increment is sufficiently short. While vortex models have not been widely used in the wind industry in the past, they are seen to be gaining popularity today, as the continuing increases in

computer speed make their use in optimizing simulation studies quite feasible. While they model the turbine and flow field with less accuracy than CFD models and thus, can be expected to yield less accurate results, they require far, far less computer resources while incorporating much greater fidelity than is present in momentum models. Additional information on vortex models for both HAWTs and VAWTs may be found in Kocurek [20], Snel [16], and Strickland et al. [21]. Murray and Barone [22] describe the development of a current-generation vortex model program that is capable of analyzing both HAWTs and VAWTs, including those with unconventional geometries.

#### **43.2.1.3 Limitations Common to the Momentum and Vortex Models**

Both the momentum-based and the vortex models normally utilize airfoil performance characteristic tables (lift and drag coefficients as functions of angle of attack, such as are shown in [Figure 43.8](#)) and air velocity to determine the blade lift and drag. These performance tables are generated from static two-dimensional wind tunnel test results or from static two-dimensional airfoil design code predictions. The table contents are modified with empirical, semiempirical, or analytic methods and used to estimate blade loads under the three-dimensional, dynamic conditions actually experienced by the turbine blades. The greatest difficulty in obtaining accurate load distribution predictions with either the momentum models or the vortex models is the challenge of accurately determining the appropriate airfoil performance characteristics.

#### **43.2.1.4 Computational Fluid Dynamics Models**

CFD, in a broad sense, is the solution of the partial differential equations describing the flow field by approximating these equations with algebraic expressions (discretizing them) and then solving those expressions numerically with the aid of a computer. Within the wind energy community, the term CFD normally refers to the numerical solution of the unsteady Reynolds-averaged Navier–Stokes (RaNS) equations [23,24], often restricted to four partial differential equations (one conservation of mass equation and conservation of momentum equations in three orthogonal directions) that describe general ideal-gas, incompressible, nonreacting, fluid flow.

One might argue that the most detailed and physically realistic method of predicting the performance of and loads on a wind turbine is to utilize CFD to model the airflow around the turbine and through the rotor, calculating the airfoil lift and drag directly. The flow field in the vicinity of the wind turbine is approximated as a computational grid of variable density, and the discretized Navier–Stokes equations are applied to each element of that grid. The computational grid close to the turbine blades must be very, very dense in order to capture the details of the airflow around the blades; it becomes less dense as the distance from the blades becomes greater, and the effect of the blades on the airflow decreases. The resulting set of simultaneous equations must be solved, frequently in a time-marching manner, to determine the time-dependent nature of the entire flow field.

Duque et al. [25] describe a 2002 CFD investigation of a wind turbine in which they utilized a complex grid with 11.5 million points to model the flow around a 10 m diameter HAWT rotor and tower combination. A steady-flow solution (rotor facing directly into the wind) for that model at a single wind speed, utilizing eight PC processors, each operating at 1.4 GHz in a parallel processor computer configuration, required approximately 26 h. An unsteady-flow solution (rotor yawed at an angle to the wind) with the same computing resources required over 48 h for each rotor revolution. Obviously, these

computations can be performed much more quickly with the computing resources available today. Sørensen et al. [26], Johansen et al. [27], and Chow and van Dam [28,29] report other CFD modeling efforts.

At this point, CFD is suitable for research use or final design verification only—it is still too slow and requires far too many computer resources to be considered for use as a routine design tool. CFD also suffers from some shortcomings that limit its accuracy in performance and loads calculations. First, it does not consistently yield highly accurate results for airfoil lift and drag, because it cannot adequately model the transition of flow over the airfoil surface from laminar, well-ordered, basically two-dimensional flow to inherently three-dimensional and unsteady turbulent flow that is accompanied by rapid fluctuations in both velocity and pressure (most wind turbines today utilize airfoils that will experience such a transition in the flow). Second, most CFD models today cannot adequately predict the effects of separated flow, especially three-dimensional separated flow, such as will occur near the hub of the wind turbine rotor under most operating conditions. In spite of these limitations, CFD models, when run by an expert who devotes a lot of effort to validate the results, can yield very useful information, as illustrated by the work reported in Chow and van Dam [28,29]. Efforts to improve the accuracy of CFD codes continue.

#### **43.2.1.5 Hybrid Models**

The hybrid model approach is an attempt to get the increased accuracy that CFD models are capable of without the heavy computing resources. It typically models the air-flow in the immediate vicinity of the airfoil and close to the turbine with the discretized Navier–Stokes equations, similar to the procedure used by the CFD models. However, to model the mostly undisturbed flow away from the turbine, the model uses nonviscous or potential flow equations that are much less complex and that can be solved much faster than the Navier–Stokes equations. The two solutions must be merged at the boundary between the two regions. The result is a code with the accuracy of the CFD model, but one that requires an order of magnitude less computing resources to solve. Xu and Sankar [30] and Schmitz and Chattot [31] describe two such codes. Even these hybrid models require a large amount of computer resources and are too slow and expensive to be utilized for parametric optimization studies; they are apt to be reserved for research work or detailed analysis of a proposed turbine design.

#### **43.2.1.6 Model Results**

None of these aerodynamic models is capable of accurately predicting the performance of and detailed loads on an arbitrary wind turbine operating at a variety of wind speeds. In order to have high confidence in the code predictions for a turbine design, the code must be calibrated against the measured performance and loads obtained from turbines of similar size and shape. Simms et al. [32] report on the ability of 19 codes based on the earlier models to predict the distributed loads on and performance of an upwind HAWT with a 32.8 ft (10 m) diameter rotor that was tested in the NASA/Ames 80 ft by 120 ft (24.4 m by 36.6 m) wind tunnel in 2000. Although the rotor was small compared to the 262 ft (80 m) diameter and larger commercial turbines that are being built today, a panel of experts from around the world concluded that it was large enough to yield results representative of what would be observed on the larger turbines. The comparisons of the code predictions and the experimental results were, in general, poor—turbine power predictions ranged from 30% to 275% of measured, and blade-bending moment predictions ranged from 85%

to 150% of measured for what is considered to be the most easy-to-predict conditions of no yaw, steady state, and low wind speed. Many aerodynamic code developers have spent considerable effort over the years since that comparison attempting to identify the sources of the discrepancies and improving the accuracy of their various codes.

In 2006, the Energy Research Center of the Netherlands led a second wind tunnel test of a heavily instrumented 15 ft (4.5 m) diameter wind turbine in the Germany/Dutch Wind tunnel organization 31 ft × 31 ft (9.5 m × 9.5 m) open-jet wind tunnel. This effort, known as the Model Experiments in Controlled Conditions or MEXICO experimental campaign, was funded by the European Union Framework Programme 5. An extensive literature list dealing with the experiment and related analyses is available on the MEXICO experiment website at [www.mexnext.org/resultsstatus](http://www.mexnext.org/resultsstatus). Calculations from several models have been compared to the MEXICO results, with generally good qualitative agreement between calculations and measurements down to the flow detail level, even in yawed conditions. However, none of the calculations have been able to accurately predict both the velocities and the loads; they all overpredict the velocities and/or overpredict the loads. While one explanation for the anomalies could be tunnel effects rather than model inaccuracies, that has not been supported by CFD calculations such as that performed by Réthoré et al. [33].

Additional information and references on wind turbine aerodynamics models may be found in Manwell et al. [34] and Burton et al. [35] for HAWTs and in Touryan et al. [17], Wilson [15], and Murray and Barone [22] for VAWTs.

Most wind turbine companies today continue to use the very fast momentum-based models for design optimization purposes, in spite of the approximations and inaccuracies that are inherent in these models. The analysts doing the studies tweak these models to get good comparison with measurements from an existing turbine and then use them to predict performance and loads for new turbines that are fairly close in size and geometry to the existing turbine. If the new turbine is significantly different in size and shape from the reference turbine, the performance predictions are considered to be subject to considerable error. Performance tests on a prototype of the new turbine are required to further refine the actual performance and loads. There does appear to be a trend toward adapting a vortex-based code to replace the momentum-based codes in these applications, and that should reduce the amount of error inherent in the predictions. Performance tests on prototypes of new turbines will still be required with these codes, however, to refine the actual performance and loads.

---

### 43.3 Offshore Wind

All of the wind power development in the United States to date is land-based, most of it in the West and Midwest, where the wind offers a good resource and there are large areas of land available on which to place wind farms. However, this resource is far from the major metropolitan centers near the coastline, and building the transmission line capacity that is necessary to carry the power to those centers is very, very expensive. The offshore wind resource, on the other hand, is very large, and much of it is relatively close to major coastal metropolitan areas (see [Figure 37.8](#)), making the possibility of offshore wind attractive, in spite of the additional costs involved. In Europe, where very little land is available for siting turbines, large amounts (over 6 GW) of offshore wind have been installed at shallow-water sites (water depth of less than 30 m), fixed to the seafloor (the turbines are mounted on piles driven into the seafloor or on concrete gravity bases) in the past decade.

### 43.3.1 Offshore Platform Hydrodynamics

When turbines are located offshore, regardless of the depth of the water, the turbine supporting platform is subjected not only to the wind-generated loads transmitted through the turbine to its base, as is the case for the land-based turbine, but also to water-generated (or hydrodynamic) loads. In addition, the mounting platform now experiences a much larger range of motion than would the gravity foundation of a typical land-based turbine. Thus, the analysis of the wind turbine becomes much more complex—the platform must be modeled as a moving body, subjected to the hydrodynamic loads, that is coupled to the flexible wind turbine structure at the base. At shallow water sites of less than about 30 m water depth, the turbine can economically be mounted on a monopile driven into the seabed or on a conventional concrete gravity foundation (both referred to as fixed-bottom support platforms). For these turbines, the analysis of the hydrodynamic loads acting on the platform can be approximated by applying a number of simplifying assumptions. However, at greater water depth, fixed-bottom support platforms are no longer economically feasible. For water depths between 30 and 60 m, space-frame substructures, including tripods, quadpods, or lattice frames, will be required to maintain the strength and stiffness requirements at the lowest possible cost. At depths of 60 m and greater, economics drive the selection of a floating support platform moored to the sea bottom [36]. The offshore oil and gas industry has demonstrated the long-term survivability of offshore floating structures, so the technical feasibility is not in question, but high-fidelity modeling and accurate analysis are required to enable the development of economical floating platforms.

These more complex structures and hydrodynamic loading in the deeper waters can no longer be adequately modeled with the simplifying assumptions that are typically used for the shallow-water fixed-bottom platforms. Many frequency- and time-domain analyses have investigated wind turbines mounted in water depths in excess of 30 m, but they all contain approximations and limitations. Jonkman provides a very comprehensive review of the analyses that have been done and the approximations and limitations inherent in them [36]. Rather than attempting to summarize the development of the very complex hydrodynamics modeling here, I refer you to Jonkman [36] for a detailed explanation of his development of models that accurately represent the hydrodynamic and mooring forces acting on the floating platform. He has incorporated these models into the NREL-supported HydroDyn code; that code, used in conjunction with the publically available and NREL-supported FAST code for wind turbine modeling and analysis, is capable of analyzing the transient response of a wide variety of offshore wind turbine/support platform/mooring system configurations in waters of moderate to great depth.

---

### 43.4 Wind Turbine Loading

Wind turbines are typically fatigue-driven structures; they normally fail not as the result of a single application of a large-amplitude load, but as a result of the repeated application and removal (or cycling) of small-amplitude loads. Each load cycle causes microscopic damage to the structure, and the accumulated effect of many, many cycles of varying amplitude eventually leads to failure of the structure, a process referred to as fatigue failure. In general, the smaller the amplitude of the load, the larger the number of load cycles

the structure can withstand before failing. Therefore, it is very important that the loads acting on a wind turbine be well understood; if the loads are larger than expected, fatigue failure may occur much earlier than anticipated. If the loads are smaller than expected, the turbine will more expensive than necessary for the desired lifetime.

The wind is random or stochastic in nature, with significant short-term variations or turbulence in both direction and velocity. Wind turbine aerodynamic loads may be regarded as falling into one of two broad categories—the deterministic loads occurring in narrow frequency bands resulting from the mean steady atmospheric wind, wind shear, rotor rotation, and other deterministic effects, and the random loads occurring over all frequencies resulting from the wind turbulence. Prior to about 1995, the deterministic loads were frequently predicted with an aerodynamics code, such as those described earlier, utilizing a uniform wind input, while the random loads were estimated with empirical relations. However, turbine designers now recognize that this approach may lead to serious under-prediction of both the maximum and random blade loads, resulting in costly short-term component failures. Most analysts today utilize an aerodynamics performance code with a wind model that includes a good representation of the turbulence of the wind in all three dimensions to predict long-term wind turbine loads. The appropriate method of determining the wind-induced extreme events and random loads that limit the lifetime of a turbine remains the subject of ongoing research.

In contrast, designers of offshore turbines can look to the offshore oil and gas industry for guidance on hydrodynamic loading analysis, and Jonkman [36] and others have developed quite comprehensive hydrodynamic load simulation capabilities.

Any lack of knowledge about loads that the turbine/mounting platform will encounter is typically compensated for in the design process by incorporation of large safety margins, leading to excess material and cost.

Civil engineers have spent decades developing statistical methods for predicting wind and wave loads on offshore drilling platforms, to help reduce the cost and increase the reliability of those platforms. The wind turbine industry is now starting to apply that technology to predict the wind and wave loads on wind turbines.

---

## **43.5 Wind Turbine Structural Dynamic Considerations**

Input loads resulting from wind and, in the case of offshore turbines, waves, together with dynamic interactions of the turbine components with each other, result in forces, moments, and motions in wind turbines, phenomena referred to as structural dynamics. By applying various analysis methods, the impact of changes in turbine configurations, controls, and subsystems on the behavior of the turbine can be predicted. General wind turbine structural dynamic concerns and methods of analysis are discussed in the following paragraphs.

### **43.5.1 Horizontal-Axis Wind Turbine Structural Dynamics**

Small horizontal-axis turbine designs usually use fairly rigid, high-aspect-ratio (the blade length is much greater than the blade chord) blades, cantilevered from a rigid hub and main shaft. As turbine size increases, the flexibility of the components tends to increase, even if the relative scales remain the same, so the blades on larger turbines tend to be

quite flexible, and the hub and main shaft tend to be far less rigid than corresponding components on the small turbines. The entire drive train assembly is mounted on and yaws about a tower that may also be flexible. These structures have many natural vibration modes, and some of them may be excited by the wind or the blade rotation frequency to cause a *resonance* condition, amplifying vibrations and causing large stresses in one or more components. Operating at a resonance condition can quickly lead to component failure and result in the destruction of the turbine. Careful structural analysis during the turbine design may not guarantee that the turbine will not experience a resonance condition, as analysis techniques are not infallible, but ignoring the analysis altogether or failing to properly conduct parts of it may dramatically increase the probability that the turbine will experience one or more resonance conditions, leading to early failure. While the relatively rigid small turbines are not likely to experience these resonance problems, the very flexible, highly dynamic larger turbines may well experience resonance problems unless they are very carefully designed and controlled. Turbines that operate over a range of rotational speeds (variable-speed turbines) are especially challenging to design. The designer will usually try to minimize the number of resonances that occur within the operational speed range and then implement a controller that will avoid operating at those resonance conditions. The actual resonances typically depend on the rotor speed, and the severity of the resonance depends on the wind speed, so the controller logic can become quite complicated.

It is possible to develop techniques in the frequency domain to analyze many aspects of the turbine dynamics. The frequency-domain calculations are fast, but they can be applied only to linear, time-invariant systems and therefore cannot deal with some important aspects of wind turbine operations such as aerodynamic stall, start-up and shut-down operations, variable-speed operation, and nonlinear control system dynamics. In spite of these limitations, frequency-domain solutions of modal formulations are frequently used in the preliminary design of a wind turbine, when quick analyses of many configurations are required.

The large relative motion between the rotor and the tower frequently precludes the use of standard commercial finite-element analysis codes and requires the use of a model constructed specifically for the analysis of wind turbines. Development of such a model can be a rather daunting task, as it requires the formulation and the solution of the full nonlinear governing equations of motion. The model must incorporate the yaw motion of the nacelle, the pitch control of the blades, any motion and control associated with hinged blades, the time-dependent interaction between the rotor and the supporting tower, etc. If the full equations of motion are developed with either finite-element or multibody dynamics formulations, the resultant models contain moderate numbers of elements and potential motions (degrees of freedom or DOF), and significant computer resources are required to solve the problem. On the other hand, a modal formulation utilizing limited DOF may be able to yield an accurate representation of the wind turbine, resulting in models that do not require large computing resources. The development of the modal equations of motion may require somewhat more effort than does the development of the finite-element or multibody equations, and the equations are apt to be more complex. The modal degrees of freedom must include, at a minimum, blade bending in two directions, blade motion relative to the main shaft, drive train torsion, tower bending in two directions, and nacelle yaw. Blade torsion (twisting about the long axis) is not normally included in current modal models, but it may become more important as the turbine sizes continue to increase and the blades become more flexible. The accuracy of some modal formulations is limited by their inability to model the direction-specific nonlinear variation of airfoil lift with an

angle of attack that occurs as a result of aerodynamic stall. However, this is not an inherent limitation of the technique, and some modal formulations are free of this limitation. These modal formulations (NREL's wind-turbine-specific FAST [36] is an example of such a code) are extremely fast running and are arguably the most widely used HAWT structural analysis tools today.

The most accurate structural dynamics models utilize general, commercially available finite-element codes such as ABAQUS [37] or multibody dynamics codes such as ADAMS [38] or wind-turbine-specific multibody dynamics codes such as HAWC2 [39] and BLADED [40]. These require significantly more computer resources than do modal formulation codes, but they can still be run fairly quickly on a PC. FAST, the NREL wind-turbine-specific version of ADAMS, HAWC2, and BLADED have been verified through measurements and comparisons with other codes, and they include all of the modules required to simulate both land-based and offshore wind turbines, including both aerodynamic and hydrodynamic loading.

All of these structural dynamics codes use separate aerodynamics codes, most based on BEM models, to furnish the aerodynamic loads that act on the turbine blades.

Regardless of the methods used in preliminary design, the state of the art in wind turbine structural analysis today is to use highly detailed multibody or finite-element-based, time-accurate structural codes, coupled with blade loadings derived from BEM-based aerodynamics models and support platform loadings derived from hydrodynamic models (for offshore configurations) to analyze the turbine behavior for the detailed final design calculations.

Malcolm and Wright [41] and Molenaar and Dijkstra [42] provide reviews of some of the available land-based HAWT dynamics codes that have been developed, together with their limitations. Buhl et al. [43] compare some of the land-based HAWT dynamics codes that have been extensively verified and that are widely used today, and Quarton [44] provides a good history of the development of land-based HAWT wind turbine analysis codes. More general finite-element dynamics codes are described in [45,46], and additional information on both land-based and offshore HAWT dynamics models can be found in Manwell et al. [34] and Burton et al. [35].

### **43.5.2 Vertical-Axis Wind Turbine Structural Dynamics**

Darrieus turbine designs normally use relatively slender, high-aspect-ratio structural elements for the blades and supporting tower. As with large HAWTs, the result is a very flexible, highly dynamic structure, with many natural modes of vibration that again must be carefully analyzed to ensure that the turbine will avoid structural resonance conditions under all operating environments. The guy cables and turbine support structure can typically be analyzed with commercial or conventional finite-element codes, but the tower and blades require a more refined analysis, usually requiring the use of a finite-element code possessing options for analyzing rotating systems. With such a code, the blades and tower of a VAWT are modeled in a rotating coordinate frame, resulting in time-independent interaction coefficients. The equations of motion must incorporate the effects of the steady centrifugal and gravitational forces, the aerodynamic loading due to the turbulent wind, the hydrodynamic loading due to the water waves and current for offshore configurations), and the forces arising from rotating coordinate system effects. Detailed information on finite-element modeling of land-based VAWTs may be found in Lobitz and Sullivan [47], and information on more general finite-element modeling that includes offshore VAWTs may be found in Owens et al. [48].

### 43.6 Peak Power Limitation

All turbines incorporate some method of regulating or limiting the peak power produced. The entire turbine, including the rotor, the transmission, and the generator, must be sized to handle the loads associated with peak power production. While high winds (above, say, 25 m/s) contain large amounts of available power, they do not occur very often, and the energy that can be captured is very small. This is illustrated in Figure 43.13 for the Amarillo, TX, airport. In this figure, the power density is the power per unit of rotor area (normalized to yield a value under the curve of unity) that is available for capture by a wind turbine. This takes into account the amount of time that the wind actually blows at each wind speed (the probability density that is also shown on the figure). Amarillo does occasionally experience very high winds, but as seen from this probability density, that does not happen very often, and the energy that could be captured from winds above 24 m/s is negligible.

Generators and transmissions operate most efficiently at their design conditions, typically close to their maximum capacity. These efficiencies drop off quickly at conditions below design. Cost trade-off studies reveal that it is far more cost effective to limit the maximum power level to that achieved at wind speeds of, say, 13–14 m/s and to shut the turbine down completely at a cutout wind speed of, say, 26 m/s, as illustrated in Figure 43.14, than to try to capture the maximum amount of power at the higher wind speeds. Limiting the peak power limits the peak loads that the entire drive train, the tower structure, and the blades must withstand, so the turbine can be built with far less material (and at lower cost) than that required for a turbine that generates peak power at a wind speed of 25 m/s. Under these conditions, the transmission and generator are operating near design conditions a good part of the time, so they are operating at close to their maximum efficiency. The additional energy captured due to the increase in generator and transmission efficiencies at the lower wind speeds is usually many times greater than that lost due to limiting

**FIGURE 43.13**

Wind speed and wind power probability densities for Amarillo, TX, airport.

**FIGURE 43.14**

Sample power curves for stall-regulated and pitch-regulated wind turbines.

the peak power at the rather infrequent winds above 14 m/s (refer to the wind speed distribution in Figure 43.13).

Most small horizontal-axis turbines incorporate passive features, such as tail vanes and furling, that turn the rotor so the rotor axis is no longer aligned with the wind in order to limit peak power production in high winds. Older turbines and some small turbines are designed with fixed-pitch blades and rely on airfoil stall at high winds to limit the maximum power output of the machine. However, nearly all modern large horizontal-axis turbines now use blade pitch control, where either the entire blade or a portion of it is rotated about the blade longitudinal axis to change the effective angle of attack, and thus the power output, of the blade to limit peak power. The blade may be rotated so as to decrease the effective angle of attack as the wind speed increases (commonly referred to as *pitch to feather*), causing decreased blade lift and limiting the peak power to the desired level, or it may be rotated to increase the effective angle of attack (commonly referred to as *pitch to stall*), causing blade stall and limiting peak power. Either pitch to feather or pitch to stall results in better average peak power control than can be achieved with fixed-pitch stall control.

Although pitch-to-feather control results in decreased drag loads at high winds, a major disadvantage is poor peak-power control during high-wind stochastic conditions—sudden increases in wind speed will result in corresponding increases in angle of attack, loads, and power generation. Power excursions can exceed twice the rated power levels before the high-inertia blade pitch system can compensate for gust-induced wind speed increases. Blade stall control (either fixed pitch or pitch to stall), on the other hand, results in better peak power control at high winds. Major disadvantages of stall control include increased blade drag loads as the wind speed increases (even after stall) and possible large dynamic loads due to wind turbulence.

Most VAWTs utilize stall regulation with fixed-pitch blades to control peak power, but some straight-bladed VAWTs are equipped with full-span passive or active pitch controls.

Pitch control can be either passive or active. The pitch control may be included in each blade mounted on a very simple hub, it may be incorporated into a sophisticated hub with

blades that are nothing special, or it may be distributed between the hub and the blades. Therefore, discussions about turbine pitch control normally refer to the combination of hub and blades—the rotor.

- Passive pitch-control techniques automatically adjust the blade pitch angle by using hub-mounted cams activated by centrifugal loads or by using tailored blade materials that permit the blade to twist toward feather or stall under high loads. These devices are very carefully tailored to maintain peak performance at lower wind speeds but limit the peak power and blade loads at high wind speed. A major disadvantage of these techniques is that they cannot readily be adapted to site-specific conditions—a hardware change is required to make any changes to the control.
- Active-pitch control rotors are equipped with one or more motors (typically mounted on the hub) to change the blade pitch angle on command from the turbine controller. These rotors are much more expensive than fixed-pitch stall control blades, but they open the possibility for much refined control of the turbine, potentially leading to reductions in loads for the entire drive train. Changes to the control can usually be implemented by simply changing the controller software program.

Sample power curves for fixed-pitch stall regulated and active pitch (pitch to feather) 500 kW turbines are shown in [Figure 43.14](#).

---

## 43.7 Turbine Subsystems

The wind turbine incorporates many subsystems, in addition to the actual turbine, in order to generate power. The electrical power generation, yaw, and control systems are the only ones that will be discussed here.

### 43.7.1 Electrical Power Generation Subsystem

Once a wind turbine has converted the kinetic energy in the wind into rotational mechanical energy, that rotational energy is usually converted by a generator into electricity that can be readily transported to where it is needed. In many configurations, the generator input shaft speed is much higher than the turbine shaft speed, requiring the use of a speed-up transmission (or *gearbox*) that increases the turbine shaft speed to that required by the generator. Other configurations utilize *direct-drive* (DD) generators to eliminate this need for a gearbox with the generator input shaft directly connected to the turbine drive shaft.

In the past, most grid-connected turbines have utilized either synchronous or induction generators. Synchronous generators are more complex and tend to be more expensive than induction generators, but they provide excellent voltage and frequency control of the generated power and can deliver reactive power to the grid. However, these generators are not intrinsically self-starting (the turbine blades are usually pitched to start the turbine, which drives the generator), do not provide power-train damping, and require sophisticated controls for connecting to the grid, as the output frequency (and thus,

the speed of the generator) must be precisely matched to the grid frequency before the connection is made.

Induction generators, in contrast, have a simple, rugged construction; they may readily be used as motors to spin a turbine up to speed; they are cheaper than synchronous generators; they may be connected to and disconnected from the grid relatively easily, and they provide some power-train damping to smooth out the cyclic torque variations inherent in the wind turbine output. However, they require reactive power from either power electronics or the grid, and they can contribute to frequency and voltage instabilities in the grid to which they are connected. These adverse effects can usually be solved fairly quickly and at low cost with modern power electronics. Induction generators are, therefore, the most common type found on wind turbines.

Synchronous *permanent magnet* (PM) generators replace the separate excitation, slip rings, and rotor windings (with associated losses) of a typical synchronous machine with powerful PMs, leading to a simple, rugged construction. Virtually all PM generators utilize *rare-earth* (RE) materials for the PMs due to the very high flux density that can be achieved with these materials. The power produced by PM generators is usually variable-voltage and variable-frequency AC that must be converted to DC or to fixed-voltage and fixed-frequency AC with power electronics before it can be fed into the grid. Even with this requirement for additional power electronics, these machines tend to achieve higher efficiency at low power ratings (92.9% at 25% load versus 94.4% at full load) than either induction or synchronous generators, leading to increased energy capture. The cost of these generators has historically been somewhat higher than that of induction or synchronous generators, due primarily to the high cost of the RE material, but technology advances have resulted in price decreases, making the technology quite competitive with the older technologies. As a result, PM generators are becoming very common. Fuchs et al. [49] describe the development of a PM generator for wind turbine use.

While the earlier discussion covers the generator technologies most commonly used on wind turbines in the past, many other types of technologies are used today. Discussion of those generator technologies may be found in Manwell et al. [34] and Burton et al. [35].

Direct-drive generators are normally synchronous machines (with either conventional or permanent magnet excitation) of special design, built with a sufficient number of poles to permit the generator rotor to rotate at the same speed as the wind turbine rotor. This eliminates the need for a gearbox or transmission. Benefits of a direct-drive generator include a drive train with far fewer parts, leading to potentially higher reliability and lower maintenance, and a lower system tower-top weight. The primary drawback to a direct-drive generator is the very high torque that it must handle; the power produced by the rotor is proportional to torque multiplied by rpm, so the torque that is applied to the generator goes up as the generator operating rpm decreases. A typical 1.5 MW turbine rotor rpm might be 15 rpm, with a conventional generator rpm of 1800 rpm. Replacing this generator with a direct-drive generator would drop the generator rpm to 15 rpm, requiring a direct-drive generator torque rating of  $1800/15 = 120$  times that of the conventional generator. Direct-drive generators are usually used in conjunction with power electronic converters to decouple the generator from the network and provide flexibility in the voltage and frequency requirements of the generator.

Direct-drive PM generators require very strong magnetic fields (and corresponding large amounts of RE materials), due to the very high torque levels at which the generators must operate. In large amounts, RE components are still quite expensive, as China is currently the primary source, and they are severely limiting export. Thus, direct-drive

PM generators tend to be more expensive than more conventional direct-drive generators. Moderate-speed PM generators (lower rotational speed than traditional synchronous or induction generators, but higher rotational speed than direct-drive generators) operate at much reduced torque levels and thus require much less RE. This configuration still requires the use of a gearbox, but it can be a fairly simple single-stage design due to the moderate speed step-up requirements.

The direct-drive generator technology advantage in reduced drive train weight increases with size, but as the power rating approaches the 8–10 MW range, current technology results in generators that rapidly grow larger and heavier, due to the high torque requirements. This, in turn, requires a heavier tower structure to carry the extra weight and torque. These large generators also present design challenges. As with PM generators, an alternative then becomes a relatively light, single-stage gearbox with a much smaller, lighter generator that still offers many of the direct-drive advantages.

Most older turbines (built prior to about 2000) operated at a single fixed rotational speed, but many newer turbines, and especially the large ones, are variable speed, operating within a fixed range of rotational speeds. Variable-speed turbine operation offers several major advantages over fixed-speed operation:

1. The aerodynamic efficiency of the rotor at low to moderate wind speeds may be improved by lowering the rotational speed to keep the turbine operating close to the optimum tip-speed ratio, maximizing the power coefficient. At higher wind speeds, the turbine rotates at maximum rotational speed, and the blades are either in stall or are pitched to limit peak power. The rotor speed may also be adjusted to fine-tune peak power regulation.
2. System dynamic loads may be attenuated by the inertia of the rotor as it speeds up and slows down in response to wind gusts.
3. The turbine may be operated in a variety of modes, including operation at maximum efficiency to maximize energy capture at lower wind speeds and operation to minimize fatigue damage.

As mentioned earlier, for variable-speed operation, certain rotational speeds within the operating-speed range will likely excite turbine vibration modes, causing structural resonance and increased rates of fatigue damage. These rotational speeds must be avoided during operation, leading to complex control schemes.

Variable-speed operation is possible with any type of generator, including direct-drive and PM generators. As is the case for fixed-speed, direct-drive and PM generators, variable-speed operation results in variable-frequency/variable-voltage AC power. Interfacing the turbine to the power grid requires the use of power electronics to convert this power to high-quality, constant-frequency/constant-voltage AC power. Several methods have been developed for accomplishing this with sophisticated power electronics (see, e.g., Smith [50]), but research to develop improved methods with higher efficiencies continues. Manwell et al. [34] and Burton et al. [35] give brief overviews of some common types of power converters and provide references for more extensive discussions of these devices.

For a conventional, non-PM generator, electrical efficiency tends to drop off rapidly as the generated power falls below the rated generator capacity, so single-generator wind turbines tend to be very inefficient at low wind speeds. Some turbine designs address this deficiency by incorporating multiple smaller generators; at low wind speed, only

one generator is attached to the drive train, with more being added as the wind speed increases. The net result is that each generator operates close to its rated power much of the time, increasing the overall generator efficiency. Similar increases in generator efficiency at low power levels can be obtained with a single generator utilizing pole switching or multiple windings. Other generator designs that overcome this loss in efficiency at lower power levels have been developed in recent years.

### **43.7.2 Yaw Subsystem**

The rotor of an HAWT must be oriented so that the rotor axis is parallel to the wind direction for peak power production. While small turbines usually rely on passive systems, such as tail vanes, to accomplish this, most large upwind HAWTs and a few downwind HAWTs incorporate active yaw control systems, using a wind direction sensor and a drive motor/gear system to orient the rotor with respect to the wind direction. Most downwind HAWTs are designed to utilize the wind itself to automatically orient the rotor. Active yaw systems tended to be extremely problematic in early turbines, basically because the loads acting on them were not well understood. Yaw loads are much better understood today, and these systems are no longer a major problem area.

As mentioned earlier, VAWTs do not require orientation with respect to the wind and thus do not require yaw systems.

### **43.7.3 Control Subsystem**

One or more control systems are needed to integrate the operation of the many components of a wind turbine and to safely generate power. In a very general sense, a wind turbine control system consists of a number of sensors, a number of actuators, and a system of hardware and software that processes the signals from the sensors to generate signals to control the actuators. A turbine usually contains a minimum of two distinct controllers—a safety controller that will override all other controllers to bring the turbine to a safe state (usually stopped, with the brakes applied) in case of an abnormal event, and an operational controller that handles the normal operation of the turbine. Any particular turbine may incorporate many additional secondary or slave controllers, each of which handles only a limited number of tasks. An example of a secondary/slave controller might be a blade pitch controller that pitches the blades to follow a predetermined schedule during start-up and shutdown of the turbine and that pitches the blades as necessary to regulate the power output of the turbine at the rated level in above-rated wind speeds.

#### **43.7.3.1 Safety Controller**

The safety controller acts as a backup to the operational controller and any secondary or slave controllers; it takes over if the other controllers fail to maintain the turbine in a safe operating mode. It is normally triggered by the activation of certain safety sensors (such as excessive vibration, excessive rotor speed, or excessive generator power) that are independent of the sensors connected to the operational and/or slave controllers, but it may also be activated by an operator-controlled emergency stop button. This system must be as independent from the normal operations control system as possible and must be designed to be fail-safe and highly reliable, since it may be the last line of defense to save a

turbine from self-destruction. The safety controller will normally consist of a hard-wired fail-safe circuit monitoring a number of sensors. If any of the sensors indicates a problem, the safety controller assumes full turbine control and ensures that the turbine is brought to a safe condition. This might include, for example, de-energizing all electrical systems, pitching the blades to the feather position, and engaging the spring-applied emergency brakes (that are held off in normal operation).

#### **43.7.3.2 Operational Controller**

The regular operational controller is usually computer or microprocessor based; a basic turbine operational controller will normally start and stop the machine; connect the generator to or disconnect the generator from the power grid, as needed; control the operation of the yaw and pitch systems (if present); perform diagnostics to monitor the operation of the machine; and perform normal or emergency shutdown of the turbine as required.

For older turbines, the operational controller was frequently a fairly generic device that was simply added to the turbine and then programmed with either hardware or software modifications to implement the control functions specific to that particular turbine. The operational controllers on newer turbines, especially the large, variable-speed/variable-pitch machines, incorporate much more intelligence than the old, generic type, and they are custom tailored (with software) to reflect the capabilities and characteristics of each specific turbine. Modern controllers (or, more accurately, the turbine control software programs) are usually designed from scratch as an integral component of the wind turbine and must be included in the models of system aerodynamics and structural dynamics to obtain accurate estimates of loads and motions. The controller dictates how the pitch, rotor speed, and generator torque systems are used to limit peak power and/or torque, control rotor speed, maximize energy capture, trade-off energy capture and load mitigation, reduce power fluctuations, control power quality, actively control some turbine dynamics, or perform many other functions. These controllers may consist of a single physical unit performing all of the assigned tasks, or they may consist of multiple physical units, each performing a small number of tasks, all coordinated by a supervisory controller.

#### **43.7.3.3 Turbine Power/Load Control Programming**

The operational control hardware mentioned in the last section must be programmed to perform the appropriate functions for the turbine. This section discusses some of the specific scenarios that may be implemented in the control system.

Figure 43.15 illustrates the three distinct operational regions of wind turbine operation, which are as follows:

1. Region 1 is where the wind speed is too low to overcome the drive train resistance of the turbine.
2. Region 2 is that region between the cut-in wind speed (where the turbine starts to generate power) and the rated wind speed (where the turbine reaches rated or maximum power).
3. Region 3 is between the rated wind speed and the shut-down wind speed (where the turbine is shut down to protect it).

**FIGURE 43.15**

Wind turbine operating regions and ideal turbine power curve.

The pitch and rotor rotational speed capabilities of a turbine determine how the turbine controller can increase energy capture and limit blade and generator loads in these regions. The ideal path of turbine power as a function wind speed, as shown on Figure 43.15, requires that the turbine be operated at maximum efficiency in region 2 and then limit the power production in region 3. This requires that the rotor rotational speed (commonly referred to as the rotor speed) be correlated to the wind speed throughout region 2 so that the turbine is always operating at its maximum efficiency (the turbine  $C_{p,max}$  curve), and the turbine must be able to dump excess power in order to limit the turbine power and wind-induced loads in region 3.

The early turbines were restricted to constant rotor speed and fixed blade pitch (referred to as constant speed/fixed pitch). These turbines are constrained to follow some suboptimal energy capture path through region 2 (the precise path depends on the preset blade pitch and the fixed rotor speed). They rely on blade stall to limit peak power and loads in region 3, but stall can lead to some very high power peaks and loads in this region in response to positive wind gusts. Large turbine design has evolved through the years to include variable rotor speed and variable blade pitch (referred to as variable-speed/variable-pitch) capabilities that enable modern turbine controllers to better approximate the ideal power path of Figure 43.15 and capture more energy. These capabilities enable the turbine (as directed by the control program) to very closely follow the optimal turbine performance path; within region 2, the turbine sets the optimum blade pitch angle and then operates at the rotor speed that optimizes turbine performance at each wind speed; within region 3, the turbine operates at maximum rotor speed and utilizes blade pitch to control peak power and wind-induced loads. The turbines may also utilize the variable rotor speed capability to smooth out power and load fluctuations due to wind gusts throughout regions 2 and 3.

The turbine controller determines the precise manner in which these capabilities are utilized. It is typically designed with two distinct operating algorithms for the two regions, with some kind of transition between the two that mitigates the very large drive train loads that can result from an abrupt switch between the variable-speed/fixed-pitch operation in region 2 and the fixed-speed/variable pitch operation in region 3. This transition usually results in a lowering of the actual power curve in the vicinity of change between the operating regions—some energy capture is sacrificed to mitigate drive train loading. A turbine is normally designed to spend a lot of time in this transition region in order to maximize energy capture, so even a small lowering of the power curve here can result in considerable energy capture loss over time. Given the reality that a 1% loss in energy capture for every turbine results in income loss of over \$2 million annually for 1 GW of

installed capacity, there is a tremendous amount of interest in optimizing control in this region to maximize power while minimizing loads.

Many other areas of control offer the opportunity to increase energy capture and/or mitigate loads. A few of those areas are mentioned in the following paragraphs.

Early variable-pitch turbines utilized collective blade pitch, where all the blades pitch the same amount at the same time, often driven by a single motor. As turbines became larger, this design changed to use an electric motor for each blade, enabling each blade to be pitched independently of the others. Research has shown that utilizing this capability has the potential to significantly decrease blade fatigue loads [51]. However, this control strategy leads to increased use of blade pitch motors; retrofitting it on existing turbines could lead to early pitch motor burnout. In addition, implementation of this capability without an update to the existing turbine controller software has sometimes been found to lead to a small loss in turbine energy capture. This technology remains the subject of active research.

The blades on large turbines are very large; some exceed 80 m in length. Pitching a blade of this size is slow, and this limits the amount of load mitigation that can be achieved with full-span pitch. One variation on active blade pitch is the use of only a portion of the airfoil surface (typically including the blade tip) as a control surface. Adjusting the pitch (and, thus, the lift and drag) of this portion of the blade independently of the remainder of the blade (so-called partial-span control) can be used to control the peak power output of the turbine. This control surface is usually much smaller than the full blade, so it can respond to wind changes and mitigate loads much faster than can the full-span blade. However, partial-span devices have proven to be very difficult to integrate into a blade, and the gaps between the devices and the surrounding blade tend to generate noise.

Some recent research work has investigated the use of very small load control devices that can generate large changes in lift and drag while experiencing small loads. The chord-wise dimensions of these devices are typically on the order of 1% of the blade chord; their small size means they can be activated very quickly to alleviate excess loads, and they are less likely to create large amounts of noise. Mayda et al. [52] discuss the use of CFD to investigate the effects of some of these devices. An excellent summary of work on this concept prior to 2009 may be found in a survey article written by Barlas and van Kuik [53], while Barlas et al. [54] and Berg et al. [55] provide information on two recent demonstration efforts.

Other areas of controls research include the following:

- Maximizing turbine and/or wind-farm-generated power while mitigating structural loads.
- Maximizing turbine and/or wind farm power quality.
- Preview control, where the wind is measured upwind of the turbine and load mitigation and/or enhanced energy capture actions can be initiated before the wind actually strikes the turbine.
- Maximum power point control, where the controller *learns* the exact method of operation that will yield the maximum possible power output (especially in region 2), rather than relying on a nominal maximum efficiency curve.

While traditional turbine controls seem to work fairly well for the fixed-bottom offshore turbines, the field of offshore floating wind turbine control is so new that very little is known about what will be needed.

## 43.8 Other Wind Energy Conversion Considerations

The actual turbine system is the single most important and most costly item of a wind energy conversion system, but there are many other aspects of the system that must be considered and carefully optimized before wind energy can be produced at a cost-competitive price. These aspects include things like turbine siting, installation and foundations; operating and maintenance costs; manufacturing processes; transport of components to the site; turbine payback period; wind energy COE and environmental concerns. Turbine siting has already been discussed in Chapter 37. This section will discuss only materials, installations, grid integration, wind forecasting, energy payback period, wind turbine costs and COE, and some environmental concerns. Additional information, including extensive reference lists, on all of these aspects can be found in Manwell et al. [34], Burton et al. [35], and Spera [56].

### 43.8.1 Wind Turbine Materials

As mentioned earlier, wind turbines are fatigue critical structures (their design is driven by consideration of the cyclic fatigue loads they must endure), and the number of fatigue cycles they experience in a 20–30-year design life is three orders of magnitude beyond the  $10^6$  cycles that has been the common limit of fatigue data for most materials. Most of the materials used in the construction of wind turbines are typical of those materials that are used in other rotating machinery and towers—relatively common structural materials such as metal, wood, concrete, and glass-fiber-reinforced plastic (GFRP) composites. Towers are typically made of steel; a few have been built of concrete. Drive trains, generators, transmissions, and yaw drives are made of steel. These components can readily be designed so they experience very low stresses and will have a fatigue life of 20–30 years. HAWT blades, however, must be built with a minimum of lightweight material to minimize the gravity-induced cyclic loads on the blades, drive train, and tower. Over the past 20 years or so, high-cycle fatigue databases for many potential blade materials have been developed specifically for wind turbine applications. Mandell and Samborsky [57] and Mandell et al. [58] describe the main U.S. high-cycle fatigue database; the latest database, together with new reports and recent publications and presentations regarding the database, may be found at [www.coe.montana.edu/composites/](http://www.coe.montana.edu/composites/). De Smet and Bach [59] and Kensche [60] describe the European counterpart, which has now been included in the OPTIMAT materials database maintained by the WMC Knowledge Centre of the Netherlands. The latest version of this database is available at [www.wmc.eu/optimatblades\\_optidat.php](http://www.wmc.eu/optimatblades_optidat.php), and a reference document describing the contents of the database is provided by Nijssen [61].

The material with the best all-around structural properties for wind turbine blades appears to be carbon-fiber/epoxy composite, but it is significantly more expensive than other potential materials. In light of that, the blade material of choice today (as it has been for the past couple of decades) is GFRP, due to the high strength and stiffness that can be obtained, the ease of tailoring blades made of GFRP to handle the loads, and the relatively low cost of GFRP [62]. However, the trend to larger and larger turbines, with the resultant increase in blade weight and flexibility, has created intense interest in utilizing some carbon fiber in the blades to decrease weight and add stiffness. The expense of carbon fiber, even in the cheapest form available today, means that turbine designers must incorporate it into blades in a cost-effective manner. According to Griffin [63] and Jackson et al. [64], one very efficient method of utilizing carbon fiber is to place it in the longitudinal spar

caps, near the maximum thickness area of the blade, where its lightweight and extra stiffness yield maximum benefits.

Obviously, the materials must be protected from the environment in some fashion. While paints and gel coats have been deemed adequate for most land-based installations in the past, long-term exposure to sunlight and high winds (and the dust and debris carried by those high winds) has resulted in considerable degradation of the GFRP blades, especially the leading edges, leading to considerable loss of turbine performance. Quantifying the performance loss due to this surface degradation is an active research area at the current time [65].

The offshore environment is much different and much more demanding than the onshore environment. Testing techniques must be developed to determine the suitability of materials proposed for use in offshore turbines. Miller et al. [66] describe the challenges they have encountered in developing techniques to evaluate the performance of composite materials in a seawater environment and present some initial results.

### 43.8.2 Wind Turbine Installations

Chapter 37 of this handbook discusses wind turbine siting considerations in some depth. Although individual turbines or small clusters of turbines may be used to provide power to small loads such as individual residences or businesses, the most common arrangement for producing large amounts of energy from the wind is to locate many wind turbines in close proximity to each other in a wind farm or wind park. Figure 43.16 is a photograph of several of the General Electric 1.5 MW turbines comprising the 204 MW New Mexico Wind Energy Center in eastern New Mexico (mentioned earlier in the case study in Chapter 37), while Figure 43.17 shows a few of the turbines in the huge offshore

**FIGURE 43.16**

Typical land-based wind farm installation—New Mexico Wind Energy Center in eastern New Mexico.

**FIGURE 43.17**

Offshore wind farm installation—London Array Wind Farm in Thames River Estuary, United Kingdom. (Courtesy of London Array Limited.)

London Array. Operating turbines in this manner leads to lower COE, as fixed construction costs, such as electrical grid interconnections and project development and management costs, and fixed maintenance costs, such as cranes, replacement parts, and repair facilities, can be spread over a larger investment. As of the date this is written (November 2013), the offshore London Array wind power project in the United Kingdom is the world's largest wind farm. The fleet of 175 wind turbines stationed in the salty waters of the outer Thames estuary, where the river Thames empties into the North Sea, boasts a nameplate capacity of 630 MW, enough to power nearly half a million U.K. homes.

### 43.8.3 Wind Power Integration into Grid Operations and the Need for Forecasting

The following discussion borrows heavily from two papers that have been recently published in the *IEEE Power & Energy Magazine* [67,68].

#### 43.8.3.1 Grid Integration

One common argument that wind energy critics raise is that grid systems are capable of accepting power only from *dispatchable* (capable of providing the operator-specified amount of power at any time) power systems; wind's inherent variability precludes its efficient integration into a grid system. Most conventional generators are, in reality, quite constrained in their ability to quickly change their output to a desired amount of power and must be operated with careful consideration of their start-up times, minimum run times, and ramp-rate limitations, and all conventional generators are subject to occasional failure—thus, even they cannot be considered to be truly dispatchable. Wind can usually adjust output very quickly within the range between zero and the power available from the wind, while many conventional units ramp slowly and within a more limited range. In fact, the components of the electric power system have always been uncertain and variable to some degree, but the addition of wind energy (or other variable sources of energy)

increases the need to directly manage these attributes in more sophisticated ways; the growth of wind energy is forcing the development of the next generation of tools and practices for continued efficient and reliable electric system operations.

At the current time, larger markets are, in general, more adept at handling higher wind penetration rates for several reasons:

- Larger markets are typically more geographically diverse, and this diversity of wind resources reduces the short-term fluctuations and forecast errors in the wind power.
- Larger markets typically use centralized wind power forecasts and sophisticated tools for scheduling power resources.
- Larger markets typically have made a larger effort to better understand the issues specific to a high penetration of variable resources and to find methods of alleviating those issues.

In general, analysis by system operators has shown the need for increased generation fleet flexibility (for all types of generation units), including flexibility from the wind plants.

Several grids in the United States, including New York Independent System Operator, Alberta Electric System Operator, Energy Reliability Council of Texas (ERCOT), Midcontinent Independent System Operator, California Independent System Operator, and the PJM regional transmission organization have successfully integrated extensive amounts of wind into their systems, and they are all preparing for significantly more in the near future [67]. Most of these grids have integrated wind into their security-constrained economic dispatch systems to allow the grid operator to treat wind the same as they treat other power plants, requiring them to furnish precise levels of output for the next few minutes and penalizing them if they fail to deliver. The keys to these successful integrations are the use of 5-minute (the de facto North American standard interval) rolling dispatch—rebalancing the calls for power from all resources every 5 minutes—and the demonstrated reliable persistence of wind over that time frame.

ERCOT, which efficiently dispatches wind and uses energy dispatch and non-spinning reserves (no spinning reserves) to compensate for wind uncertainty, has carried out detailed analysis of the costs of wind variability and uncertainty for the 9% of their energy supplied by wind in 2011. They have concluded that the costs of wind power variability and day-ahead forecast uncertainty together amount to only 1%–2% of the value of that wind-generated energy, with about one-third of that amount due to variability and two-thirds due to the day-ahead uncertainty attributable to imperfect wind power forecasts.

While this discussion has focused on integration of wind into North American grid systems, European grids have experienced similar success in integrating wind, utilizing a different approach for aggregating wind plant output and an hourly dispatch schedule.

#### **43.8.3.2 Wind Forecasting**

The success of these operators in integrating wind energy into their systems is not to say that there is no need to continue to advance the state of the art in wind power forecasting; additional improvements will help reduce those wind-related additional costs and will be of great value to system operators, wind plant owners, financial traders, and even traditional generators. However, better forecasts will likely be more valuable for smaller grid systems with less generating options and a lower frequency of dispatch than for the huge grid systems with very frequent dispatching discussed earlier.

Wind power predictions or forecasts utilize a combination of weather forecasting models and wind farm-specific models (to model the complexity and interactions of wind turbines with each other and with the localized terrain). Weather forecasts and wind power forecasts are far from perfect, but, as seen earlier, experience has shown that forecasts do not need to be perfect to be very useful and valuable; currently available forecasting models perform reasonably well for several days in the future and may be marginally adequate for large grid operators.

While a cheap and simple wind power forecast can be produced with no real-time data using a publicly available numeric weather prediction model to provide the wind speed and combining that with geographic location, wind power plant size, and a turbine power curve, having more data means getting better forecasts, up to a point. Basic data such as the geographic center of the wind power plant, turbine hub height, measures of the metered power output of the power plant, and historic output data will greatly improve the simple forecast mentioned earlier. On the other hand, forecasting systems that make use of great volumes of data are frequently cumbersome and complex; the cost-effectiveness of such approaches may well be lower than that of simpler methods. The continuing goal must be to improve both the accuracy of numerical weather prediction models (by improving our fundamental knowledge of the physics involved) and the quality, quantity, and timeliness of the environmental data required to define the initial state of the atmosphere, ocean, and land surface for those models.

Not all interested parties will derive the same benefits from these improved wind forecasts. For some grid operators (especially smaller ones, with limited generator options available), the ability to more precisely forecast rapid increases or decreases in available wind power (ramp forecasting) may be of great value as that will directly affect the ability of these operators to match energy demand and supply. On the other hand, increasing the precision of ramp forecasting might not be a major issue if the grid system has gas combustion turbines online that can readily adapt to rapid changes in wind contribution, but increasing the certainty associated with 1–5 day-ahead forecasts may enable that operator to confidently plan maintenance on conventional generators.

Significant advances in forecasting are being made, with high-quality wind power forecasts now available from a number of forecast providers and new research promising continued incremental improvements in the future. Cooperation between the public and private sectors is needed to maximize that rate of improvement. When these advances are combined with the appropriate operating practices and market rules that are now evolving, increasing amounts of wind energy will be economically and reliably integrated into our power system.

#### 43.8.4 Energy Payback Period

A certain amount of energy is used in the manufacture, installation, and eventual scrapping of any energy-producing machine. The time required for the machine to generate as much energy as was used in its manufacture, installation, and end-of-life scrapping is referred to as the *energy payback period*. Studies by Krohn [69] and Milborrow [70] have found that the energy payback period for modern wind turbines ranges between 3 and 10 months, depending on the wind speed at the site and the details of turbine manufacturing and installation. This payback period is among the shortest for any type of electricity producing technology.

#### 43.8.5 Wind Turbine Costs

By the mid- to late-1990s, the configuration for utility-scale wind turbines had evolved to the three-bladed upwind design. About this time, the University of Sunderland in the

United Kingdom developed a set of scaling tools for wind turbines, together with several models to predict the impact of machine size on turbine components. That work was further advanced by DOE-funded efforts starting in about 2000. In 2005, researchers at NREL's National Wind Technology Center began developing a spreadsheet model of these scaling relationships. The result is a set of models that can be used to project the total COE for a wind turbine over a range of sizes and configurations; they are not intended to predict turbine *pricing* [71]. These models allow projections of costs for both land-based and offshore technologies, though the offshore technologies are very early in their development, and forecast costs are very rough.

The model cost estimates are based on turbine rating, rotor diameter, hub height, and other key turbine descriptors. Cost scaling functions have been developed for major components and subsystems. Annual energy production is estimated based on the Weibull probability of wind speeds. The cost metric used is the levelized cost of energy (LCOE), given by

$$\text{LCOE} = \frac{(\text{ICC} \times \text{FCR}) + \text{AOE}}{(\text{AEP}_{\text{net}}/1000)}$$

where

ICC (initial capital cost) in \$/kW is the sum of the turbine system cost and the balance of station cost

FCR (fixed charge rate) in % is the annual amount per dollar of initial capital cost needed to cover the capital cost, a return on debt and equity, and various other fixed charges

AOE (annual operating expense) in \$/kW/year includes land lease cost, levelized operations and maintenance cost, and levelized replacement/overhaul cost

$\text{AEP}_{\text{net}}$  in MW h/MW/year is the net annual energy production

LCOE values are expected to be greater than actual wind energy prices because these calculations do not include the value of the production tax credit or any other renewable energy credit or subsidy.

NREL recently issued a report documenting their use of this model to develop their estimate for the cost of both land-based and offshore wind energy in the United States for 2011 [72]. In this report, their land-based turbine is a 1.5 MW machine with a hub height of 80 m at 50 m wind speed of 7.25 m/s (7.75 m/s at hub height). The turbine is assumed to be included in a 200 MW wind farm of 133 turbines. Their offshore or fixed-bottom turbine is a 3.6 MW machine with a hub height of 90 m at 50 m wind speed of 8.4 m/s (8.0 at hub height). This turbine is assumed to be included in a 500 MW wind farm of 139 turbines, mounted on monopile foundations in an average water depth of 15 m and situated 20 km from shore. Additional details on terminology, study assumptions, and calculations may be found in the NREL reports [71,72].

Results of the study for the land-based turbine are presented in Table 43.1, while the results for the offshore turbine are presented in Table 43.2; the LCOE for the land-based turbine is \$72/MW h, while for the offshore turbine, it is \$225/MW h. Again, keep in mind that these figures are not intended to reflect actual energy prices, but rather to reflect relative costs of these electricity-generating projects at this point in time.

The installed capital costs for the two configurations as given in Tables 43.1 and 43.2 are summarized in Figures 43.18 and 43.19. From these results, it is obvious that reductions in any single component of capital cost will not lead to dramatic changes in turbine COE.

**TABLE 43.1**

## Initial Capital Cost Breakdown for Land-Based Turbine

	1.5 MW (\$/kW)	1.5 MW (\$/MW h)
Rotor	292	9
Blades	178	5

**FIGURE 43.18**  
Initial capital cost breakdown for land-based wind turbine. (From Tegen, S. et al., 2011 Cost of wind energy review, NREL/TP-500-56266, National Renewable Energy Laboratory, Golden, CO, 2013.)

**FIGURE 43.19**

Initial capital cost breakdown for offshore wind turbine. (From Tegen, S. et al., 2011 Cost of wind energy review, NREL/TP-500-56266, National Renewable Energy Laboratory, Golden, CO, 2013.)

For example, the rotor contribution to the capital costs (and the total COE) of the land-based turbine is only 13%, so a 20% decrease in the rotor contribution only yields a 3% decrease in total COE; the drive train contribution to the total capital costs is 37%, so a 20% decrease there yields only a 7% decrease in total COE. On the other hand, any improvement in a component that leads to increased turbine energy production may lead to a significant decrease in COE. A 20% increase in rotor energy capture at no additional capital or O&M cost, for example, would lead directly to a 20% decrease in COE.

#### 43.8.6 Environmental Concerns

Although wind turbines generate electricity without causing any air pollution or creating any radioactive wastes, like all human-built structures, they do cause an impact on the environment. Wind turbines require a lot of land, but only about 5% of that land is used for turbine foundations, roads, electrical substations, and other wind farm application. The remaining 95% of the land is available for other uses such as farming or livestock grazing.

Wind turbines do generate noise as well as electricity, but with proper siting restrictions, noise should not be a problem with newer wind turbines. Current industry standards call for characterization of turbine noise production and rate of decay of that noise with distance as part of the turbine testing process, so noise information is readily available. Since noise decreases quickly with distance from the source, the noise level due to a typical large modern wind turbine 300 m distant is usually roughly comparable to the typical noise level in the reading room of a library. Placing wind turbines at appropriate distances from local homes has proven to be an effective means of suppressing perceived noise, in most cases. However, certain weather conditions in some locations can cause focusing of

turbine-generated noise, leading to propagation of that noise to much greater distances and resulting in great irritation for nearby residents.

The visual impact of wind turbines is extremely subjective. What one person considers highly objectionable, another might consider as attractive or at least not objectionable. The relatively slow rotation of today's large wind turbines is viewed by most people as far less intrusive than the fast rotation of the early small turbines. Visual impact can be minimized through careful design of a wind farm. The use of a single model of wind turbine in a wind farm and uniform spacing of the turbines help alleviate concerns in this area. Computer simulation can be very helpful in evaluating potential visual impacts before construction begins.

## For Further Information

Excellent summaries of HAWT and VAWT aerodynamic principles together with extensive reference lists, are presented by Hansen and Butterfield [14], and by Touryan et al. [17], respectively. Vol. 1(1) of *Wind Energy*, Wiley, 1998 contains a comprehensive set of review papers covering wind turbine rotor aerodynamics, design analysis, and overall system design, and excellent updates on the status of wind turbine aeroelasticity and aerodynamics and be found in articles in Vol. 6(3), 2003 of that journal.

The latest developments in the field of wind energy in the United States and Europe may be found in the following annual conference proceedings:

*Proceedings of WINDPOWER* American Wind Energy Association (AWEA), Washington, DC, [www.awea.org](http://www.awea.org).

*Proceedings of the European Wind Energy Association*, European Wind Energy Association, Brussels, Belgium, [www.ewea.org](http://www.ewea.org).

The books by Manwell et al. [34], Spera [56] and Burton et al. [35] contain a wealth of fairly current information on wind energy conversion, history, and technology, together with extensive reference lists.

Extensive information on wind energy conversion technology may also be found on the World-Wide Web. Excellent sites to start with include those of the U.S. National Renewable Energy Laboratory, Wind Energy Technology Center at [www.nrel.gov/nwtc/](http://www.nrel.gov/nwtc/), the Sandia National Laboratories, Wind Energy Technology Department at [http://energy.sandia.gov/?page\\_id=344](http://energy.sandia.gov/?page_id=344), the Danish Technical University, Department of Wind Energy at [www.vindenergi.dtu.dk](http://www.vindenergi.dtu.dk), the American Wind Energy Association at [www.awea.org](http://www.awea.org), the European Wind Energy Association at [www.ewea.org](http://www.ewea.org), and the Danish Wind Energy Association at [www.windpower.org/en](http://www.windpower.org/en).

**44.1 Introduction**

Photovoltaic (PV) conversion is the direct conversion of sunlight into electricity with no intervening heat engine. PV devices are solid state; therefore, they are rugged and simple in design and require very little maintenance. Perhaps the biggest advantage of solar PV devices is that they can be constructed as stand-alone systems to give outputs from micro-watts to megawatts. That is why they have been used as the power sources for calculators, watches, water pumping, remote buildings, communications, satellites and space vehicles, and even megawatt-scale power plants. PV panels can be made to form components of building skin, such as roof shingles and wall panels. With such a vast array of applications, the demand for PVs is increasing every year. With net metering and governmental incentives, such as feed-in laws and other policies, grid-connected applications such as building-integrated PV have become cost-effective even where grid electricity is cheaper.

**FIGURE 44.1**

Worldwide production of PV panels. (From EPIA, Global market outlook for photovoltaics, European Photovoltaic Industries Association, Brussels, Belgium, <http://www.epia.org>.)

As a result, the worldwide growth in PV production has averaged over 43% per year from 2000 to 2012 and 61% from 2007 to 2012 (see Figure 44.1). The cumulative installed global PV capacity grew to over 100 GW by the end of 2012.

In the early days of solar cells in the 1960s and 1970s, more energy was required to produce a cell than it could ever deliver during its lifetime. Since then, dramatic improvements have taken place in the efficiencies and manufacturing methods. The present energy payback periods have been reduced to 0.68 for thin-film CdTe cells to less than 2 years for crystalline silicon cells [1]. The costs of PV panels have come down from about \$30 to less than \$1 per peak watt over the last three decades.

With panel costs as low as \$0.55/W (large quantities) to \$2/W (retail), the system costs are in the range of about \$1.50/W for megawatt-range systems to about \$3–\$4/W for small systems, and the PV systems have finally become cost-effective for on-grid applications. The PV panel costs are reaching the limits of cost reduction; however, the costs of the balance of the system (BOS) have room for further reduction. The U.S. Department of Energy has a goal to reduce the BOS costs, which would bring the total costs of a PV system down to \$1/W and the cost of power to \$0.06/kWh [1b]. At present, module efficiencies are as high as 21%. The main constraint on the efficiency of a solar cell is related to the bandgap of the semiconductor material of a PV cell. As explained later in this chapter, a photon of light with energy equal to or greater than the bandgap of the material is able to free up one electron, when absorbed in the material. However, the photons that have energy less than the bandgap are not useful for this process. When absorbed on the cell, they just produce heat. And for the photons with more energy than the bandgap, the excess energy above the bandgap is not useful in generating electricity. The excess energy simply heats up the cell. These reasons account for a theoretical maximum limit on the efficiency of a conventional single junction PV cell to less than 30%. The actual efficiency is even lower because of the reflection of light from the cell surface, shading of the cell due to current collecting contacts, internal resistance of the cell, and recombination of electrons and holes before they are able to contribute to the current.

**FIGURE 44.2**

Energy conversion from a two-layered stacked PV cell. (From Goswami, D.Y. et al., *Principles of Solar Engineering*, 2nd edn., Taylor & Francis, Philadelphia, PA, 2000.)

The limits imposed on solar cells due to bandgap can be partially overcome by using multiple layers of solar cells stacked on top of each other, each layer with a bandgap higher than the layer below it. For example (Figure 44.2), if the top layer is made from a cell of material A (bandgap corresponding to  $\lambda_A$ ), solar radiation with wavelengths less than  $\lambda_A$  would be absorbed to give an output equal to the hatched area A.

The solar radiation with wavelength greater than  $\lambda_A$  would pass through A and be converted to give an output equal to the hatched area B. The total output and therefore the efficiency of this tandem cell would be higher than the output and the efficiency of each single cell individually. The efficiency of a multijunction cell can be about 50% higher than a corresponding single cell. The efficiency would increase with the number of layers. For this concept to work, each layer must be as thin as possible, which puts a very difficult if not an insurmountable constraint on crystalline and polycrystalline cells to be made multijunction. As a result, this concept is being investigated mainly for thin-film amorphous or microcrystalline solar cells. Efficiencies as high as 37.7% have been reported for multijunction cells in the literature [2]. For concentrated PV, efficiencies as high as 44% have been reported [2].

In this chapter, the physics of PV electrical generation will be briefly reviewed, followed by a discussion of the PV system design process. Several PV system examples will be presented, then a few of the latest developments in crystalline silicon PV will be summarized, and finally, some of the present challenges (2004–2005) facing the large-scale deployment of PV energy sources will be explored. Emphasis will be on nonconcentrating, crystalline or multicrystalline silicon, terrestrial PV systems, since such systems represent nearly 95% of systems currently being designed and built. However, the design procedures outlined at the end of the chapter also can be applied to other PV technologies, such as thin films. While multijunction III–V semiconductor concentrating PV cells have been fabricated with efficiencies that are double the efficiencies of silicon cells, the cost of these cells is so high that their use is only justified in extraterrestrial applications. As a result, the typical reader of this material will not become involved in the use of these technologies.

## 44.2 PV Cell

### 44.2.1 $p$ - $n$ Junction

PV cells have been made with silicon (Si), gallium arsenide (GaAs), copper indium diselenide (CIS), cadmium telluride (CdTe), and a few other materials. The common denominator of PV cells is that a  $p$ - $n$  junction, or the equivalent, such as a Schottky junction, is needed to enable the PV effect. Understanding the  $p$ - $n$  junction is thus at the heart of understanding how a PV cell converts sunlight into electricity.

Figure 44.3 shows a Si  $p$ - $n$  junction.

The junction consists of a layer of  $n$ -type Si joined to a layer of  $p$ -type Si, with an uninterrupted Si crystal structure across the junction. The  $n$ -layer has an abundance of free electrons and the  $p$ -layer has an abundance of free holes. Under thermal equilibrium conditions, meaning that temperature is the only external variable influencing the populations of free holes and electrons, the relationship between hole density,  $p$ , and electron density,  $n$ , at any given point in the material, is given by

$$np = n_i^2, \quad (44.1)$$

where  $n_i$  is approximately the density of electrons or holes in intrinsic (impurity-free) material. When impurities are present, then  $n \cong N_d$  and  $p \cong N_a$ , where  $N_d$  and  $N_a$  are the densities of donor and acceptor impurities. For Si,  $n_i \cong 1.5 \times 10^{10} \text{ cm}^{-3}$  at  $T = 300 \text{ K}$ , while  $N_d$  and  $N_a$  can be as large as  $10^{21} \text{ cm}^{-3}$ . Hence, for example, if  $N_d = 10^{18}$  on the  $n$ -side of the junction, then  $p = 2.25 \times 10^2 \text{ cm}^{-3}$ .

Both electrons and holes are subject to random diffusion within the Si crystalline structure, so each tends to diffuse from regions of high concentration to regions of low concentration. The enormous concentration differences of hole and electron concentrations between the  $n$ -side and the  $p$ -side of the junction cause large concentration gradients across the junction. The net result is that the electrons diffuse across the junction into the  $p$ -region and the holes diffuse across the junction into the  $n$ -region, as shown in Figure 44.3.

Before formation of the junction, both sides of the junction are electrically neutral. Each free electron on the  $n$ -side of the junction comes from a neutral electron donor impurity

**FIGURE 44.3**

The  $p$ - $n$  junction showing electron and hole drift and diffusion. (From Messenger, R. and Ventre, G., *Photovoltaic Systems Engineering*, 2nd edn., CRC Press LLC, Boca Raton, FL, 2004.)

atom, such as arsenic (As), while each free hole on the  $p$ -side of the junction comes from a neutral hole donor (acceptor) impurity atom, such as boron (B). When the negatively charged electron leaves the As atom, the As atom becomes a positively charged As ion. Similarly, when the positively charged hole leaves the B atom, the B atom becomes a negatively charged B ion. Thus, as electrons diffuse to the  $p$ -side of the junction, they leave behind positively charged electron donor ions that are covalently bound to the Si lattice. As holes diffuse to the  $n$ -side of the junction, they leave behind negatively charged hole donor ions that are covalently bound to the Si lattice on the  $p$ -side of the junction. The diffusion of charge carriers across the junction thus creates an electric field across the junction, directed from the positive ions on the  $n$ -side to the negative ions on the  $p$ -side, as shown in Figure 44.3. Gauss's law requires that electric field lines originate on positive charges and terminate on negative charges, so the number of positive charges on the  $n$ -side must be equal to the number of negative charges on the  $p$ -side.

Electric fields exert forces on charged particles according to the familiar  $f = qE$  relationship. This force causes the charge carriers to drift. In the case of the positively charged holes, they drift in the direction of the electric field, that is, from the  $n$ -side to the  $p$ -side of the junction. The negatively charged electrons drift in the direction opposite the field, that is, from the  $p$ -side to the  $n$ -side of the junction. If no external forces are present other than temperature, then the flows of holes are equal in both directions and the flows of electrons are equal in both directions, resulting in zero net flow of either holes or electrons across the junction. This is called the law of detailed balance, which is consistent with Kirchhoff's current law.

Carrying out an analysis of electron and hole flow across the junction ultimately leads to the development of the familiar diode equation:

$$I = I_o \left( e^{\frac{qV}{kT}} - 1 \right), \quad (44.2)$$

where

$q$  is the electronic charge

$k$  is Boltzmann's constant

$T$  is the junction temperature in K

$V$  is the externally applied voltage across the junction from the  $p$ -side to the  $n$ -side of the junction

#### 44.2.2 Illuminated $p$ - $n$ Junction

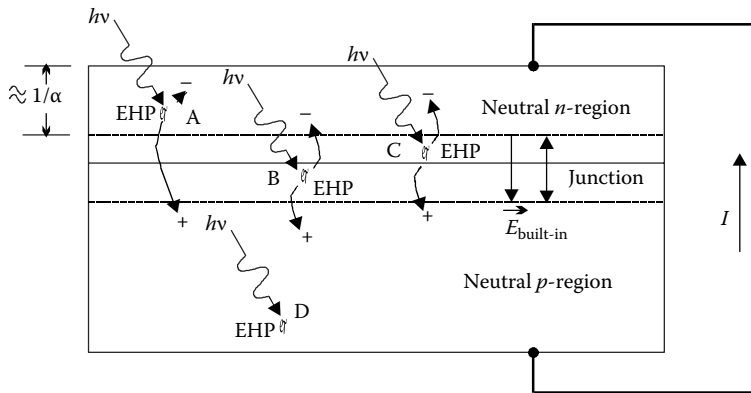

Figure 44.4 illustrates the effect of photons impinging upon the junction area.

The energy of a photon is given in the following equation, where  $\lambda$  is the wavelength of the photon,  $h$  is Planck's constant ( $6.625 \times 10^{-34}$  J s), and  $c$  is the speed of light ( $3 \times 10^8$  m/s):

$$e = hv = \frac{hc}{\lambda}, \quad (44.3)$$

The energy of a photon in electron volts (eV) becomes  $1.24/\lambda$ , if  $\lambda$  is in  $\mu\text{m}$  ( $1 \text{ eV} = 1.6 \times 10^{-19}$  J). If a photon has an energy that equals or exceeds the semiconductor bandgap energy of the  $p$ - $n$  junction material, then it is capable of creating an electron-hole pair (EHP). For Si, the bandgap is 1.1 eV, so if the photon wavelength is less than  $1.13 \mu\text{m}$ , which is in the near-infrared region, then the photon will have sufficient energy to generate an EHP.

**FIGURE 44.4**

The illuminated  $p$ - $n$  junction showing desirable geometry and the creation of electron-hole pairs. (From Messenger, R. and Ventre, G., *Photovoltaic Systems Engineering*, 2nd edn., CRC Press LLC, Boca Raton, FL, 2004.)

Although photons with energies higher than the bandgap energy can be absorbed, one photon can create only one EHP. The excess energy of the photon is wasted as heat. As photons enter a material, the intensity of the beam depends upon a wavelength-dependent absorption constant,  $\alpha$ . The intensity of the photon beam as a function of penetration depth into the material is given by  $F(x) = F_0 e^{-\alpha x}$ , where  $x$  is the depth of penetration into the material. Optimization of photon capture, thus, suggests that the junction should be within  $1/\alpha$  of the surface to ensure transmission of photons to within a diffusion length of the  $p$ - $n$  junction, as shown in Figure 44.4.

If an EHP is created within one minority carrier diffusion length,  $D_x$ , of the junction, then, on the average, the EHP will contribute to current flow in an external circuit. The diffusion length is defined to be  $L_x = \sqrt{D_x \tau_x}$ , where  $D_x$  and  $\tau_x$  are the minority carrier diffusion length and lifetime for electrons, respectively, in the  $p$ -region if  $x = n$ , and  $D_x$  and  $\tau_x$  are the minority carrier diffusion length and lifetime for holes, respectively, in the  $n$ -region if  $x = p$ . So the idea is to quickly move the electron and hole of the EHP to the junction before either has a chance to recombine with a majority charge carrier. In Figure 44.4, points A, B, and C represent EHP generation within a minority carrier diffusion length of the junction. But if an EHP is generated at point D, it is highly unlikely that the electron will diffuse to the junction before it recombines.

The amount of photon-induced current flowing across the junction and into an external circuit is directly proportional to the intensity of the photon source. Note that the EHPs are swept across the junction by the built-in E-field, so the holes move to the  $p$ -side and continue to diffuse toward the  $p$ -side external contact. Similarly, the electrons move to the  $n$ -side and continue to diffuse to the  $n$ -side external contact. Upon reaching their respective contacts, each contributes to external current flow if an external path exists. In the case of holes, they must recombine at the contact with an electron that enters the material at the contact. Electrons, on the other hand, are perfectly happy to continue flowing through an external copper wire.

At this point, an important observation can be made. The external voltage across the diode that results in significant current flow when no photons are present is positive from  $p$  to  $n$ . The diode current and voltage are defined in this direction, and the diode thus is defined according to the passive sign convention. In other words, when no photons impinge on the junction, the diode dissipates power. But when photons are present, the photon-induced

**FIGURE 44.5**

*I*-*V* characteristics of real and ideal PV cells under different illumination levels. (From Messenger, R. and Ventre, G., *Photovoltaic Systems Engineering*, 2nd edn., CRC Press LLC, Boca Raton, FL, 2004.)

current flows **OPPOSITE** to the passive direction. So current **LEAVES** the positive terminal, which means that the device is *generating* power. This is the PV effect. The challenge to the manufacturers of PV cells is to maximize the capture of photons and, in turn, maximize the flow of current in the cell for a given incident photon intensity. Optimization of the process is discussed in detail in [4]. When the photocurrent is incorporated into the diode equation, the result is

$$I = I_{\ell} - I_o \left( e^{\frac{qV}{kT}} - 1 \right) \cong I_1 - I_o e^{\frac{qV}{kT}}. \quad (44.4)$$

Note that in (44.4), the direction of the current has been reversed with respect to the cell voltage. With the active sign convention implied by (44.4), the junction device is now being defined as a cell, or PV cell. Figure 44.5 shows the *I*-*V* curves for an ideal PV cell and a typical PV cell, assuming the cell has an area of approximately 195 cm<sup>2</sup>.

It is evident that the ideal curve closely represents that of an ideal current source for cell voltages below 0.5 V, and it closely represents that of an ideal voltage source for voltages near 0.6 V. The intersection of the curve with the *V* = 0 axis represents the short-circuit current of the cell. The intersection of the curve with the *I* = 0 axis represents the open-circuit voltage of the cell. To determine the open-circuit voltage of the cell, simply set *I* = 0 and solve (44.4) for *V*<sub>OC</sub>. The result is

$$V_{OC} = \frac{kT}{q} \ln \frac{I_1}{I_o}. \quad (44.5)$$

The direct dependence of *I* on *I*<sub>1</sub> and the logarithmic dependence of *V*<sub>OC</sub> on *I*<sub>1</sub> is evident from (44.4) and (44.5) as well as from Figure 44.5.

The departure of the real curve from the ideal prediction is primarily due to unavoidable series resistance between the cell contacts and the junction.

### 44.2.3 Properties of the PV Cell

Another property of the  $I$ - $V$  curves of Figure 44.5 is the presence of a single point on each curve at which the power delivered by the cell is a maximum. This point is called the maximum power point of the cell and is more evident when cell power is plotted vs. cell voltage, as shown in Figure 44.6.

Note that the maximum power point of the cell remains at a nearly constant voltage as the illumination level of the cell changes.

Not shown in Figure 44.5 or 44.6 is the temperature dependence of the photocurrent. It turns out that  $I_0$  increases rapidly with temperature. Thus, despite the  $KT/q$  multiplying factor, the maximum available power from a Si PV cell decreases at approximately  $0.47\%/^{\circ}\text{C}$ , as shown in Figure 44.7.

Furthermore, the maximum power voltage also decreases by approximately this same factor. An increase of  $25^{\circ}\text{C}$  is not unusual for an array of PV cells, which corresponds to a decrease of approximately 12% in maximum power and in maximum power voltage. Because of this temperature degradation of the performance of a PV cell, it is important during the system design phase to endeavor to keep the PV cells as cool as possible.

## 44.3 Manufacture of Solar Cells

### 44.3.1 Manufacture of Crystalline and Multicrystalline Silicon PV Cells

While crystalline and multicrystalline silicon PV cells require highly purified, electronic-grade silicon, the material can be about an order of magnitude less pure than semiconductor-grade silicon and still yield relatively high-performance PV cells. Recycled or rejected semiconductor-grade silicon is often used as the feedstock for PV-grade silicon. Once adequately refined silicon is available, a number of methods have been devised for the production of single-crystal and multicrystalline PV cells. Single-crystal Si PV cells have been fabricated with conversion efficiencies just over 20%, while conversion efficiencies of champion multicrystalline Si PV cells are about 16% [5,6].

Single-crystal Si cells are almost exclusively fabricated from large single-crystal ingots of Si that are pulled from molten, PV-grade Si. These ingots, normally *p*-type, are typically on the order of 200 mm in diameter and up to 2 m in length. The Czochralski method (Figure 44.8a) is the most common method of growing single-crystal ingots.

A seed crystal is dipped in molten silicon doped with a *p*-material (Boron) and drawn upward under tightly controlled conditions of linear and rotational speed and temperature. This process produces cylindrical ingots of typically 10 cm diameter, although ingots of 20 cm diameter and more than 1 m long can be produced for other applications. An alternative method is called the float zone method (Figure 44.8b). In this method, a polycrystalline ingot is placed on top of a seed crystal and the interface is melted by a heating coil around it. The ingot is moved linearly and rotationally, under controlled conditions. This process has the potential to reduce the cell cost. Figure 44.9 illustrates the process of manufacturing a cell from an ingot.

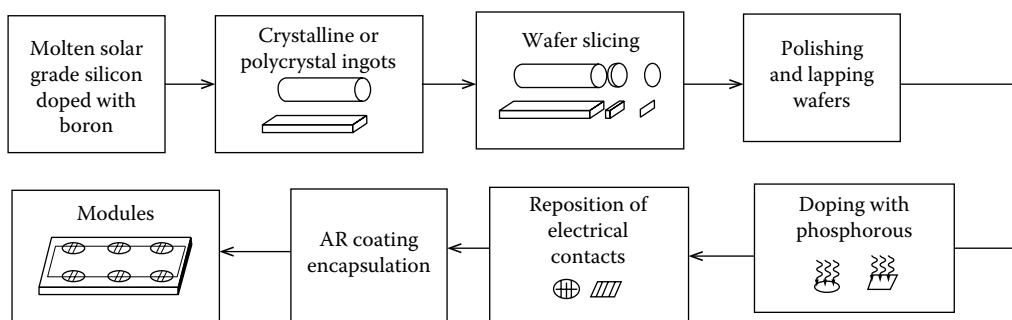

The ingots are sliced into wafers that are approximately 0.25 mm thick. The wafers are further trimmed to a nearly square shape, with only a small amount of rounding at the corners. Surface degradation from the slicing process is reduced by chemically etching the wafers. In order to enhance photon absorption, it is common practice to use a preferential etching process to produce a textured surface finish. An *n*-layer is then diffused into the wafer to produce a *p-n* junction, contacts are attached, and the cell is then encapsulated into a module (Figure 44.10).

Detailed accounts of cell and module fabrication processes can be found in [2,4,6,7].

**FIGURE 44.8**

Crystalline silicon ingot production methods: (a) Czochralski method and (b) float zone method. (From Goswami, D.Y. et al., *Principles of Solar Engineering*, 2nd edn., Taylor & Francis, Philadelphia, PA, 2000.)

**FIGURE 44.9**

Series of processes for the manufacture of crystalline and polycrystalline cells. (From Goswami, D.Y. et al., *Principles of Solar Engineering*, 2nd edn., Taylor & Francis, Philadelphia, PA, 2000.)

**FIGURE 44.10**

Assembly of solar cells to form a module. (From Goswami, D.Y. et al., *Principles of Solar Engineering*, 2nd edn., Taylor & Francis, Philadelphia, PA, 2000.)

Growing and slicing single-crystal Si ingots are highly energy intensive and, as a result, impose a relatively high energy cost on this method of cell fabrication. This high energy cost imposes a lower limit on the cost of production of a cell, and although the cell will ultimately generate as much energy as was used to produce it, the energy pay-back time (EPBT) is longer than desirable. Reducing the energy cost of cell and module fabrication has been the subject of a great deal of research over the past 40 years. The high energy cost of crystalline Si led to the work on thin films of amorphous Si, CdTe, and other materials, which is described later in this handbook. A great deal of work has also gone into developing methods of growing Si in a manner that will result in lower energy fabrication costs.

Three methods that are less energy intensive are now commonly in use—crucible growth, the EFG process, and string ribbon technology. These methods, however, result in the growth of multicrystalline Si, which, upon inspection, depending upon the fabrication process, has a speckled surface appearance, as opposed to the uniform color of single-crystal Si. Multicrystalline Si has electrical and thermodynamic characteristics that match single-crystal Si relatively closely, as previously noted.

The crucible growth method involves pouring molten Si into a quartz crucible and carefully controlling the cooling rate (Figure 44.11).

A seed crystal is not used, so the resulting material consists of a collection of zones of single crystals with an overall square cross section. It is still necessary to saw the ingots into wafers, but the result is square wafers rather than round wafers that would require

**FIGURE 44.11**

Polycrystalline ingot production. (a) Mold, (b) polycrystalline ingot. (From Goswami, D.Y. et al., *Principles of Solar Engineering*, 2nd edn., Taylor & Francis, Philadelphia, PA, 2000.)

additional sawing and corresponding loss of material. Wafers produced by this method can achieve conversion efficiencies of 15% or more [2].

The edge-defined film-fed growth (EFG) process is another method currently being used to produce commercial cells [8]. The process involves pulling an octagon tube, 6 m long, with a wall thickness of 330  $\mu\text{m}$ , directly from the Si melt. The octagon is then cut by a laser along the octagonal edges into individual cells. Cell efficiencies of 14% have been reported for this fabrication method [5]. Figure 44.12 illustrates the process.

A third method of fabrication of multicrystalline Si cells involves pulling a ribbon of Si, or dendritic web, from the melt (Figure 44.13).

**FIGURE 44.12**

Thin-film production by EFG. (From Goswami, D.Y. et al., *Principles of Solar Engineering*, 2nd edn., Taylor & Francis, Philadelphia, PA, 2000.)

**FIGURE 44.13**

Thin-film production by dendritic web growth. (From Goswami, D.Y. et al., *Principles of Solar Engineering*, 2nd edn., Taylor & Francis, Philadelphia, PA, 2000.)

Controlling the width of the ribbon is the difficult part of this process. High-temperature string materials are used to define the edges of the ribbon. The string materials are pulled through a crucible of molten Si in an Ar atmosphere after the attachment of a seed crystal to define the crystal structure of the ribbon. The nonconducting string material has a coefficient of thermal expansion close to that of Si, so during the cooling process, the string material will not affect the Si crystallization process [6]. The ribbons of Si are then cut into cells, typically rectangular in shape, as opposed to the more common square configuration of other multicrystalline technologies. Once the multicrystalline wafers have been fabricated, further processing is the same as that used for single-crystal cells.

#### 44.3.2 Amorphous Silicon and Multijunction Thin-Film Fabrication

Amorphous silicon (*a*-Si) cells are made as thin films of *a*-Si:H alloy doped with phosphorous and boron to make *n* and *p* layers, respectively. The atomic structure of an *a*-Si cell does not have any preferred orientation. The cells are manufactured by depositing a thin layer of *a*-Si on a substrate (glass, metal, or plastic) from glow discharge, sputtering, or chemical vapor deposition (CVD) methods. The most common method is by an RF glow discharge decomposition of silane ( $\text{SiH}_4$ ) on a substrate heated to a temperature of 200°C–300°C. To produce *p*-silicon, diborane ( $\text{B}_2\text{H}_6$ ) vapor is introduced with the silane vapor. Similarly, phosphene ( $\text{PH}_3$ ) is used to produce *n*-silicon. The cell consists of an *n*-layer, and intermediate undoped *a*-Si layer, and a *p*-layer on a substrate. The cell thickness is about 1  $\mu\text{m}$ . The manufacturing process can be automated to produce rolls of solar cells from rolls of substrate. Figure 44.14 shows an example of roll-to-roll *a*-Si cell manufacturing equipment using a plasma CVD method.

This machine can be used to make multijunction or tandem cells by introducing the appropriate materials at different points in the machine.

The four previously mentioned cell fabrication techniques require contacts on the front surface and on the back surface of the cells. Front surface contacts need to cover enough

**FIGURE 44.14**

A schematic diagram of a roll-to-roll plasma CVD machine. (Adapted from [www.ase-international.com](http://www.ase-international.com).)

area to minimize series resistance between cell and contact, but if too much area is covered, then photons are blocked from entering the crystal. Thus, it is desirable, if possible, to design cells such that both contacts are on the back of the cell. Green and his PV team at the University of South Wales have devised a buried contact cell [9] that has both contacts on the back and also is much thinner, thus much less material intensive, than conventional Si cells. In conventional cells, charge carrier flow is perpendicular to the cell surface, while in the buried contact cell, even though the multiple  $p$ - $n$  junctions are parallel to the cell surfaces, charge carrier flow is parallel to the cell surfaces. The fabrication process involves depositing alternate  $p$ -type and  $n$ -type Si layers, each about  $1\ \mu\text{m}$  thick, on an insulating substrate or superstrate. Grooves are laser cut in the layers and contacts are deposited in the grooves. Elimination of the ingot and wafer steps in processing, along with the reduced amount of material used, reduces correspondingly the energy overhead of cell production. Conversion efficiencies in excess of 20% and high cell fill factors have been achieved with this technology.

#### 44.4 PV Modules and PV Arrays

Since individual cells have output voltages limited to approximately 0.5 V and output currents limited to approximately 7 A, it is necessary to combine cells in series and parallel to obtain higher voltages and currents. A typical PV module consists of 36 cells connected in series in order to produce a maximum power voltage of approximately 17 V, with a maximum power current of approximately 7 A at a temperature of 25°C. Such a module will typically have a surface area of about 10 ft<sup>2</sup>. Modules also exist with 48 or more series cells so that three modules in series will produce the same output voltage and current as four 36-cell modules in series. Other larger modules combine cells in series and in parallel to produce powers up to 300 W per module.

Modules must be fabricated so the PV cells and interconnects are protected from moisture and are resistant to degradation from the ultraviolet component of sunlight. Since the modules can be expected to be exposed to a wide range of temperatures, they must be designed so that thermal stresses will not cause delamination. Modules must also be resistant to blowing sand, salt, hailstones, acid rain, and other unfriendly environmental

conditions. And, of course, the module must be electrically safe over the long term. A typical module can withstand a pressure of 50 psf and large hailstones and is warranted for 25 years. Details on module fabrication can be found in [4,7,10].

It is important to realize that when PV cells with a given efficiency are incorporated into a PV module, the module efficiency will be less than the cell efficiency, unless the cells are exactly identical electrically. When cells are operated at their maximum power point, this point is located on the cell  $I$ - $V$  curve at the point where the cell undergoes a transition from a nearly ideal current source to a nearly ideal voltage source. If the cell  $I$ - $V$  curves are not identical, since the current in a series combination of cells is the same in each cell, each cell of the combination will not necessarily operate at its maximum power point. Instead, the cells operate at a current consistent with the rest of the cells in the module, which may not be the maximum power current of each cell.

When modules are combined to further increase system voltage and/or current, the collection of modules is called an array. For the same reason that the efficiency of a module is less than the efficiencies of the cells in the module, the efficiency of an array is less than the efficiency of the modules in the array. But since a large array can be built with subarrays that can operate essentially independently of each other, in spite of the decrease in efficiency at the array level, PV arrays that produce in excess of 1 MW are in operation at acceptable efficiency levels. The bottom line is that most efficient operation is achieved if modules are made of identical cells and if arrays consist of identical modules.

---

## 44.5 Sun and PV Array Orientation

As explained in detail in Chapter 36, total solar radiation is composed of components, direct or beam, diffuse, and reflected. In regions with strong direct components of sunlight, it may be advantageous to have a PV array mount that will track the sun. Such tracking mounts can improve the daily performance of a PV array by more than 20% in certain regions. In cloudy regions, tracking is less advantageous.

The position of the sun in the sky can be uniquely described by two angles—the azimuth,  $\gamma$ , and the altitude,  $\alpha$ . The azimuth is the deviation from true south. The altitude is the angle of the sun above the horizon. When the altitude of the sun is  $90^\circ$ , the sun is directly overhead.

Another convenient, but redundant, angle, is the hour angle,  $\omega$ . Since the earth rotates  $360^\circ$  in 24 h, it rotates  $15^\circ$  each hour. The sun thus appears to move along its arc  $15^\circ$  toward the west each hour. The hour angle is  $0^\circ$  at solar noon, when the sun is at its highest point in the sky during a given day. In this handbook, we have a sign convention such that the hour angle and the solar azimuth angle are negative before noon and positive after noon. For example, at 10 a.m. solar time, the hour angle will be  $-30^\circ$ .

A further important angle that is used to predict the sun's position is the declination,  $\delta$ . The declination is the apparent position of the sun at solar noon with respect to the equator. When  $\delta = 0$ , the sun appears overhead at solar noon at the equator. This occurs on the first day of fall and on the first day of spring. On the first day of Northern Hemisphere summer (June 21), the sun appears directly overhead at a latitude,  $L$ , of  $23.45^\circ\text{N}$  of the equator. On the first day of winter (December 21), the sun appears directly overhead at a latitude of  $23.45^\circ$  south of the equator. At any other latitude, the altitude  $\alpha = 90^\circ - |L - \delta|$  when the sun is directly south (or north), that is, at solar noon. At solar noon, the sun is

directly south for  $L > \delta$  and directly north for  $L < \delta$ . Note that if  $L$  is negative, it refers to the Southern Hemisphere.

Several important formulas for determining the position of the sun [4,11] include the following, where  $n$  is the day of the year with January 1 being day 1:

$$\delta = 23.45^\circ \sin \frac{360[n - 80]}{365}, \quad (44.6)$$

$$\omega = \pm 15^\circ (\text{hours from local solar noon}), \quad (44.7)$$

$$\sin \alpha = \sin \delta \sin L + \cos \delta \cos L \cos \omega, \quad (44.8)$$

and

$$\cos \gamma = \frac{\cos \delta \sin \omega}{\cos \alpha}. \quad (44.9)$$

Solution of (44.6 through 44.9) shows that for optimal annual performance of a PV array, it should face directly south and should be tilted at an angle approximately equal to the latitude,  $L$ . For best summer performance, the tilt should be at  $L - 15^\circ$ , and for best winter performance, the array should be tilted at an angle of  $L + 15^\circ$ .

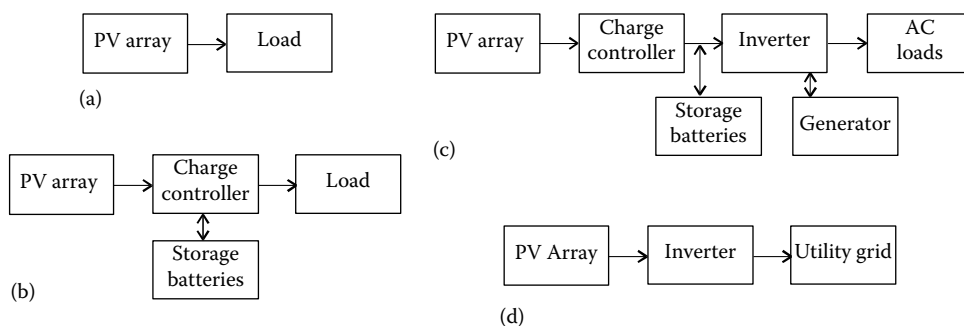

While (44.6 through 44.9) can be used to predict the location of the sun in the sky at any time on any day at any location, they cannot be used to predict the degree of cloud cover. Cloud cover can only be predicted on a statistical basis for any region, and thus the amount of sunlight available to a collector will also depend upon cloud cover. The measure of available sunlight is the peak sun hour (psh). If the sunlight intensity is measured in  $\text{kW}/\text{m}^2$ , then if the sunlight intensity is integrated from sunrise to sunset over  $1 \text{ m}^2$  of surface, the result will be measured in kWh. If the daily  $\text{kWh}/\text{m}^2$  is divided by the peak sun intensity, which is defined as  $1 \text{ kW}/\text{m}^2$ , the resulting units are hours. Note that this hour figure multiplied by  $1 \text{ kW}/\text{m}^2$  results in the daily  $\text{kWh}/\text{m}^2$ . Hence the term peak sun hours, since the psh is the number of hours the sun would need to shine at peak intensity to produce the daily sunrise to sunset kWh. Obviously the psh is also equivalent to  $\text{kWh}/\text{m}^2/\text{day}$ . For locations in the United States, the National Renewable Energy Laboratory [12] publishes psh for fixed and single-axis tracking PV arrays at tilts of horizontal, latitude  $-15^\circ$ , latitude, latitude  $+15^\circ$ , and vertical. NREL also tabulates data for double-axis trackers. These tables are extremely useful for determining annual performance of a PV array.

---

## 44.6 PV System Configurations

Figure 44.15 illustrates four possible configurations for PV systems.

Perhaps the simplest system is that of Figure 44.15a in which the output of the PV module or array is directly connected to a DC load. This configuration is most commonly used with a fan or a water pump, although it is likely that the water pump will also use a linear current booster (LCB) between the array and the pump motor. Operation of the LCB will be explained later.

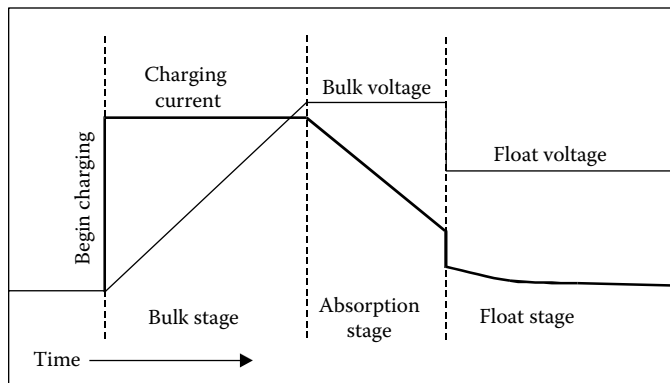

**FIGURE 44.15**

Several examples of PV systems: (a) direct-coupled DC system, (b) DC system with battery backup, (c) AC system with battery backup and fossil generator, and (d) grid-connected system.

The configuration of Figure 44.15b includes a charge controller and storage batteries so the PV array can produce energy during the day that can be used day or night by the load. The charge controller serves a dual function. If the load does not use all the energy produced by the PV array, the charge controller prevents the batteries from overcharge. While flooded lead–acid batteries require overcharging about once per month, frequent overcharging shortens the lives of the batteries. As the batteries become discharged, the charge controller disconnects the load to prevent the batteries from overdischarge. Normally PV systems incorporate deep discharge lead–acid batteries, but the life of these batteries is reduced significantly if they are discharged more than 80%. Modern charge controllers typically begin charging as constant current sources. In the case of a PV system, this simply means that all array current is directed to the batteries. This is called the *bulk* segment of the charge cycle. Once the battery voltage reaches the bulk voltage, which is an owner programmable value, as determined by the battery type and the battery temperature, the charging cycle switches to a constant voltage mode, commonly called the *absorption* mode. During the absorption charge mode, the charge controller maintains the bulk charge voltage for a preprogrammed time, again depending upon manufacturers' recommendations. During the absorption charge, battery current decreases as the batteries approach full charge. At the end of the bulk charge period, the charging voltage is automatically reduced to the *float* voltage level, where the charging current is reduced to a *trickle* charge.

Since quality charge controllers are microprocessor controlled, they have clock circuitry so that they can be programmed to automatically subject the batteries to an *equalization* charge approximately once a month. The equalization mode applies a voltage higher than the bulk voltage for a preset time to purposely overcharge the batteries. This process causes the electrolyte to bubble, which helps to mix the electrolyte as well as to clean the battery plates. Equalization is recommended *only* for flooded lead–acid batteries. Sealed varieties can be seriously damaged if they are overcharged.

Figure 44.16 shows the currents and voltages during the bulk, absorption, and float parts of the charging cycle. Note that all settings are programmable by the user in accordance with manufacturers' recommendations. Some charge controllers incorporate maximum power tracking as a part of their charge control algorithm. Since the maximum power voltage of a module or an array is generally higher than needed to charge the batteries, the array will not normally operate at its maximum power point when it is charging batteries, especially if the array temperature is low. For example, if it takes 14.4 V to charge a 12.6 V battery, and if a module maximum power voltage is 17, then the charging current can be increased by a factor of 17/14.4, or approximately 18%, assuming close to 100% efficiency of the maximum power tracker (MPT).

**FIGURE 44.16**  
Charging cycle for typical PV charge controller.

The configuration of [Figure 44.15c](#) incorporates an inverter to convert the DC PV array output to AC and a backup generator to supply energy to the system when the supply from the sun is too low to meet the needs of the load. Normally, the backup generator will be a fossil-fueled generator, but it is also possible to incorporate wind or other renewable generation into the system. In this case, the charge controller prevents overcharge of the batteries. The inverter is equipped with voltage sensing circuitry so that if it detects the battery voltage going too low, it will automatically start the generator so the generator will provide power for the load as well as provide charging current for the batteries. This system is called a hybrid system, since it incorporates the use of more than one energy source.

The first three configurations are stand-alone systems. The fourth system, shown in [Figure 44.15d](#), is a grid-connected, or utility-interactive, system. The inverter of a utility-interactive system must meet more stringent operational requirements than the stand-alone inverter. The inverter output voltage and current must be of *utility-grade* quality. This means that it must have minimal harmonic content. Furthermore, the inverter must sense the utility, and if utility voltage is lost, the inverter must shut down until utility voltage is restored to within normal limits.

## 44.7 PV System Components

### 44.7.1 Maximum Power Trackers and Linear Current Boosters

The LCB was mentioned in conjunction with the water pumping example. The function of the LCB is to match the motor  $I$ - $V$  characteristic to the maximum power point of the PV array, so that at all times the array delivers maximum power to the load. Note that the LCB acts as a DC-to-DC transformer, converting a higher voltage and lower current to a lower voltage and higher current, with minimal power loss in the conversion process. A more general term that includes the possibility of converting voltage upward defines the maximum power tracker (MPT). [Figure 44.17](#) shows the operating principle of the LCB and MPT.

Note that normally the  $I$ - $V$  characteristic of the load will not intersect the  $I$ - $V$  characteristic of the PV array at the maximum power point of the array, as shown by points A, B, C, and D for the two loads and the two sunlight intensity levels. For the lower-intensity situation,

**FIGURE 44.17**

Operation of the LCB or MPT. (From Messenger, R. and Ventre, G., *Photovoltaic Systems Engineering*, 2nd edn., CRC Press LLC, Boca Raton, FL, 2004.)

the characteristic of load 1 intersects the array characteristic at point C and the characteristic of load 2 intersects the array characteristic at point A. The two hyperbolas are the loci of points where the  $I$ - $V$  product is equal to the maximum available power from the array at the particular sunlight intensity. Hence, the intersection of these hyperbolas with the load characteristics represents the transfer of all available power from the array to the load. While the increase in power for points B and C is not particularly impressive, as shown by points  $B_{\max}$  and  $C_{\max}$ , the increase in power for points A and D is considerably greater, as shown by points  $A_{\max}$  and  $D_{\max}$ . The assumption here, of course, is 100% efficiency in the transformation. In fact, efficiencies in excess of 95% are not unusual for quality MPT and LCB devices.

The final observation for Figure 44.17 is that points  $A_{\max}$  and  $B_{\max}$  occur at voltages below the maximum power voltages of the array, while  $C_{\max}$  and  $D_{\max}$  occur at voltages above the maximum power voltages of the array. Since the input voltage and current of the MPT or LCB are the maximum power voltage and current of the array, the MPT or LCB output voltage and current points  $A_{\max}$  and  $B_{\max}$  represent down-conversion of the array voltage and points  $C_{\max}$  and  $D_{\max}$  represent up-conversion of the array voltage. These forms of conversion are discussed in power electronics books, such as [13]. The difference between the MPT and the LCB is that the LCB only performs a down-conversion, so the operating voltage of the load is always below the maximum power voltage point of the array. The terms LCB and MPT are often used interchangeably for down-conversion, but normally LCB is limited to the description of the black box that optimizes performance of pumps, while MPT is used for more general applications.

#### 44.7.2 Inverters

Inverters convert DC to AC. The simplest inverter converts DC to square waves. While square waves will operate many AC loads, their harmonic content is very high, and as a result, there are many situations where square waves are not satisfactory. Other more suitable inverter output waveforms include the quasi-sine wave and the utility-grade sine wave. Both are most commonly created by the use of multilevel H-bridges controlled by microprocessors. There are three basic configurations for inverters: stand-alone, grid-tied, and UPS. The stand-alone inverter must act as a voltage source that delivers a prescribed amplitude and frequency rms sine wave without any external synchronization.

**FIGURE 44.18**

Example of PV source and output circuits.

The grid-tied inverter is essentially a current source that delivers a sinusoidal current waveform to the grid that is synchronized by the grid voltage. Synchronization is typically sufficiently close to maintain a power factor in excess of 0.9. The UPS inverter combines the features of both the stand-alone and the grid-tied inverter, so that if grid power is lost, the unit will act as a stand-alone inverter while supplying power to emergency loads. IEEE Standard 929 [14] requires that any inverter that is connected to the grid must monitor the utility grid voltage, and if the grid voltage falls outside prescribed limits, the inverter must stop delivering current to the grid. Underwriters Laboratory (UL) Standard 1741 [15] provides the testing needed to ensure compliance with IEEE 929.

While it may seem to be a simple matter to shut down if the utility shuts down, the matter is complicated by the possibility that additional utility-interactive PV systems may also be online. Hence, it may be possible for one PV system to *fool* another system into thinking that it is really the utility. To prevent this *islanding* condition, sophisticated inverter control algorithms have been developed to ensure that an inverter will not appear as the utility to another inverter. Some PV system owners do not want their PV system to shut down when the utility shuts down. Such a system requires a special inverter that has two sets of AC terminals. The first set, usually labeled AC IN, is designed for connection to the utility. If the utility shuts down, this set of terminals disconnects the inverter output from the utility, but continues to monitor utility voltage until it is restored. When the utility connection is restored, the inverter will first meet the needs of the emergency loads and then will feed any excess output back to the main distribution panel.

The second set of terminals is the emergency output. If the utility shuts down, the inverter almost instantaneously transfers into the emergency mode, in which it draws power from the batteries and/or the PV array to power the emergency loads. In this system, the emergency loads must be connected to a separate emergency distribution panel. Under emergency operation, the loads in the main distribution panel are without power, but the emergency panel remains energized. Such a system is shown in Figure 44.18.

The reader is referred to [4,13] for detailed explanations of the operation of inverters, including the methods used to ensure that utility-interactive inverters meet UL 1741 testing requirements.

### 44.7.3 Balance of System Components

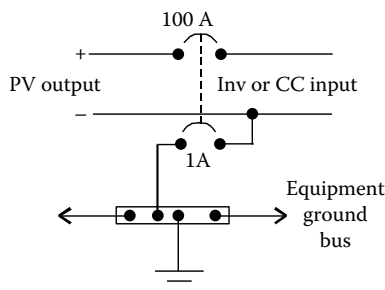

Aside from the array, the charge controller, and the inverter, a number of other components are needed in a code-compliant PV system. For example, if a PV array consists of multiple series-parallel connections, as shown in Figure 44.19, then it is necessary to incorporate fuses or circuit breakers in series with each series string of modules, defined as a source circuit.

**FIGURE 44.19**  
Use of GFDI.

This fusing is generally accomplished by using a source circuit combiner box as the housing for the fuses or circuit breakers, as shown in Figure 44.19. The combiner box should be installed in a readily accessible location. The PV output circuit of Figure 44.19 becomes the input to the charge controller, if a charge controller is used. If multiple parallel source circuits are used, it may be necessary to use more than one charge controller, depending upon the rating of the charge controller. When more than one charge controller is used, source circuits should be combined into separate output circuits for each charge controller input. In a utility-interactive circuit with no battery backup, a charge controller is not necessary. The PV output circuit connects directly to the inverter through either a DC disconnect or a DC ground fault detection and interruption (GFDI) device.

A GFDI device is required by the *National Electrical Code* (NEC) [16] whenever a PV array is installed on a residential rooftop. The purpose of the device is to detect current flow on the grounding conductor. The grounding conductor is used to ground all metal parts of the system. In a properly installed and operating system, no current will flow on the grounding conductor. Normally the negative conductor of the PV array is grounded, but this ground, if properly installed, will be attached to the grounding conductor at only one point, as shown in Figure 44.20, where the negative PV output conductor is connected to the equipment grounding bus through the 1 A circuit breaker. The 1 A circuit breaker is ganged to the 100 A circuit breaker so that if the current through the 1 A circuit breaker exceeds 1 A, both breakers will trip. When the two circuit breakers open, current flow on

**FIGURE 44.20**  
Utility-interactive PV system connections to emergency loads and to utility.

both the PV output circuit conductors and the grounding conductor is interrupted. If the fault current on the grounding conductor was the result of an arcing condition between one of the PV circuit conductors and ground, the arc will be extinguished, thus preventing a fire from starting.

The NEC also requires properly rated disconnects at the inputs and outputs of all power conditioning equipment. An additional disconnect will be needed at the output of a charge controller as well as between any battery bank and inverter input or DC load center. If the disconnect is to disconnect DC, then the NEC requires that it be rated for DC. Additional disconnects are needed at the output of any inverter. If the inverter is utility interactive with battery backup for emergency loads, it is desirable to include an inverter bypass switch at the inverter output in case inverter maintenance is required without interruption of power to emergency loads. In addition to the inverter bypass switch, many utilities require a visible, lockable, accessible, load break, disconnect between the inverter output and the point of utility connection. This switch is for use by the utility if they deem it necessary to disconnect the inverter from the line for any reason.

The point of utility connection for a utility-interactive system will normally be a backfed circuit breaker in a distribution panel. This circuit breaker is to be labeled so maintenance workers will recognize it as a source of power to the distribution panel. [Figure 44.18](#) shows the connections for an inverter bypass switch (A), the utility disconnect switch (B), and the point of utility connection circuit breaker (PUC). The figure also shows a neutral bus (C) for the connection of neutrals for the main distribution panel, the emergency panel, and the inverter. Operation of the inverter bypass switch is as follows: The two-pole unit and the one-pole unit are ganged together so that either both are off or only one is on. Under normal operation, the two-pole unit is on and the one-pole unit is off. This connects the utility to the inverter and the inverter emergency output to the emergency panel. When the two-pole is off and the one-pole is on, the utility is connected to the emergency panel and the inverter is bypassed. When both are off, the utility is disconnected from both the inverter and the emergency panel. It is interesting to note that if the PUC circuit breaker in the main distribution panel is turned off, the inverter will interpret this as an interruption in utility power and will shut down the feed from inverter to main distribution panel. Thus, the energized portions of the circuit breaker will be the same as the energized portions of the other circuit breakers in the panel. When it is on, both sides of the circuit breaker will be energized. When it is off, only the line side will be energized.

Article 690 of the NEC governs the sizing of conductors in the PV system. The serious designer should carefully review the requirements of this article, especially since many PV systems use low-voltage DC where voltage drop in the connecting wiring can be a problem. Sizing of conductors must be done carefully.

Chapter 36 provides information about storage batteries.

---

## 44.8 PV System Examples

### 44.8.1 Stand-Alone PV Well Pump System

As long as the depth of the well, the well replenishment rate, and the necessary flow rate are known, a PV pumping system can be designed. PV pumping systems are so common, in fact, that they often come in kits that include PV modules, a pump controller (LCB), and

a pump. Pump manufacturers generally provide specifications that indicate, for a given pumping height, the amount of water pumped and the current drawn by the pump for specified pump voltages.

As an example, consider a system designed to pump 2000 gal/day from a well that is 200 ft deep and has a replenishment rate that exceeds the desired pumping rate. Assume the location for the pumping system has a minimum of 5 psh/day. This means that the 2000 gal must be pumped in 5 h, which corresponds to a pumping rate of  $2000 \text{ gal}/300 \text{ min} = 6.67 \text{ gpm}$ . One pump that meets this requirement is a 1.0 HP pump that will pump 7.6 gpm to a height of 200 ft. Under these pumping conditions, the pump will draw 6.64 A at a DC voltage of 105 V. An 875 W PV array is recommended for the operation of this system by the distributor. Note that  $(6.64 \text{ A}) \times (105 \text{ V}) = 697 \text{ W}$ , indicating that the recommended PV array is rated at 125% of the system requirements.

Before committing to this system, however, it should be compared with a system that uses battery storage and a smaller pump. The cost of the 1.0 HP pump is close to \$1800, while a 0.25 HP pump that will pump 2.15 GPM while consuming 186 W can be purchased for about \$500. This pump will need to pump for 15.5 h to deliver the 2000 gal, so the energy consumption of the pump will be  $(186 \text{ W}) \times (15.5 \text{ h}) = 2884 \text{ Wh}$ . If the pump runs at 24 V DC, this corresponds to  $2884 \div 24 = 120 \text{ Ah/day}$ . For PV storage, deep discharge lead-acid batteries are normally used, and it is thus necessary to ensure that the batteries will provide adequate storage for the pump without discharging to less than 20% of full charge. Thus, the battery rating must be at least  $120 \div 0.8 = 150 \text{ Ah}$  for each day of storage. If the water is pumped into a tank, then the water itself is a form of energy storage, and if the tank will hold several days' supply of water, then the batteries will only need to store enough energy to operate the pump for a day. If it is less expensive to use more batteries than to use a larger water tank, then additional batteries can be used.

So, finally, a sensible system will probably consist of a  $\frac{1}{4}$  HP pump, an MPT charge controller for the batteries, and a minimum of 150 Ah at 24 V of battery storage. With the MPT controller, the array size, assuming 5 psh minimum per day, becomes  $(2884 \text{ Wh}) \times 1.25 \div (5 \text{ h}) = 721 \text{ W}$ , where the 1.25 factor compensates for losses in the array due to operation at elevated temperatures, battery charging and discharging losses, MPT losses, and wiring losses. This array can be conveniently achieved with 120 W modules configured in an array with two in series and three in parallel, as shown in Figure 44.21.

As a final note on the pumping system design, it is interesting to check the wire sizes. The NEC gives wire resistance in terms of  $\Omega/\text{kft}$ . It is good design practice, but not an

**FIGURE 44.21**

Water pumping system with battery storage and MPT charge controller.

absolute requirement, to keep the voltage drop in any wiring at <2%. The overall system voltage drop must be <5%. The wire size for any run of wire can thus be determined from

$$\Omega/\text{kft} \leq \frac{(\%VD)V_s}{0.2 \cdot I \cdot d}, \quad (44.10)$$

where

%VD is the allowed voltage drop in the wiring expressed as a percentage

$V_s$  is the circuit voltage

$I$  is the circuit current

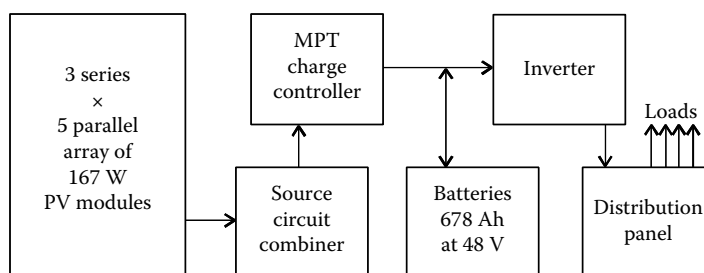

$d$  is the one-way length of the wiring

For the PV source circuit wiring,  $V_s$  will be about 34 V and  $I$  will be about 7 A. If the one-way source circuit length is 40 ft, then, for 2% voltage drop, (44.10) evaluates to  $\Omega/\text{kft} = 1.2143$ . NEC Chapter 9 Table 8 shows that #10 solid Cu wire has 1.21  $\Omega/\text{kft}$ , while #10 stranded Cu has 1.24  $\Omega/\text{kft}$ . So either type of #10 will keep the %VD very close to 2%. Since #10 THWN-2 is rated to carry 40 A at 30°C, it is adequate for the job even under most derating conditions. Since the pump will be submersed, it will need 200 ft of wire just to get out of the well. If the controller is close to the well, then  $d$  will be approximately 210 ft. Thus, for  $I = (186 \text{ W}) \div (24 \text{ V}) = 7.75 \text{ A}$ , and  $V_s = 24 \text{ V}$ , (44.10) yields  $\Omega/\text{kft} = 0.1475$ , which requires #1/0 Cu according to NEC Chapter 9 Table 8. A 3% voltage drop would allow the use of #2 Cu. In either case, this is a good example of how wire size may need to be increased to keep voltage drop at acceptable levels when relatively low-voltage DC is used. The 30°C ampacity of #2 Cu, for example, is 130 A. So even the small, low-voltage DC pump may not be the best choice. With inverter price decreasing and reliability increasing, and with AC motors generally requiring less maintenance than DC motors, at the time this article is being read, it may be more cost-effective to consider a 120 or 240 V AC pump for this application.

#### 44.8.2 Stand-Alone System for a Remote Schoolhouse

Stand-alone system design requires a tabulation of the system loads, generally expressed in ampere hours (Ah) at the battery voltage. Suppose, for example, it is desired to provide power for 400 W of lighting, 400 W of computers, and 200 W of refrigeration, all at 120 V AC. Suppose that all of the loads operate for 8 h/day. This means the load to be met is 8 kWh/day at 120 V AC. If this load is supplied by an inverter that operates with 92% efficiency, then the batteries must supply the inverter with  $8 \div 0.92 = 8.7 \text{ kWh/day}$ . If the inverter input is 48 V DC, then the daily load in Ah is  $(8700 \text{ Wh}) \div (48 \text{ V}) = 181 \text{ Ah}$ . To meet the needs for 1 day of operation, the batteries should thus be rated at 125% of 181 Ah = 226 Ah. But for a stand-alone system, it is usually desirable to provide more than 1 day of storage. For this system, 3 days would be more common, so a total of 678 Ah at 48 V should be used.

If an MPT charge controller is used, then the array can be sized based upon the daily system Wh and the available daily psh, taking losses into account. First of all, battery charging and discharging are only about 90% efficient. So to get 181 Ah *out* of the batteries, it is necessary to design for  $181 \div 0.9 = 201 \text{ Ah in}$  to the batteries. At 48 V, this is 9648 Wh. Next, it is necessary to include a 10% degradation factor for array maintenance, mismatch, and wiring losses and another 15% factor for elevated array operating temperature. So the array should be designed to produce  $9,648 \div 0.9 \div 0.85 = 12,612 \text{ Wh/day}$ . Assuming a worst-case psh = 5 h/day, this means an array size of  $12,612 \div 5 = 2,522 \text{ W}$  will be needed.

**FIGURE 44.22**

Block diagram of schoolhouse PV system.

This can be achieved with twenty 125 W modules in a 4-series-by-5-parallel array, or with 15 167 W modules in a 3-series-by-5-parallel array, or by any number of other module combinations that do not exceed the charge controller maximum input voltage limit when running open circuit. It must be remembered that to achieve the nominal 48 V source circuit output, it may take two, three, or four modules in series. Thus, each additional parallel module will require additional series modules to achieve the system voltage.

Figure 44.22 shows the block diagram of the schoolhouse system.

To this point, wind loading of the array has not been mentioned. In areas of high wind loads, the size of the module and the mounting method may or may not be adequate to meet high wind loading conditions. The final check on any PV system design must be a determination of whether the system will blow away in a high wind. This is especially undesirable considering the cost of a system as well as the fact that many systems are installed to provide power during emergencies, one of which might be a hurricane.

As a final note on system design, if an MPT charge controller is not used, then the array should be sized to provide 110% of the daily battery input Ah, using the maximum power current of the array. In this case, the daily battery input Ah is 201, so the array should be designed for 221 Ah. For 5 psh, this converts to an array current of 44.2 A. The 125 W modules have a 7 A maximum power current, so this means six in parallel will produce 42 A, which is close to the required amount. So the MPT controller saves four modules, or 500 W. At \$4/W, this is a savings of \$2000, which more than pays for the additional cost of the MPT charge controller.

It is interesting to look at a life cycle cost of the schoolhouse system. Using a discount rate of 5% and an inflation rate of 3%, an LCC cost estimate can be tabulated. In [Table 44.1](#), it is assumed that the batteries are 12 V, 110 Ah, sealed, AGM lead–acid, deep-cycle batteries with a rated lifetime of 8 years and a cost of \$150 each.

To compare this system with a gasoline generator, note that the generator would need to generate 8 kWh/day for 20 years by operating 8 h/day over this period. A typical small gasoline generator will generate 4 kWh/gal [4], so will require 2 gal of gasoline per day. The generator will require an oil change every 25 h, a tune-up every 300 h, and a rebuild every 3000 h. The LCC analysis for the generator is shown in [Table 44.2](#). Clearly, the PV system is the preferred choice. And this does not even account for the noise-free, pollution-free performance of the PV system.

### 44.8.3 Straightforward Utility-Interactive PV System

Since utility-interactive PV systems are backed up by the utility, they do not need to be sized to meet any particular load. Sometimes they are sized to meet emergency loads, but if the system does not have emergency backup capabilities, then they may be sized to fit

**TABLE 44.1**

Life Cycle Costs of a Stand-Alone Photovoltaic System for a Schoolhouse

Item	Cost (\$)	Present Worth (\$)	LCC (%)
<i>Capital costs</i>			
Array	10,000	10,000	38.1
Batteries	3,600	3,600	13.7

Annual rebuilds	146	2,447	6
		41,836	100

on a particular roof, to meet a particular budget, or to incorporate a particular inverter. Suppose the sizing criterion is the inverter, which has the following specifications:

DC input	Input voltage range	250–550 V
	Maximum input current	11.2 A
AC output	Voltage	240 V, 1 $\phi$
	Nominal output power	2200 W
	Peak power	2500 W
	Total harmonic distortion	<4%
	Maximum efficiency	94%

Note that if the input voltage is 550 V and the input current is 11.2 A, the input power would be 6160 W. Since the peak output power of this inverter is 2500 W, it would not make sense to use a 6160 W array, since most of the output would be wasted, and it might be easier to damage the inverter. So an array size of about 2500 W would make better sense.

Since cloud focusing can increase the short-circuit output current of a module by 25%, the array rated short-circuit current should be kept below  $11.2 \div 1.25 = 8.96$  A. The number of modules in series will depend upon the maximum voltage of the array at low temperatures remaining  $<550$  V and the minimum array voltage at high array operating temperatures remaining  $>250$  V.

NEC Table 690.7 specifies multipliers for open-circuit voltages for different low-temperature ranges. For design purposes, suppose the coldest array temperature will be  $-25^{\circ}\text{C}$  and the hottest array temperature will be  $60^{\circ}\text{C}$ . NEC Table 690.7 requires a multiplier of 1.25 for the array open-circuit voltage, so the maximum rated array open-circuit voltage must be less than  $550 \div 1.25 = 440$  V. If the open-circuit voltage of a module decreases by  $0.47\%/^{\circ}\text{C}$ , then it will decrease by  $35 \times 0.47 = 16.45\%$  when the module is operated at  $60^{\circ}\text{C}$ . Thus, the  $25^{\circ}\text{C}$  rated array open-circuit voltage needs to be greater than  $250 \div 0.8355 = 299$  V.

The next step is to look at PV module specifications. One module has  $P_{\text{max}} = 125$  W,  $V_{\text{OC}} = 21.0$  V, and  $I_{\text{SC}} = 7.2$  A. Thus, the maximum number of these modules in series will be  $440 \div 21.0 = 20.95$ , which must be rounded down to 20. The minimum number in series will be  $299 \div 21.0 = 14.24$ , which must be rounded up to 15. Checking power ratings gives 2500 W for 20 modules and 1875 W for 15 modules. Since 2500 W does not exceed the inverter rated maximum output power, and since the array will normally operate below 2500 W, it makes sense to choose 20 modules, as long as the budget can afford it and as long as there is room for 20 modules wherever they are to be mounted. Figure 44.15d shows the block diagram for this system.

The life cycle cost of this type of system is usually looked at somewhat differently than that of the schoolhouse system. In this case, the cost of electricity generated is usually compared with the cost of electricity from the utility, neglecting pollution and other externalities. In regions with an abundance of trained installers, it is currently possible to complete a grid-connected installation for less than  $\$7/\text{W}$ . The installed cost of the 2,500 W system would thus be approximately  $\$17,500$ . It is reasonable to expect an average daily output of 10 kWh for this system in an area with an average of 5 psh. The value of the annual system output will thus be approximately  $\$365$  at  $\$0.10/\text{kWh}$ . This amounts to a simple payback period of 48 years—almost double the expected lifetime of the system.

Of course, what is not included in the analysis is the significant amount of  $\text{CO}_2$  production that is avoided, as well as all the other pollutants associated with nonrenewable generation. Also not included are the many subsidies granted to producers of nonrenewable energy that keep the price artificially low. For that matter, it assumes that an abundance of fossil fuels will be available at low cost over the lifetime of the PV system. Finally, it should be remembered that the energy produced by the PV system over the lifetime of the system will be at least four times as much as the energy that went into the manufacture and installation of the system.

If the cost of the system could be borrowed at 3% over a period of 25 years, the annual payments would be  $\$1005$ . Thus, if a grid-connected system is considered, unless there is a subsidy program, it could not be justified with simple economics. It would be purchased simply because it is the right thing to do for the environment. Of course, if the installation cost were less, the value of grid electricity were more, and the average sunlight were higher, then the numbers become more and more favorable. If the values of externalities, such as pollution, are taken into account, then the PV system looks even better.

Because of the cost issue, as well as local PUC regulations or lack of them, ill-defined utility interface requirements, etc., few grid-connected PV systems are installed in areas that do not provide some sort of incentive payments. In some cases, PV system owners

are paid rebates based on dollars per watt. The problem with this algorithm is that there is no guarantee that the system will operate properly. In other cases, PV system owners are guaranteed a higher amount per kWh for a prescribed time, which guarantees that the system must work to qualify for incentive payments. In fact, at present, more kW of PV is installed annually in grid-connected systems than are installed in stand-alone systems [17].

---

#### 44.9 Present Status of Technology and Future Challenges for PV Systems

The PV technology has made tremendous progress in the last decade, where the PV system deployment around the world has been increasing at an average annual rate of more than 50%. The costs of PV panels have come down by an order of magnitude over the last decade. The present panel costs for both polycrystalline silicon and thin-film panels are less than \$0.75/W, which has resulted in the system costs of \$2–\$2.50/W for small-scale systems and around \$1.50–\$2.00/W for large-scale systems. Large-scale PV systems are being constructed in the range 1 MW to as large as hundreds of MW. The challenge is to reduce the panel costs further to less than \$0.50/W and the BOS costs also to less than \$0.50/W, which will make PV competitive without government incentives. For PV panels, this will be achieved by further improvements in panel efficiencies. As of 2013, the efficiencies achieved in the laboratory for the various PV technologies are given in [Table 44.3](#). Efficiency table for concentrating PV is given in Chapter 46.

The PV industry is currently engaged in an effort to ensure quality control at all levels of system deployment, including manufacturing, distribution, design, installation, inspection, and maintenance. At this point in time (2013), most of the technical challenges for PV system components have been overcome. PV modules are very reliable, and most are warranted for 25 years. Reliability of other system components continues to improve, and at this point, PV system power conditioning equipment has proven to operate very reliably. So, once installed properly, modern PV systems require very little maintenance. In fact, systems without batteries require almost no maintenance.

The biggest challenge for PV systems is storage. As the contribution of PV in the grid continues to increase, the electrical utilities are becoming more concerned with the transients in the grid due to solar radiation transients. Battery storage, however, is very expensive. With the cost of battery storage of over \$500/kWh<sub>c</sub>, batteries are not cost-effective in large-scale systems. Although a great deal of battery and supercapacitor research is being conducted around the world, the costs are not expected to get below \$100/kWh<sub>c</sub> in this decade.

If the cost of a PV system were to be measured in energy units, then perhaps the importance of PV systems would become more obvious. By the early 1980s, Odum and Odum [17] and Henderson [18] had proposed using the Btu as the international monetary standard. However, at that time, they reported that the EPBT of PV panels was more than their entire lifetime. In the last decade, Battisti and Corrado [19] reported EPBTs of approximately 3 years and CO<sub>2eq</sub> payback times of about 4 years for PV systems. Since that time, the EPBTs have come down further. By 2011, the EPBTs of commercial rooftop PV systems had reduced to as little as 0.68 year for CdTe technology and 1.96 years for monocrystalline silicon [1]. Since the life expectancy of a PV system exceeds 20–25 years, this equates to as much as 30:1 return on the energy invested.

## Nomenclature

$C$	Speed of light ( $3 \times 10^8$ m/s)
$D_x$	Minority carrier diffusion length
$E$	Energy of photon (eV)
$F(x)$	Intensity of the photon beam as a function of penetration depth into the material
$F_o$	Initial intensity of the photon beam at the material surface
$h$	Planck's constant ( $6.625 \times 10^{-34}$ J s)

$I$	Current (A)
$I_1$	Short-circuit current (A)
$k$	Boltzmann's constant ( $1.381 \times 10^{-23}$ J/K)
$L$	Latitude angle
$L_x$	Diffusion length
$n$	Electron concentration
$n$	Day of year
$N_a$	Density of acceptor impurities
$N_d$	Density of donor impurities
$n_i$	Intrinsic carrier concentration
$p$	Hole concentration
$P_{\max}$	Maximum power (W)
$Q$	Charge of an electron ( $1.602 \times 10^{-19}$ C)
$T$	Junction temperature (K)
$V$	Voltage (V)
$V_{OC}$	Open-circuit voltage (V)
$X$	Depth of penetration into material

### Symbols

$\Lambda$	Wavelength ( $\mu\text{m}$ )
$A$	Absorption constant
$A$	Altitude angle of the sun
$\Delta$	Declination angle
$\Gamma$	Azimuth angle of the sun
$\Omega$	Hour angle
$\Omega$	Resistance (ohm)
$\tau_x$	Minority carrier lifetime

### Acronyms

$a$ -Si	Amorphous silicon
CVD	Chemical vapor deposition
EHP	Electron-hole pair
GFDI	Ground fault detection and interruption
HIT	Heterojunction with intrinsic thin layer
LCB	Linear current booster
MPT	Maximum power tracker
psh	Peak sun hour

## 45.1 Introduction

### 45.1.1 Historical and Current Developments

Crystalline silicon (c-Si) technology has a lion's share in the present photovoltaic (PV) industry, contributing more than 85% through the cells and modules based on poly-, mono-, and multicrystalline wafer technology (Mints and Donnelly 2011). The recent growth rate of PV industry and market is phenomenal, with a substantial surge on average over 40% recorded globally during the last decade and expected to sustain the trend from short to medium time frame. During the early developmental phase of c-Si PV technology, the continuous feedstock support offered by Si-based electronics industry played a key role in its growth. The high purity and even second-grade wafer materials obtained at a relatively cheaper price proved favorable for PV industry as they led to a reasonable efficiency ( $\eta$ ) figures for standard size modules (average  $\eta > 16\%$ – $18\%$ ) and extremely good performance stability (more than 25 years) that are two essential requirements for any technology to successfully demonstrate its potential for market (Chopra et al. 2004; Jäger-Waldau 2004). However, continuously increasing demand for PV modules and the need for low-cost PV options in the last decade had stretched these advantages to the limit and had exposed some inherent disadvantages of c-Si technology, such as the scarcity of feedstock material, costly processing of materials and device fabrication steps, as well as the inability for monolithic interconnections. These, in turn, had restricted the potential of Si wafer technology and made it difficult to achieve PV module production cost below €1/W (1€ is about U.S. \$1.35), which was considered essential for cost-competitive generation of solar electricity (Hegedus and Luque 2003; von Roedern et al. 2005; Zweibel 2000). However, recently, there has been a dramatic upsurge in the production of c-Si modules in China for the last 2 years, which were made available at and below \$0.6/W and as low as \$0.50/W in some cases. While there is speculation that the low module cost from China perhaps did not reflect the real costs, the fact remains that the PV module prices have seen significant reduction in the recent years. The PV module cost depends on the total manufacturing cost

**FIGURE 45.1**

Comparison of estimated costs achievable with different PV technologies as a function of manufacturing cost (€/m<sup>2</sup>) and conversion efficiency. (Courtesy M. Green, UNSW, Sydney, New South Wales, Australia.)

of the module per square area, conversion efficiency, and long-term performance stability. Figure 45.1 gives an estimate of achievable cost with c-Si technology and comparison with projected achievable costs with other PV technologies. It was generally agreed that c-Si wafer technology would be unable to meet the low-cost targets, while thin-film technologies will have the potential to provide a viable alternative in the near future. However, the cost of modules from China available for as low as \$0.50/Wp recently has made these speculations look very weak as the gap between thin film and c-Si modules has shrunk considerably. Although the thin-film PV still has better potential to lower the cost of modules further, this will require appreciable increase in the energy conversion efficiencies of the technologies, in order to stay in competition with c-Si. Recently, the cost projection by First Solar for CdTe modules has shown a competitive cost of \$0.49/W for the module efficiencies over 14%. It is thus clear that thin-film technologies have to significantly improve their efficiencies in order to stay in competition with c-Si (Osborne 2013). The world record efficiency of 20.4% for small area and 17% efficient CdTe champion modules announced recently by First Solar and 20.9% small area efficiency achieved on CIGS technology by Solar Frontier and 16.4% CIGS modules by Avancis definitely show a great promise in a short span of time.

The PV market although appears to be promising, the share of the technologies remains very difficult to predict. An optimistic and ambitious forecast by Hanergy Solar with their multigigawatt production in a few years' time on a-Si, along with production on CIGS technology as well, provides a projection of about 50% market share by 2018 (Hanergy Annual Report 2013). However, a more conservative approach adopted by NPD Solarbuzz provides a forecast of around 10% share of thin-film technologies by 2020 (Colville 2014).

Figure 45.2 (NREL 2013) summarizes the best laboratory scale (cell area less than 1 cm<sup>2</sup>) efficiencies of some prominent thin-film technologies. Out of these, an efficiency of 20.8% achieved at ZSW (has been improved further by Solar Frontier to 20.9% on CIS recently), with CIGS, makes it the most efficient thin-film PV device that has narrowed the gap further between existing c-Si and thin-film technologies.

Silicon wafers are fragile, solar cell area is limited by the wafer size, and the modules are bulky, heavy, and nonflexible. To overcome some of the problems of c-Si wafer technology, efforts were made to develop monocrystalline and polycrystalline thin-film silicon solar cells on glass substrates, as reviewed by Bergmann (1999). However, these efforts to develop

**FIGURE 45.2**

Development of *champion* thin-film solar cell efficiencies with emerging PV. (Based on Efficiency chart, National Renewable Energy Laboratory (NREL), 2014, <http://www.nrel.gov/ncpv/>.)

efficient crystalline silicon thin films on glass (CSG) have not gained much success over these years and efficiencies have been limited around or just over 10% mark with much more processing costs involved. One of the techniques used to form poly-Si films on glass has been based on solid phase crystallization (SPC) and had resulted in 10.5% efficient cells (Keevers et al. 2007). The open circuit voltage ( $V_{oc}$ ) up to 500 mV was one of the stumbling blocks for its progress. The TU-Hamburg-Harburg and Helmholtz-Zentrum Berlin, Germany, presented a new type of poly-Si thin-film solar cell on glass using electron-beam crystallization (EBC) through liquid phase and have achieved an improved  $V_{oc}$  of 545 mV (Amkreutz et al. 2011). The EBC process is based on a line-shaped electron beam, which is scanned across the silicon layer on glass with a typical rate of 1 cm/s. Recently, an analogue laser crystallization (LC) process has been investigated as an alternative to EBC, using which the University of New South Wales in Australia and Suntech R&D, Australia, have recently reached a new record single-junction efficiency of 11.7% for poly-Si thin-film solar cells on glass (Dore et al. 2014). A current status and some latest developments on CSG have been covered in a report (Becker et al. 2013) recently. It is expected that by using the aforementioned techniques, 15% efficient single junction CSG can be achieved in near future (Rech 2013).

It has been realized that application of thin-film technologies to grow solar cells and modules based on other materials can prove to be an alternative to the silicon-wafer technologies. However, the efficiency of the thin-film PV technologies has to match or exceed the current c-Si technology. Thin-film deposition of materials of required quality and suitable properties depends on the processes used and the control of several parameters. However, once optimized, these methods provide over an order of magnitude cheaper processing cost and low energy payback time, which is certainly a big advantage. For example, even at lower module efficiencies as compared to c-Si, the cost of CdTe modules have lower pay-back time owing to less energy intensive and easier processing steps involved.

Research on alternative to c-Si already started over four decades back, considering that it has low absorption coefficient ( $\sim 10^3 \text{ cm}^{-1}$ ) and its narrow bandgap ( $E_g \sim 1.1 \text{ eV}$ ). Some

**TABLE 45.1**

Bandgap of Different Semiconductor Materials Suitable as Light Absorber in Solar Cells

Compound/Alloys	Bandgap (eV)	Compound/Alloys	Bandgap (eV)
c-Si	1.12	Zn <sub>3</sub> P <sub>2</sub>	1.50
a-Si	1.70	CuInSe <sub>2</sub>	1.04
GaAs	1.43	CuGaSe <sub>2</sub>	1.68
InP	1.34	Cu(In,Ga)Se <sub>2</sub>	1.20
Cu <sub>2</sub> S	1.20	CuInS <sub>2</sub>	1.57
CdTe	1.45	Cu(In,Ga)(S,Se) <sub>2</sub>	1.36
Cu <sub>2</sub> ZnSnS <sub>4</sub>	1.5	Cu <sub>2</sub> ZnSnSe <sub>4</sub>	1.0

of the most interesting semiconducting materials that have received considerable attention are cadmium telluride (CdTe), gallium arsenide (GaAs), indium phosphide (InP), zinc phosphide (Zn<sub>3</sub>P<sub>2</sub>), copper sulfide (Cu<sub>2</sub>S), copper indium diselenide (CIS), copper indium gallium diselenide (CIGS), and copper zinc tin diselenide (CZTS). These all have the electronic and optical properties suitable for the efficient utilization of the sun's spectrum (see Table 45.1 for bandgaps). Multijunction solar cells based on III–V materials (GaAs, InP, GaSb, GaInAs, GaInP, etc.) show high efficiency, exceeding 35%, but due to the high production cost and low abundance of their constituent materials, these solar cells are not considered suitable for cost-effective terrestrial applications though they are still very important for space PV applications.

Thin-film technology has answers and potential to eliminate many existing bottlenecks of c-Si PV programs experienced at different levels from module production to its applications viz. space programs and BIPV. Thin-film PV modules are manufactured on either rigid glass substrates or flexible substrates (thin metallic or plastic foils). Some of the advantages of the thin-film technologies are the following:

- The high absorption coefficient ( $\sim 10^5 \text{ cm}^{-1}$ ) of the absorber materials is about 100 times higher than c-Si (Figure 45.3); thus, about 1–2  $\mu\text{m}$  of material thickness is sufficient to harness more than 90% of the incident solar light. This helps in reducing the material mass significantly to make modules cost effective.
- The estimated energy payback time of the thin-film PV is considerably lower than that of c-Si PV. Estimation suggests that CdTe has the lowest payback time among all PV technologies. With recent improved cell and modules efficiencies of 17%, the payback time could be as low as 6 months.
- The formation of heterojunction and better device engineering for reduction of photon absorption losses and enhanced collection of photogenerated carriers are possible.
- Large-area deposition (in the order of  $\text{m}^2$ ) along with the monolithic integration (interconnection of cells during processing of rigid and flexible devices) is possible that minimizes area losses, handling, and packaging efforts.
- Roll-to-roll manufacturing of flexible solar modules is possible that gives high throughput and thus can further reduce the energy payback time significantly.
- Tandem or multijunction devices could be realized to utilize full solar spectrum to achieve higher efficiency devices. A theoretical limit of 66.7% had been estimated for large number of multiple junction, which can cover the entire spectrum of the sun (Honsberg et al. 2001; Shockley and Queisser 1961).
- Flexible and lightweight PV facilitates several attractive applications.

**FIGURE 45.3**

The optical absorption ( $\alpha$ ) versus photon energy of the c-Si and some of the prominent light-absorbing materials that are used in thin-film solar cells.

Historically, cadmium sulfide and copper sulfide ( $\text{CdS/Cu}_2\text{S}$ ) heterojunctions were one of the early technologies almost contemporary to c-Si but could not survive due to the astounding success of c-Si technology that was efficient, stable, backed by electronic industries and widely supported by space programs. Despite  $\text{Cu}_x\text{S}$  having stability issues, the technology went to pilot production in the late 1970s or early 1980s. But with the advent of a-Si and CdTe thin-film solar cells, it was abandoned before mid-1980s.

Currently, a-Si, CdTe, and CIGS are considered the mainstream thin-film technologies. Out of these, a-Si has suffered some setbacks due to difficulties in improving the stabilized efficiency numbers and bankruptcy issues of the leading company United Solar recently; however, there is a good promise on reemergence of this technology with newer ways of achieving high efficiency in the future. Besides, CdTe and CIGS have not only proven potential to become leading technologies, but they have already achieved significant production capacities around multi-GW per year recently through the efforts of First Solar and Solar Frontier. Currently, the world record efficiencies in both CdTe and CIGS technologies are led by the aforementioned companies.

Figure 45.4 gives the market share of all the leading PV technologies including c-Si based on the cumulative deployment by 2013. Their thin-film market share is about 10%, with CdTe being leader, with 6% share on absolute scale.

Recently, several companies have started production-related activities and production volume is expected to increase during next few years. Recent developments on a new technology on organic and dye-sensitized solar cells (DSSCs), especially solid-state perovskite-based solar cells (a kind of solid state analogue of DSSCs), appear to be quite interesting. The efficiency figures for this technology has taken an unprecedented leap from near 4% in 2009 (Kojima et al. 2009) to 17% in 2014 (Snaith and coworkers 2014; Bennett 2014) (described in a separate section later). These technologies with their low-temperature and cheaper processing cost on flexible substrates (Docampo et al. 2013; Kumar et al. 2013)

make them potentially very attractive for various niche applications. However, there are important issues of instability and degradation, which need to be addressed. Perovskite solar cells are at infancy of their development at the moment and would require considerable efforts and time to come out as a commercially viable option.

Table 45.2 summarizes the current status of thin-film solar cell and module development at laboratory and industrial level on rigid and flexible substrates (with one exception). These contain some latest developments and global efforts to make thin-film PV technology a viable option for cost-effective and competitive electrical energy production.

#### 45.1.2 Cost Potentials and Material Availability Issues

Estimates in the past decade had suggested that solar cell production costs as low as €0.30/W are possible depending on the volume of production (Bruton et al. 1997; Keshner and Arya 2004; Woodcock et al. 1997). At present, there is a significantly large gap between the efficiencies of the solar cells at the R&D level and those at the industrial modules level because of the process scalability-related issues during the early phase of industrial development. The current production cost of the thin-film PV modules is rather high because of low volume of production through pilot-production lines or small capacity (less than 30 MW) plants. However, with larger production volumes and higher module efficiencies, the cost is expected to decrease significantly in near future. It is estimated on the basis of the trend derived from the past experiences of cumulative production versus price variations (learning curve) that the module prices decrease by 20% for every doubling of the cumulative production (Surek 2003). These trends had predicted that with a growth rate of 25%, the cumulative production would reach ~75 GW by year 2020 and the target cost below \$1/Wp was achievable with existing thin-film technologies. It is striking to note that the cumulative production in 2013 was alone close to 140 GW and set to achieve annual production of about 50 GW in 2014 (Burger 2013). More surprisingly, what was not believed

at that time, the c-Si technology has tremendously brought down the module cost to as low as \$0.5/Wp (Metha 2013). An excellent cost estimation and projection of the PV technologies has been made by U.S. Department of Energy (Sunshot Vision Study February 2012), with a mission to achieve future affordable electricity price below grid parity. This in-depth analysis was conducted by the National Renewable Energy Laboratory (NREL) with contributions from the Solar Energy Industries Association, Solar Electric Power Association, and many other related organizations.

Currently, the conventional module assembly procedures used by the c-Si industries and adopted by thin-film industries restrict the overall cost of the thin-film modules. Thus, the advantage of using *less material* in thin-film technology under *back end* schemes of assembling is drastically reduced. Some frameless mounting schemes (PV laminates on membranes) have also been developed and pursued for a-Si technology, which were shown to have potential to bring significant reduction in cost (Arya 2004). Figure 45.5 shows distribution of materials costs in framed (a) and unframed (b) Si-based modules. As may be compared, the cost of packaging and framing components has been drastically lowered from 25.5% to only 4%, which is significant; consequently, the cost reduction in materials and its processing will have more meaning with further advancements in technologies of all the components.

Tuttle et al. (2000, 2005) had given cost estimates of CIGS solar modules from 2 to 2000 MW/year capacity production plants including cost of equipment and materials. Similarly, there are several reviews and reports available that summarize the cost potential of thin-film modules in terms of different component costs and address some future concerns related with the cost and availability of materials: In, Ga, Se, and Te used in the leading thin-film technologies and future electricity generation cost estimation (Gross et al. 2013). An estimate in the subcontractor's report at NREL (Keshner and Arya 2004) suggested a decade ago that the production of these elements had to be accelerated in order to fulfill the demand of 2–3 GW/year generation of electricity.

An important report (out of DoE Solar Energy Technologies Programme and PV FAQ, [www.nrel.gov](http://www.nrel.gov)) also exists (U.S. Department of Energy 2005) that brings the judgment in favor of In, Ga, and Se and speculates that Ga and Se will not be constrained by supply, and a steady production growth rate of 0.16% per year for Se would be sufficient to meet the demand of annual PV production of 20 GW/year by 2050. Furthermore, it is also estimated that In will also keep a steady supply as it is a by-product of Zn, which is relatively higher in abundance and more in demand by various industries. There could be some concern about the availability of Te for multi-GW plants, but with the advancement in thin-film technology, the thickness of the material may be reduced by implementation of

**FIGURE 45.5**

Distributions and breakup of the materials cost in (a) framed and (b) unframed a-Si based modules.

light-trapping schemes, thus relieving the burden on production of materials also through clever and efficient recycling methods. A good account of material scarcity issues (such as the sustainability of Te and In materials) that might arise when the production will reach several tens of GW capacity for the CdTe and CIGS technologies has been addressed by Candelise et al. 2011. The estimations made by the authors after reviewing the literature on claims of In and Te scarcity suggest that there is a high uncertainty in the estimates of the resource-constrained thin-film PV potential as well as in data and methodologies used to assess future availability of the targeted materials. The reviewed evidence does not support the contention that the availability of tellurium and indium will necessarily constrain CdTe and CIGS technologies respectively in their ability to supply expected future PV market growth.

In the following sections, the frontline thin-film technologies such as a-Si, CdTe, and CIGS, along with some of the emerging technologies such as CZTS and recently explored perovskite solar cells, are discussed in detail relating to their material and device aspects, current status, and issues related with environmental concerns.

---

## 45.2 Thin-Film Silicon Solar Cells

### 45.2.1 Material and Properties

The oil crisis of early 1970s gave an impetus to the PV R&D activities and several concepts for thin-film PV started to emerge. The first report on thin-film a-Si based solar cells appeared in 1976 (Carlson and Wronski 1976). It took only 5 years to see the indoor consumer products appearing in the market with this technology in the 1980s, although it took a significant amount of time to understand the basics of the material and device properties and their inherent bottlenecks. Amorphous-Si is now the most studied and applied material for thin-film solar cells as compared to its other counterparts. Silicon has the advantage of the material being in abundance in the earth's crust; therefore, following the trends of c-Si technology, a-Si has developed over the years into an industrially mature technology (Rech and Wagner 1999). Besides, a-Si has several other non-PV applications that provided it an additional standing.

Crystalline Si has long-range atomic ordering extending up to a few centimeters size in the single crystals, whereas a-Si has got short-range atomic ordering of less than 1 nm, and thus, the material is not a crystal. Amorphous silicon has a disordered lattice showing localized tetrahedral bonding schemes but with broken Si–Si bonds of random orientation, as shown in Figure 45.6. These broken (or unsaturated) bonds are called *dangling bonds* and contribute to the defect density in the material. Because of disorder, the momentum conservation rules are relaxed and a higher absorption coefficient ( $\alpha$ ) is observed in a-Si material. The absorption coefficient of a-Si is about two orders of magnitude higher than the c-Si; thus, it only requires a couple of micron thickness for effective absorption and utilization of solar spectrum. However, due to predominant disordered structure, high density ( $\sim 10^{19} \text{ cm}^{-3}$ ) of localized defect states is created within the energy gap that causes the Fermi level pinning, and hence the material cannot be doped because the defect states act as trap for all free carrier generated in the material.

One effective way to overcome this problem is to passivate the unsaturated bonds of a-Si with the help of small size atoms that could get into the crystal and attach themselves

**FIGURE 45.6**

A schematic presentation of tetrahedral bonding scheme in crystalline Si (a) and network of a-Si:H exhibiting broken silicon atom dangling bonds, which are passivated by hydrogen atoms (b).

with the available bonds. This is precisely done by adding 5%–10% atomic hydrogen into a-Si, which attaches itself to the uncoordinated bonds due to its high activity; this reduces the dangling bonds density from  $\sim 10^{19}$  to  $\sim 10^{15} \text{ cm}^{-3}$ . At this order of defect density, the required doping of material is possible, and hence, the material can be made as p- or n-type using boron and phosphorous as dopants. However, the defect density still remains so high that even with high doping, the Fermi level is not significantly shifted; it remains mostly within the donor and defect levels at the center of the gap in the case of n-doping.

Amorphous silicon may be considered as an alloy of silicon with hydrogen. The distortion of the bond length and bond angle after passivation with hydrogen modifies the defect distribution and consequently changes the optical and electronic properties. By changing the deposition conditions (Guha et al. 1981, 1986; Vetterl et al. 2000), hydrogen-diluted microcrystalline silicon ( $\mu\text{c-Si}$ ) can be obtained, which has rather different properties. Figure 45.3 compares the absorption coefficient of the a-Si:H, c-Si, and  $\mu\text{c-Si:H}$  along with some of the other PV materials. The absorption bands (plateau) appearing at low energy values for a-Si:H and  $\mu\text{c-Si}$  are ascribed to the presence of large density of midgap defects and band tail states. The absorption coefficient ( $\alpha$ ) of c-Si (mono-crystalline silicon wafers) and microcrystalline thin-film Si has more or less same onset of transition, but  $\mu\text{c-Si}$  has higher  $\alpha$  in low wavelength ( $\lambda$ ) region. However,  $\alpha$  for  $\mu\text{c-Si}$  is lower than of a-Si; therefore, thicker  $\mu\text{c-Si}$  layers are required compared to a-Si for the absorption of solar spectrum. A stacked combination of the two—microcrystalline and amorphous Si layers—is attractive for absorption of the most useful part of the spectrum in thin layers. This has been successfully employed first by IMT Neuchatel, Switzerland, and later by several other groups to develop a-Si/ $\mu\text{c-Si}$  tandem (also often called *micromorph*) solar cells.

The bandgap of a-Si can also be tailored by addition of O, C, and Ge to produce amorphous materials of wider or narrower bandgaps, for example, with the addition of C and Ge in a-Si:H, bandgaps of 2.2–1.1 eV are achievable but with inferior electronic properties. Table 45.3 provides the list of these alloys with their respective bandgaps. Suitable a-SiC:H and a-SiGe:H for solar cell devices have bandgaps  $\sim 2.0$  and 1.3 eV, respectively.

**TABLE 45.3**

Energy Bandgaps ( $E_g$ ) of Certain Alloys of a-Si:H with Germanium and Carbon Used in Multiple Junction Solar Cell Structures

Material (Semiconductor/Alloy)	$E_g$ min (eV)	$E_g$ max (eV)
c-Si	1.1	1.1
$\mu$ c-Si:H	1.0	1.2
a-Si:H	1.7	1.8
a-SiC:H	2.0 (in 20% C)	2.2
a-SiGe:H	1.3 (in 60% Ge)	1.7
a-Ge:H	1.1	

### 45.2.2 Deposition Techniques

Perhaps the most important feature of a-Si material is that a wide range of temperatures, from room temperature to 400°C, can be used for its deposition. Room temperature deposition allows the use of a variety of substrates, viz., glass, metal, and plastic, and in particular the possibility to use low-cost plastic polyethylene terephthalate (PET) could be of significant advantage in reducing the cost of the modules. There are various processes used for the deposition of the a-Si:H material. Silane ( $\text{SiH}_4$ ), which is the basic precursor gas, is used in nearly all processes using chemical vapor deposition (CVD) method but excluding sputtering that is not preferred for active semiconductor layers in a-Si:H. Typical deposition temperature for a-Si:H has to be below 500°C; otherwise, the incorporation of hydrogen in the film is not possible. At low substrate temperatures, the predissociation of  $\text{SiH}_4$  does not take place easily. Hence, room temperature deposited layers give rise to inferior quality and efficiency. Therefore, plasma is used for dissociation of silane gas. Two most commonly used methods are plasma-enhanced chemical vapor deposition (PECVD) and glow discharge CVD. Typically, 13.56 MHz plasma excitation frequencies with optimal plasma excitation power at 0.1–1 mbar pressure are used.  $\text{SiH}_4$  always diluted with hydrogen (~10%) is used in the deposition of a-Si:H, while increasing hydrogen dilution results in  $\mu$ c-Si:H layers, but with lower growth rates. The typical deposition rates for a-Si cells (in R&D) is ~1 Å/s and results in fairly long deposition times (50 min for 0.3  $\mu$ m thick a-Si:H cell and 5 h for a 1.8  $\mu$ m thick  $\mu$ c-Si:H cell), while 3 Å/s or higher deposition rates are generally preferred in production plants. For high deposition rates, the deposition technologies based on very high frequency (VHF) microwave, and high-pressure plasma are currently being pursued at R&D level. Rates as high as 10 Å/s have been achieved at laboratory scale.

Alternative deposition methods using hot wire CVD (HWCVD) technique, electron cyclotron resonance reactor (ECR), and also the combination of HWCVD and PECVD are also being carried out to increase the deposition rate. A detailed account of some of these techniques can be found in the following references: Carabe and Gandia (2004), Deng and Schiff (2003), Klein et al. (2004), Lechner and Schade (2002), Shah et al. (2004), Shah et al. (2013), and Sopori (2003).

### 45.2.3 Amorphous Silicon Solar Cells and Configurations

The conventional p–n junction configuration for a-Si:H-based solar cells suffers from inherent limitations due to the presence of large number of defect states even after H-passivation.

**FIGURE 45.7**

The schematic representation of single junction a-Si solar cell in superstructure configuration (a) and the energy band diagram of the p-i-n solar cell structure (b). Ethylene vinyl acetate (EVM) is the polymer coating used for encapsulation of solar cell.

The doping of a-Si:H further increases this concentration, which reduces the average lifetime of the free carriers as a result of very high recombination probabilities and low diffusion lengths  $\sim 0.1 \mu\text{m}$ ; thus, solar cells in the p-n configuration do not work and are not considered suitable. The basic structure of a-Si solar cell configuration is a p-i-n junction shown in Figure 45.7a, which illustrates qualitatively the thickness of different layers grown in the device in the *superstrate* configuration along with applied texturing (roughness) of the transparent conducting electrodes for enhanced light trapping in a-Si layer, as will be described later.

The p-i-n type configuration for a-Si solar cell was introduced by Carlson et al. at RCA laboratories, United States (Carlson and Wronski 1976), where an intrinsic (i) layer of a-Si:H is sandwiched between the n- and p-type doped layers of a-Si:H or its alloys. Because of very short lifetime (or high recombination) of the carriers, the doped layers do not contribute to the photocurrent generation, that is, the photons absorbed in these layers contribute to optical losses, but these p- and n-layers build up the electrical field across the i-layer. This electrical field drives the electrons and holes in opposite direction that are photogenerated in i-layer, which essentially acts as the absorber layer in a-Si:H solar cells. The electrical field depends on the doping concentration of p- and n-layers as well as the thickness of the i-layer. Because the p- and n-doped layers do not contribute to the photocurrents and can cause further recombination of the generated carriers before sweeping across the layer, it is essential to minimize their thickness that is typically  $\sim 10\text{--}30 \text{ nm}$ . There is an upper limit to the thickness of the i-layer ( $\sim 0.5 \mu\text{m}$ ), because charge defects reduce the effective field, and thus, if the width of the i-layer exceeds the space charge width, then the extra width would act as *dead* layer without actually contributing to photocurrent.

#### 45.2.3.1 Stability and Recombination Issues in a-Si Solar Cell

The initial results of a-Si cells in the 1970s indicated very promising potential for attaining efficiencies well above 10%. However, it was soon observed and realized that a-Si solar cells suffer from an inherent problem of light-dependent degradation on their performance under continuous light exposure, later attributed to Staebler–Wronski effect (SWE) (Staebler and Wronski 1977). It was observed that in a timescale of a few months, the performance of the cells dropped about 30%–40%, then stabilized at efficiency lower than the initial values. This initial drop in performance is significant and takes the edge off the promise shown by this cheaper alternative to c-Si technology, keeping it much below the efficiency threshold limit (generally accepted ~12% module efficiency for thin-film vacuum-based technologies). An explanation for the light-induced degradation (SWE) is that with light exposure, the Si–H bonds break and further increase the density of the dangling bonds. Thus, the system is driven into an excited or higher energy state, with active defect centers leading to higher recombination of the free carriers and hence reduction in efficiency. The efficiency drop depends on the illumination level and operating temperature of the solar cell. It has been observed that efficiencies may be partially recovered on heating the cells. The heating recovery depends on the temperature of the cells, that is, annealing at 70°C helps in stabilizing the system better than at room temperature.

The control of defect (trap) states and dangling bonds passivation for effective doping of the a-Si:H layers are significant in the a-Si cell's overall design. The first inherent problem of the technology is that the SWE cannot be eliminated but can be reduced by engineering of device structure, for example, by employing a thinner i-layer at the expense of absorption loss. It has been verified by several groups that efficiency degradation in a-Si solar cells and modules with thinner i-layer is lower. The second problem is that the doping of the a-Si leads to an increase of the trap density, leading to a pronounced recombination effects in the device; therefore, limiting the thickness of the doped layers to 10–30 nm is needed for minimized recombination effects. The limits on i-layer and n- and p-doped layer thicknesses together have a direct bearing on the overall device structure and performance stability.

#### 45.2.3.2 a-Si Solar Cell Configurations

An advantage of a-Si is that the solar cells can be grown in both *superstrate* and *substrate* configurations as shown in Figure 45.8. In the *superstrate* configuration, the cell is grown in the p–i–n sequence (starting with p-layer followed by i and n layers) onto a substrate that must be transparent (such as glass), and hence, this configuration is not suitable for metal or highly opaque polymeric substrates. On the other hand, the *substrate* configuration can be grown on any type of substrates that could be rigid glass or flexible metal or polymer foil. It bears n–i–p configuration (cell growth starting with n-layer followed by i and p layers), and the light enters through the last grown p-layer.

Generally, a-Si solar cells on glass are available in the *superstrate* configuration starting with the transparent conducting oxides (TCOs) window having p–i–n layers grown on it followed by another TCO layer and a metallic back reflector layer, as shown in Figure 45.8. One of the leading United States-based companies in a-Si (unfortunately out of business now due to bankruptcy in 2013), United Solar (USOC, formerly USSC), had been using *substrate* configuration for roll-to-roll production of cells on stainless steel (SS) and polymer foils. The layers can be grown in n–i–p or p–i–n sequence but irrespective

**FIGURE 45.8**

Schematic presentation of a-Si solar cell in *superstrate* (p-i-n) configuration (a) and *substrate* (n-i-p) configuration (b).

of the *substrate* or *superstrate* configuration, incident light is allowed through the p-side, as it has higher bandgap than i- or n-parts. Also, because the mobility of holes is smaller as compared to electrons, a thin front p-layer supports hole collection in the device (Rech and Wagner 1999).

The choice of TCO material as well as its electrical and optical properties is not only important for electrical contacts but also for efficient light trapping through the device. Light trapping is essential for efficient performance of a-Si solar cells where device thickness is limited by several inimical factors: for example, thinner i-layer is desired for minimizing light-induced performance degradation. Consequently, the thickness of intrinsic layer that acts as an absorber is generally limited to only ~300 nm, which is not sufficient for absorption of a large part of solar spectrum. In order to effectively utilize the incident photons, the applied strategies are to reduce the reflection through refractive index grading structures for the entire spectral wavelength range cell response and allow multiple scattering of light for enhanced absorption of photons in the i-layer. These are achieved by an antireflection coating used on the glass, where the light enters into the PV module, and also through suitable surface texture of TCO with the feature sizes comparable to the wavelength and application of metal reflectors. For detailed description of TCOs and light scattering, refer to the publications by Goetzberger et al. (2003), Granqvist (2003), Muller et al. (2004), and Shah et al. (2004). TCOs such as  $\text{SnO}_x\text{:F}$ , ITO, and  $\text{ZnO:Al}$  have been extensively used in a-Si solar cells. Some of the requirements for a good a-Si:H solar cells are the following:

- Glass and front TCO should have a high (>80%) transparency over the whole spectral range.
- TCO with a sheet resistance of at the most 10–15  $\Omega/\text{square}$  (high conductivity) to be obtained by enhancing carrier mobility rather than the carrier concentration to minimize free carrier absorption over the near-infrared region.
- TCO layers and doped silicon layers, which do not contribute to photogeneration and collection, should be kept as thin as possible and have very low absorption coefficients.

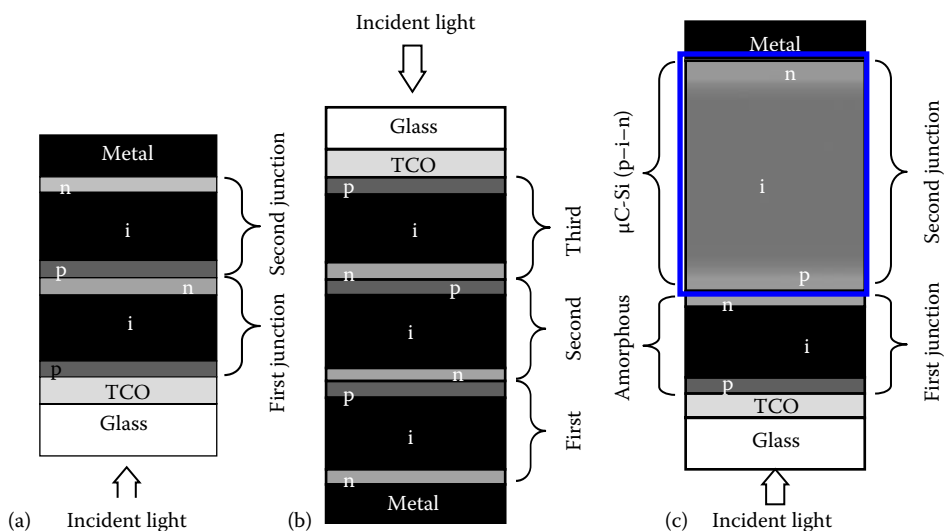

- TCO layer should not degrade by chemical reduction during a-Si:H deposition.
- Use of back reflectors with as little absorption as possible.

The properties of doped and intrinsic layers have been widely studied, and layers are employed in optimized conditions. However, light trapping through various structure and patterns are relatively recent advancements and thus open up much more scope in the improvement of the device performance (Granqvist 2003; Muller et al. 2004). There are other innovations related with device architecture by making use of tandem or multiple junction and heterojunction cells for efficiency and stability improvements, which are discussed in the following sections.

#### 45.2.3.3 Multiple Junction or Tandem Solar Cells

The light-induced degradation (SWE) has become the biggest bottleneck of the a-Si technology and it has serious implications. Besides, the general effects of high density of trap and recombination centers have put restrictions on the thickness of the device layers, which consequently limits the absorption of the incoming light. The clever p–i–n configuration once thought with great promise of good efficiency at cheaper cost was also masked by this instability component. To work within the limits of intrinsic layer thickness of ~300 nm and making use of different light-trapping arrangements, the concept of tandem cells using double and triple junctions has been thoroughly pursued worldwide. Single junction a-Si solar cells are hardly used these days because of low efficiency and stability problems. Multijunction solar cells are used for better utilization of solar spectrum and to improve the stability of the solar cells. The state-of-the-art efficiency for single junction solar cells of small area is 9.3%, while for double junction it is 12.4%, and for triple junction with a-Si:H and its alloys 13.0% efficiency has been achieved (Guha 2004). Figure 45.9 schematically presents different multijunction structures. The developments of multijunction solar cells are based on following strategies:

1. The first strategy for tandem design is based on the use of only a-Si:H intrinsic layers shown in Figure 45.9a. Such double junction devices have been developed by Fuji Electric & Co., Japan, and Phototronics (part of RWE Schott), Germany, and others. A stabilized laboratory efficiency of ~8.5% and module efficiency at about 5.5% are commercially available (Diefenbach 2005; Ichikawa et al. 1993).
2. The second strategy includes the use of a-Si and Ge alloys with different band-gap (lower than 1.7 eV) combinations to form tandem junctions, where the top cell is 1.7 eV a-Si:H based and bottom cells have a-SiGe:H alloy layers of lower (1.5–1.3 eV) bandgaps, as shown in Figure 45.9b. United Solar (USSC) has developed 13% stabilized efficiency triple junction solar cell (small area) in *substrate* configuration and is selling their triple junction modules on SS at stabilized efficiency of about 6.5%.
3. The third strategy introduced in 1994 by IMT Neuchatel, Switzerland, is based on a novel concept of combining  $\mu$ c-Si:H (with a bandgap of 1.1 eV)- and a-Si:H (with a bandgap of 1.7 eV)-based solar cells. This has a promising potential because of significantly reduced light-dependent degradation effect in tandem solar cell (Meier et al. 1994; Shah et al. 2004). The only degradation observed comes from

**FIGURE 45.9**

The schematics of multijunction cell architecture showing double junction *superstrate* configuration (a), triple junction in *substrate* configuration (b), and *micromorph* junction in *superstrate* configuration (c), that is, glass/TCO/p-i-n (a-Si:H)/p-i-n ( $\mu$ C-Si:H).

a-Si part, which is optimized at 0.2–0.3  $\mu\text{m}$ , while the  $\mu\text{C-Si:H}$  layer is kept around 1–2  $\mu\text{m}$ . Figure 45.9c shows the schematic of the design in p-i-n/p-i-n configuration on a rigid glass substrate. Kaneka Corporation, Japan, had achieved large-area modules ( $910 \times 455 \text{ mm}^2$ ) of initial efficiency ~13.2% and with stabilized efficiency approaching toward 10%. Using the concept of intermediate TCO reflector layer for novel light trapping, Yamamoto et al. (2004) have shown an initial efficiency of 14.7% for a test cell. The reason for a good efficiency of the cells lies in the spectral response of the combination of 1.7 eV a-Si:H-based cells and 1.1 eV  $\mu\text{C-Si:H}$ -based second part. The superposition of the two results in a quantum efficiency spreading around 80% between 500 and 800 nm, covering a large part of the solar spectrum.

#### 45.2.3.4 Hybrid Solar Cells

Amorphous silicon cells have been combined with nanocrystalline silicon junction and the cells of other materials, for example, junction with CIGS (Mitchell et al. 1988a; Yamamoto et al. 1998). Another significant development in the design is the formation of a thick/thin type of interface structure (heterostructure) between a-Si:H layer and c-Si wafer referred to as heterojunction with intrinsic thin-film layer (HIT) cells that were developed by Sanyo, Japan. Efficiency close to 21% over a cell area  $101 \text{ cm}^2$  was reported (Sakata et al. 2000) initially with a good promise. This technology uses n-type of Cz-silicon wafer as the base (light absorber) and low-temperature processes with the device structure being a-Si( $\text{p}^+$ )/a-Si(i)/c-Si(n)/a-Si(i)/a-Si( $\text{n}^+$ ). The intrinsic a-Si layer is important as it contacts c-Si at both ends, and provides passivation as well as extra stability to the system. As per reports of Sanyo, the cells had exhibited excellent stability. Subsequently, further improvement in efficiencies was reported by Sanyo crossing 23% mark and recently record efficiency has

been claimed by Panasonic corporation for crystalline silicon-based PV cell of a *practical* size (101 cm<sup>2</sup>) with an efficiency of 24.7%. Japan's Institute of Advanced Industrial Science and Technology has evaluated the efficiency (Gifford 2013).

#### 45.2.4 Flexible a-Si Solar Cells and Modules

##### 45.2.4.1 Monolithic Modules

All solar modules require a number of solar cells to be electrically connected in series to provide power, depending on size and cell efficiency. Additional processing steps such as attachment of leads and encapsulation for protection against external influences are done to finalize the module structure. The *superstrate* configuration has advantages for monolithic electrical interconnection of solar cells to form solar modules since substrate (glass, polymer) is insulating. While in *substrate* configuration individual large-area solar cells are mechanically connected, cell to cell, as done in c-Si technology, USSC, United States, follows this electrical contacting approach for triple junction a-Si solar cells on steel foils.

Figure 45.10 illustrates the monolithic interconnection scheme to develop solar modules in *superstrate* configuration. For interconnection of solar cells, layers are laser-scribed in three stages: first separating front TCO contact, then scribing a-Si layers to connect individual cells, and finally isolating the conducting backelectrode to obtain series interconnection. This approach removes the need for separating and connecting of cells, which is time consuming, costly, and complex in conventional c-Si technology.

##### 45.2.4.2 Flexible a-Si Solar Cells

Another important perspective of thin-film PV technology is the flexible modules that are lucrative owing to their applications related with strategic space and military use, integration in roofs and facades of buildings, portable power source, automobiles, consumer electronics, value-added products, etc. Therefore, the technology has attracted

**FIGURE 45.10**

Schematic presentation of a monolithic module design with a single junction a-Si cell in *superstrate* configuration. Similar strategy can also be used for modules on polymer foils or multijunction solar cells, which may have different sequence of layers.

**TABLE 45.4**

Summary of the Companies Active in Flexible a-Si Thin-Film Si PV. Generally, the Module Efficiencies Are in 3%–8% Range (as in Year 2007)

Companies	Technology	Production	Remarks
United solar <sup>a</sup>	Triple junction SiGe alloys On SS RF-PECVD	30 MW line, RF-PECVD, modules, and consumer products	Modules between 6.5% and 6.8%. Cutting-assembling process modules with 8% for military and space application
VHF-Technology	a-Si on PEN, polyimide VHF-PECVD	Pilot production and consumer products	Product efficiency ~4%
Iowa thin-film technology (ITFT)	a-Si on polyamide, RF-PECVD	Pilot production and consumer products	Product efficiency ~4%
Fuji Electric	a-Si/a-Si on polyamide RF-PECVD	Pilot production and consumer products	Feed-through contacts through the substrates, 7% module, 8% active area stable efficiency
Sanyo	a-Si on plastic RF-PECVD	Consumer products	
Canon	μc-Si:H/a-Si:H on SS (VHF-PECVD)	Development	
Akzo Nobel	Amorphous p-i-n on Al RF-PECVD	Development, pilot line	Al sacrificial substrate dissolved after cell deposition

<sup>a</sup> The company United Solar; the largest a-Si manufacturer went bankrupt in 2013.

recently major players of thin-film PV to venture in this area. Because they can be available in different shades (even semitransparent), shapes, and sizes, these flexible a-Si solar cells once were potential candidates for low-to-medium range of power applications.

Some of the prominent companies that were involved in the production (as on year 2007) and development of flexible a-Si based modules are listed in Table 45.4 (some significant record efficiencies may also be found in Table 45.2). Out of these, United States-based United Solar, Iowa thin films, and Japanese companies like Sanyo and Fuji had entered into relatively large-scale production, while European companies such as Flexcell (Switzerland) and Akzo Nobel (the Netherlands) were also involved in production plants for consumer electronics-oriented market. a-Si offers cheaper processing and materials cost; however, for it to remain as frontline thin-film technology would mainly depend on its efficiency for larger module with high throughput, which is the biggest bottleneck for the technology. Module efficiency above ~12% and a long-term (more than 30 years) stable performance of the large-area modules would make it compete effectively with c-Si and remain the leader among other thin-film counterparts if low-cost modules could be developed with production processes that give high throughput and yield. Oerlikon solar had created a world record of stabilized efficiency of over 10% modules for single junction a-Si solar cells (Benagli et al. 2009). Despite these successes, the lack of dynamism in this technology area had been due to stagnant efficiency of a-Si by most of the manufacturers, while other thin-film technologies are growing faster.

The future of larger-scale amorphous silicon solar panels does not look very bright: Sharp retired 160 out of their 320 MW production capacity in Japan earlier in 2014. Optisolar, Signet Solar, Unisolar, and many other companies that were touting the amorphous technology are acquired, bankrupt, or closed (energyinformative.org). The a-Si technology could return back to gain the thin film market leadership only when the SWE effect of the degradation of cells could be tackled (Fehr et al. 2014; Yu et al. 2014).

Efforts are ongoing in countries around the world to overcome this barrier, especially in Japan where this technology is widely accepted. A good account on the future of a-Si technology was presented at Asian PVSEC meeting in Taiwan (Konagai 2013). Under Japan's NEDO mission PV2030+, the target module conversion efficiencies of a-Si thin-film solar cells are 14% for 2017 and 18% for 2025. To attain these goals, conventional a-Si/ $\mu$ -Si double-junction tandem solar cells must be superseded by triple-junction solar cells. The development targets of triple-junction solar cells include those for a-Si/ $\mu$ -Si/ $\mu$ -Si and a-Si/a-SiGe/ $\mu$ -SiGe structures as well as for the a-Si/a-SiGe/ $\mu$ -Si structure. Under this strategy, two collaborative university–industry research consortia that focus on innovative Si thin-film solar cells have been initiated. One is the *thin-film full-spectrum solar cells* project of METI/NEDO and the other is the *Si nanowire solar cells* project of MEXT/JST. In each project, which involves a study period of 5–7 years, domestic research organizations as well as foreign countries have been included, with a budget that exceeds four billion yen over the entire period.

With a success in the efficiency figures in a-Si technology, Hanergy Solar in China (who are currently producing thin film PV up to 3 GW) along with a few other Chinese companies (who have ambitious plan to use this technology for BIPV and BAPV [Building Attached PV]) have also set their eyes on this technology for enhanced production in coming years. A European roadmap for a-Si technology was built around these factors some time ago with a short-term goal of 15% stabilized cell efficiency from 2008 to 2013, through fundamental understanding of electronic properties of the layers and the interfaces followed by an increase up to 17% by 2020 (Sinke 2007).

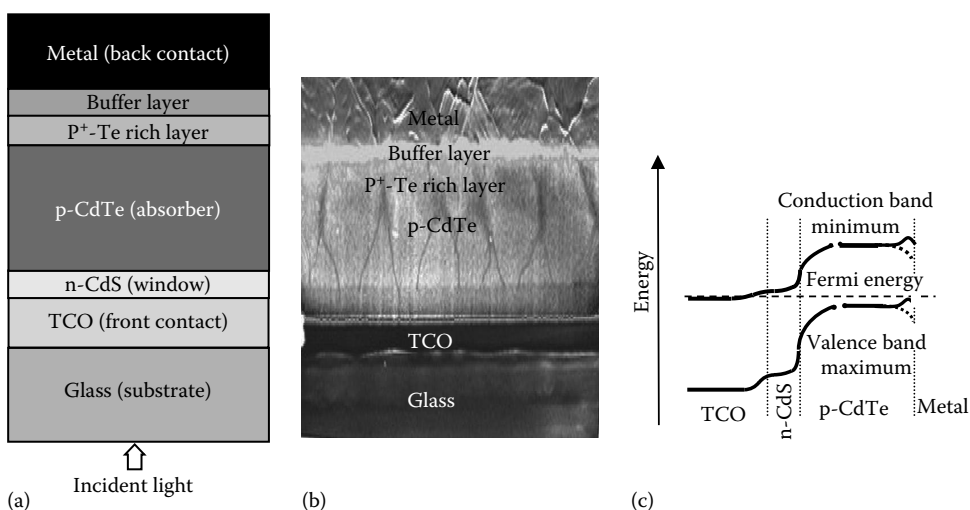

## 45.3 Cadmium Telluride Solar Cells

### 45.3.1 Material and Properties

Cadmium telluride (CdTe) is a direct band-gap material and comes under the family of II–VI materials referred to as metal chalcogenides. Its band-gap energy of  $\sim 1.45$  eV is quite favorable for the requirement of highest conversion of solar spectrum into electricity with a single junction solar cell. Besides, very high optical absorption ( $10^5$  cm $^{-1}$ , see [Figure 45.3](#)) and p-type conductivity make it an ideal material for PV application. It has a *zincblende* crystal structure and a simple phase diagram as the constituents have high vapor pressure. The layers of CdTe can be deposited using a number of processes and the compound can easily be grown in stoichiometric form at temperatures over 400°C. Like other II–VI materials, the electronic doping is controlled by substitution of atoms at vacancy sites. While n-type doping control is relatively easier, it is difficult to vary the doping concentration in p-type CdTe because of compensation effects. The most common CdTe thin-film solar cell structure comprises of a p-type CdTe absorber layer and n-type CdS-based window layer forming a heterojunction, which has an intermixed interface region.

First development of CdTe heterojunction solar cell started around 1962 using n-CdTe in combination with Cu $_x$ Te (Bonnet 2004; Cusano 1963; Lebrun 1966). Though 5%–6% efficiencies were achieved, the cells suffered from degradation due to Cu diffusion from Cu $_x$ Te (similar to CdS/Cu $_x$ S solar cells). A breakthrough in 1972 was achieved when a new heterojunction structure between CdTe and CdS was developed by Bonnet and Rabenhorst (1972) and 6% efficiency was reported. Current solar cell structures are based on the device structure shown in [Figure 45.11](#). By 2001, significant progress had raised the efficiency to

**FIGURE 45.11**

Schematic presentation of CdTe/CdS solar cell in *superstrate* configuration showing different layers and their nomenclature (a), a corresponding SEM picture illustrating different layers (b), and the energy band diagram of the solar cell (c).

16.5% (Wu et al. 2002). Historical developments of CdTe PV technology have been reviewed by McCandless and Sites (2003).

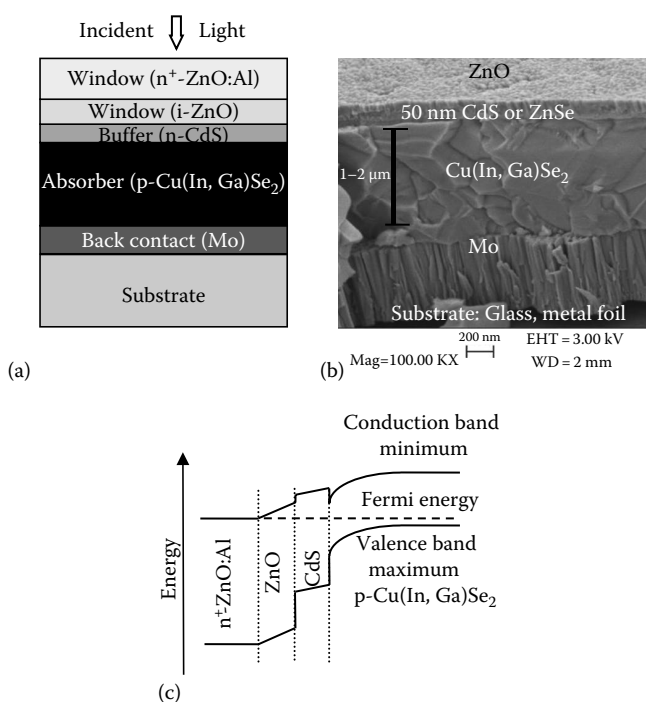

The most attractive features of CdTe compound are its chemical simplicity and the robust stability. Because of its highly ionic nature, the surfaces and grain boundaries (GBs) tend to passivate and are not detrimental (that is a reason that polycrystalline CdTe solar cells are more efficient than single crystal counterpart). CdTe material is inherently stable under solar spectrum since its bonding strength of  $\sim 5.7$  eV is much higher than the incident photon energy of the solar spectrum. This accounts for the excellent material stability and device performance. CdTe is not only stable for terrestrial applications, but it has also been demonstrated that CdTe has excellent stability under high-energy photon and electron irradiation for space applications, superior to Si, GaAs, CIGS, etc. (Bätzner et al. 2004).

Table 45.2 lists the efficiency of the CdTe solar cells reported by laboratories and prominent manufacturers. The theoretical efficiency of CdTe solar cell is estimated by detailed balance calculations to be  $\sim 32\%$  ( $J_{sc} \sim 31$  mA/cm<sup>2</sup> and  $V_{oc} \sim 1.1$  V), which is higher than c-Si; therefore, there is plenty of scope for improvement in the conversion efficiency in the future. Important issues in R&D are shallow acceptor doping of the CdTe absorber, formation of good ohmic contact on p-CdTe, and reduction of optical absorption losses from the CdS and TCO front contact layers. These are some inherent critical issues requiring further investigation to achieve cell efficiency well above 20% with single junction device. Progress of CdTe technology has also been hampered because of perception involving environmental concerns due to cadmium and shall be discussed later in Section 45.7.

### 45.3.2 CdTe Solar Cell Device Structure

The CdTe solar cells can be grown in both *substrate* and *superstrate* configurations. Until today the highest efficiencies have been achieved in *superstrate* configuration. Figure 45.11a gives the schematics of CdTe solar cell grown on TCO-coated glass substrate in a superstrate configuration. The glass substrate can be a low-cost soda lime glass for processing

**FIGURE 45.12**

Schematic presentation of CIGS solar cell in *substrate* configuration (a), SEM cross-section image of CIGS device showing microstructure of layers (b), and the qualitative energy band diagram of CIGS solar cell (c).

temperature below 600°C or alkali-free glass (generally borosilicate) for high-temperature processing above 600°C.

Substrate configuration would allow CdTe to be deposited on opaque substrates such as metal or polyimide foils. Stability of the backcontact especially was believed to be the main limiting factor in this configuration, as CdTe/CdS layers need to be grown at so high temperatures where interdiffusion degrades the CdTe backcontact interface and cells are shunted. Only recently, the substrate configuration was reconsidered and the development of a novel doping method allowed solar cell efficiencies close to 14% (Kranz et al. 2013a) (Figure 45.12).

In the *superstrate* configuration layers of TCO, CdS, CdTe and the metal backcontact are sequentially grown on glass substrates. There are some intermediate processing steps that will be described later. An antireflecting coating on the glass rear surface is often applied to reduce the reflection at the air–glass interface. The incident light passes through the glass, TCO, and CdS and gets absorbed in CdTe layer where it creates electron–hole pairs that contribute to the PV power.

#### 45.3.2.1 TCO Front Electrical Contact

A highly transparent and n-type conducting TCO layer with an electron affinity below 4.5 eV is required to form an ohmic contact and to have good band alignment with n-CdS. Most of the TCOs such as SnO<sub>x</sub>:F, ITO, ZnO:Al, and Cd<sub>2</sub>SnO<sub>4</sub> (cadmium stannate) have been used in combination with a highly resistive and transparent (HRT) layer such as resistive ZnO, SnO<sub>x</sub>, or Zn<sub>2</sub>SnO<sub>4</sub> to grow high-efficiency solar cells (Wu et al. 2002).

The bilayer (combination of high and low resistive TCO stack) is often used to protect against shunts caused by pinholes in thin CdS layers. Most commonly used TCO in industrial production is  $\text{SnO}_x\text{:F}$  and often with a thin ITO layer. ITO front contacts are often sensitive to annealing treatment. An increase in electron affinity from around 4 to 5 eV can be caused by oxidation or PDT.

#### 45.3.2.2 *n-Type Window Layer*

CdS is commonly used as n-type window layer material. The energy bandgap of CdS is 2.4 eV with intrinsic n-type electrical conductivity and it forms a heterojunction with CdTe layer. A typical thickness of as-deposited CdS layer used in solar cells is in the range of 10–500 nm. During high-temperature steps of cell processing, this thickness can be effectively reduced because of interdiffusion with CdTe. A thin CdS layer (10–50 nm) is desired to minimize the photon absorption losses so that maximum number of photons can reach the CdTe layer. However, there has to be a compromise because very thin CdS may lead to a lower open circuit voltage and fill factor through shunting in the device. CdS layers can be grown by different methods such as chemical bath deposition (CBD), evaporation, sublimation, vapor transport (VT), metal organic chemical vapor deposition (MOCVD), and sputtering (Ferekides et al. 1993; McCandless and Sites 2003; Romeo et al. 1999, 2004a).

The relatively low energy bandgap of CdS leads to significant parasitic absorption losses of high-energy photons. Alternative materials with increased energy band-gap values such as oxygenated CdS or Zn(O,S) are under investigation in order to increase the current density toward the theoretical maximum.

#### 45.3.2.3 *CdTe Absorber Layer*

The CdTe thin film is the most important component as it absorbs the incident solar light and contributes to the photogenerated current. Because of its direct band-gap properties, only about 2  $\mu\text{m}$  thick material is sufficient to absorb the most useful part of the solar spectrum. CdTe layers may be grown by a variety of vacuum and nonvacuum methods classified into high-temperature and low-temperature processes. Some of the commonly used high-temperature methods are closed space sublimation (CSS), VT, or vapor transport deposition (VTD) with deposition temperature above 500°C, while methods such as electrodeposition (ED), screen printing (SP), chemical spraying (CS), high vacuum evaporation (HVE), and sputtering with deposition temperature below 450°C are classified under low-temperature processes (McCandless and Sites 2003; Romeo et al. 2004a). Depending on deposition methods, the typical thickness of CdTe layer in solar cells is in the range of 2–6  $\mu\text{m}$ .

#### 45.3.2.4 *Junction Activation Treatment*

The as-deposited CdTe/CdS solar cells always exhibit poor PV properties and thus require a special annealing treatment that improves the cell efficiency considerably (by a factor of 3–5). This is done by subjecting the CdTe/CdS stacks to a heat treatment under Cl–O ambient between 350 and 600°C. This is known as *CdCl<sub>2</sub> treatment* or *junction activation treatment*. After this annealing treatment, a significant enlargement of grain size, by a factor of 5–20, is observed in CdTe grown by low-temperature deposition methods, as can be seen in the [Figure 45.11b](#). The grain size of HVE CdS is in the range of 0.1–0.3  $\mu\text{m}$  and the layers are rough. If the CdS is grown by a CBD, then it consists of small grains of about 0.1  $\mu\text{m}$  widths. A treatment with CdCl<sub>2</sub> recrystallizes the CdS layers so that some of the

small grains coalesce together and form bigger grains of 0.5  $\mu\text{m}$  width (Romeo et al. 2004a). In case of high-temperature grown CdTe, this annealing treatment recrystallization is observed, but the grain size near the top surface does not increase since the grains are already few microns large even in as-deposited condition.

For high-temperature growth processes, there is a tendency of  $\text{CdS}_x\text{Te}_{1-x}$  formation by the conversion of small CdS grains into CdTe due to interdiffusion at the interface and little or low grain growth is noticed after the activation treatment. A stable CdS/CdTe interface can be obtained for 6% diffusion of sulfur atoms. However, under nonequilibrium conditions, the diffusion of S decreases the thickness of the CdS films causing pinholes and eventually leads to shorting paths across the junction. This is a critical problem in CdTe solar cells, restricting the application of thinner CdS as desired to minimize the optical absorption losses. Nevertheless, a thermal treatment of CdS layer prior to CdTe deposition is frequently applied to restrict the interdiffusion of S. The formation of  $\text{CdS}_x\text{Te}_{1-x}$  after activation actually helps in reducing the lattice mismatch between CdS and CdTe but only marginally as compared to improvement in electrical changes induced by Cl, O, and S. Apart from reduction in density of stacking faults and misfit dislocation, there is an overall increase in the shallow-acceptor concentration in CdTe, leading to enhanced p-doping in CdTe after annealing. In particular, the GB regions become more p-doped, owing to preferred GB diffusion and segregation of Cl and O. As a result, increased charge carrier collection efficiency is measured and efficiency increases by a factor of 3–5.

#### 45.3.2.5 Problems of Electrical Backcontact and Stability

An important issue in CdTe solar cell technology is the formation of efficient and stable ohmic contact on p-CdTe layer. For an ohmic contact to form on a p-type semiconductor, the work function of the metal should be higher than the sum of the bandgap and the electron affinity of the semiconductor; otherwise, Schottky contact is formed. For p-CdTe layer, a metal with a work function higher than 5.7 eV is needed since CdTe has a bandgap of 1.45 eV and electron affinity is 4.3 eV. Metals with such high work functions are not available. To overcome this problem, a heavily doped p-CdTe surface is created with the help of chemical etching and a buffer layer of high carrier concentration is often applied. Subsequent postdeposition annealing diffuses some buffer material into CdTe where it changes the band edges as a result of change in the interface state density. Thereby a lowering in interface barrier height and width results, which enables a quasi-ohmic or tunneling contact between the metal and CdTe, as shown in [Figure 45.11c](#). Commonly used buffer layer/metallization combinations are Cu/Au, Cu/graphite, or graphite pastes doped with Hg and Cu. But backcontacts containing Cu in any form are often not stable with time as Cu migration from the backcontact leads to efficiency degradation with time. However, alternate processes were being developed, among them  $\text{Sb}_2\text{Te}_3/\text{Mo}$  and Sb/Mo contacts that have provided high-efficiency and long-term stable solar cells (Abken and Bartelt 2002; Bätzner et al. 2001, 2004; Romeo et al. 2004b).

#### 45.3.3 Deposition Techniques

HVE is a simple deposition method where CdTe and CdS are congruently evaporated from crucible/boats on substrates at 150°C for CdS and ~300°C for CdTe. In this process, the layers are grown in a high vacuum ( $\sim 10^{-5}$  Torr), but the distance between the source material and substrate is kept in the range of 10–30 cm. This allows the use of substrates at relatively lower temperature. Typical deposition rates vary between 2 and 10  $\mu\text{m}/\text{h}$ .

Solar cells of ~12%–16% efficiency have been achieved by Stanford University, United States; ETH Zurich, Switzerland; and IEC, Delaware, United States (Fahrenbruch et al. 1992; McCandless et al. 1999; Perrenoud et al. 2011a).

Sputtering is another process that involves a vacuum system with ionized gases forming plasma discharge, where a CdTe target (a few mm thick plate) attached to one electrode is used as the source material. The energetic ionized atoms from plasma strike the target and remove the material atoms, and consequently, a CdTe layer gets deposited on the substrate, which is placed on the counterelectrode facing the target. Sputtering methods are suitable for large-area deposition in an industrial environment, but because of difficulty in maintaining stoichiometry, they are considered not very suitable for compound semiconductors. However, 14% efficiency has been achieved with this process at University of Toledo, United States (Compaan et al. 2004).

CSS and VT are the prominent and industrially used processes for CdTe deposition owing to its very high rate (2–5  $\mu\text{m}/\text{min}$ ) of deposition. The CSS process consists of an arrangement involving the placement of a graphite crucible with the source material (CdTe compound) in a high vacuum chamber ( $\sim 10^{-5}$  Torr). The CdTe compound sublimates at around 600°C and is deposited onto the substrate, which is kept with a separation of 1–5 mm above the crucible and heated typically above 550°C. Antec Solar GmbH in Germany uses this method for industrial production of  $60 \times 120 \text{ cm}^2$  modules on a 10 MW capacity plant. Parma University, Italy; University of South Florida, United States; and NREL, United States, have also used this method and cells of 15.5%–16.5% efficiency have been achieved. First Solar, United States, uses a variant of CSVT where instead of compound, elemental vapors are used (First Solar 2005; McCandless and Dobson 2004; Romeo et al. 2004c). First Solar is the most successful CdTe company to date with an annual production capacity of approximately 2 GWp for modules on  $60 \times 120 \text{ cm}^2$  glass substrates. First Solar and GE global research have contributed to improve the CdTe-based solar cell efficiency significantly. GE global research has achieved a ground-breaking efficiency of 19.6% on glass substrates. Early 2014, First Solar communicated 20.4% solar cell efficiency and a very remarkable full scale module efficiency of 17% (First Solar 2014).

Details of other alternative methods such as SP, spray pyrolysis, MOCVD, CVD, atomic layer deposition (ALD), and ED may be found in articles (Bonnet and Rabenhorst 1972; Romeo et al. 2004c). For flexible substrates such as polymers low-temperature methods like sputtering, HVE and ED are suitable.

#### 45.3.4 Flexible CdTe Solar Cells

Even though the technology of CdTe solar cells on glass substrates has matured and efficiencies exceeding 17% on module level have been achieved, not much effort has gone in developing these devices on flexible substrates. The R&D on flexible CdTe has been supported by NASA and defense agencies in the United States. Because of high radiation tolerance, superior to conventional Si and GaAs solar cells, against high-energy electron and proton irradiation, these solar cells are also attractive for space applications in addition to terrestrial applications.

Though the CdTe solar cells can be grown in *substrate* configuration, one of the hurdles in the development of high-efficiency CdTe solar cells on metallic substrates is that most of the metal foils do not form efficient ohmic contact with CdTe and it is difficult to incorporate an additional buffer layer as ohmic contact to increase the cell efficiency. The criteria of matching thermal expansion coefficients and work function limit the choice of available substrate materials. Another reason is that during  $\text{CdCl}_2$  annealing treatment, diffusion of

impurities changes the ohmic contact properties. Recently, by optimization of the interfaces and doping methods, flexible CdTe solar cells on metal foil have been realized with an efficiency of 11.5%. On glass substrate, an efficiency of 13.6% has been obtained with similar substrate configuration, which with little bit of more optimization over 16% can provide production avenues of CdTe on a range of both rigid and flexible substrates (Kranz et al. 2013b). Further, latest status and details on the CdTe solar cells development have been reported by Professor Ayodhya Tiwari's group at EMPA, Switzerland (Kranz et al. 2013c).

The choice of an appropriate substrate is a crucial factor for flexible solar cells in the *superstrate* configuration because the substrate should be optically transparent and should withstand the high processing temperature. Most of the CdTe/CdS cell fabrication techniques require temperatures in the range 450–500°C. Therefore, low-temperature (less than 450°C) deposition processes are required. However, NREL (United States) and EMPA (Switzerland) have reported 14.0% and 13.6% efficiency flexible cells on flexible glass and polymer foil, respectively (Kranz et al. 2013d). On polyimide foil first monolithically interconnected minimodules were demonstrated, yielding efficiencies of 8% (Perrenoud et al. 2011b). These devices were grown with HVE method, which is suitable for roll-to-roll deposition, but the concept for industrial production is yet to be demonstrated (Mathew et al 2004; Romeo et al. 2004c).

---

## 45.4 Cu(In,Ga)Se<sub>2</sub> Solar Cells

### 45.4.1 Material and Properties

Compound semiconductors from the I–III–VI<sub>2</sub> series of periodic table, such as CIS, copper gallium diselenide (CGS), and their mixed alloys CIGS, are often simply referred to as *chalcopyrites* because of their tetragonal crystal structure. These materials are easily prepared in a wide range of compositions, and their corresponding phase diagrams have been intensively investigated. Changing the stoichiometry and extrinsic doping can vary their electrical conductivity. However, for the preparation of solar cells, only slightly Cu-deficient compositions of p-type conductivity are suitable. Depending on the [Ga]/[In + Ga] ratio, the bandgap of CIGS can be varied continuously between 1.04 and 1.68 eV. The current high-efficiency devices are prepared with bandgap in the range 1.15–1.25 eV; this corresponds to a [Ga]/[In + Ga] ratio between 20% and 30%. Layers with higher Ga content, as needed to increase the bandgap toward ~1.5 eV, are of inferior electronic quality and yield lower efficiency cells.

Other chalcopyrites such as CuInS<sub>2</sub> and CuInTe<sub>2</sub> were also investigated earlier but cell efficiencies were rather low and the R&D focus was made on CIS. Interest in CuInS<sub>2</sub> resurfaced with the development of ~11.4% efficient cells at HMI Berlin. A spin-off company, Sulfurcell, based in Berlin, started setting up a pilot production line in 2003. The device structure of the CuInS<sub>2</sub> solar cell is quite similar to CIGS solar cells in terms of other constituent layers.

The first CIS solar cell was developed with single-crystal material and ~12% efficiency was reported in 1974 (Wagner et al. 1974) and the first thin-film solar cell was reported by Kazmerski in 1976 by developing ~4% cells obtained with the evaporation of CuInSe<sub>2</sub> material (Kazmerski et al. 1976). The real breakthrough in CIS thin-film technology came with the pioneering work of Boeing Corp., United States, where they used three-source

evaporation of Cu, In, and Se elements and raised the efficiency from 5.7% in 1980 to above 10% in 1982 (Mickelsen and Chen 1981, 1982). Despite the apparent complexity of material system, this efficiency jump clearly showed promising potential of the material. Later in 1987, Arco Solar, United States, raised the cell efficiency to ~14% by using a different CIS deposition process where stacked metal layer was selenized under  $\text{H}_2\text{Se}$  ambient (Mitchell et al. 1988b). Subsequent improvements in efficiency were attained by the EUROCIS consortium in Europe and later at NREL, United States, who reported efficiency of ~19.5% (Ramanathan et al. 2003). Efficiency improvements over the Boeing process occurred due to addition of Ga and S for band-gap engineering, addition of Na in absorber layer, optimization of the n-CdS (hetero-junction part of the cell), and transparent front electrical contact layers.

The first industrial production of CIS modules was started by Siemens (later Shell solar) based on the Arco Solar technology, whereas other companies such as Wurth Solar and Global Solar started development of CIS solar modules using coevaporation methods. Several other companies have been investigating various other methods of deposition such as paste printing, ED, etc. but up to now, these technologies have been less successful as compared to vacuum-based technologies.

The phase diagram of the ternary compound is described by pseudobinary phase diagram of the binary analogue, for example,  $\text{Cu}_2\text{Se}$  and  $\text{In}_2\text{Se}_3$  phase for  $\text{CuInSe}_2$  ternary. Single-phase chalcopyrite  $\text{CuInSe}_2$  exists at small copper deficiency, whereas for Cu-rich compositions, a mixed phase of  $\text{Cu}_x\text{Se}$  with  $\text{CuInSe}_2$  forms that is not suitable for PV devices. For In-rich compositions, defect-chalcopyrite phase ( $\text{CuIn}_3\text{Se}_5$ ) forms, that is generally n-type. Despite an apparent complicated crystal structure and multicomponent system, the material properties of the PV relevant compounds are fault tolerant and not particularly affected by minor deviations from stoichiometry in Cu-deficient range. Further, surfaces and GBs in CIGS compounds are easy to passivate, resulting in high-efficiency cells even with submicron grain-size materials.

The PV grade Cu-deficient CIGS material has a tetragonal crystal structure having vacancies and interstitials, which act favorably, especially because the material is self-healing, owing to the defect relaxation caused by highly mobile Cu-ions and its interaction with vacancies. Defects created in CIGS by external influence (e.g., radiation) are immediately healed up. This is an inherent advantage of the CIGS material, leading to highly stable CIGS solar cells. However, care must be taken for proper encapsulation of devices against highly damped conditions; otherwise, the degradation of electrical contacts (TCO or Mo) in moisture can lead to minor degradations in performance. Therefore, stability of encapsulated CIGS solar cells is not a problem as proven by field tests conducted by ZSW, Shell, and NREL. CIGS is also tolerant against space radiation being superior to Si, and GaAs single crystal cells, but somewhat inferior to CdTe.

#### 45.4.2 CIGS Solar-Cell Configuration

The CIGS solar cells can be grown in both *substrate* and *superstrate* configurations, but the *substrate* configuration gives the highest efficiency owing to favorable process conditions (Figure 45.12). *Superstrate* structures were investigated in the early 1980s, but efficiency was below 5%. However, recent efforts have improved the efficiency to ~13%. This has been possible with the introduction of undoped ZnO instead of CdS buffer layer and coevaporation of  $\text{Na}_x\text{Se}$  during the CIGS deposition. Further, bifacial CIGS solar cells with both front and rear transparent conducting contacts were also investigated (Nakada and Mizutani, 2002; Nakada et al. 2004).

#### 45.4.2.1 Electrical Backcontact

CIGS solar cells in substrate configuration can be grown on glass as well as metal and polymer foils. Molybdenum (Mo), grown by sputtering or e-beam evaporation, is the most commonly used electrical backcontact material for CIGS solar cells. The growth of the solar cell starts with the deposition of Mo on the substrate, which forms an electrically conducting backelectrode with CIGS. When CIGS is grown on Mo, an interface layer of MoSe<sub>2</sub> is automatically formed, which helps in ohmic transport between CIGS and Mo. Recently, alternative backcontact materials have been explored, but industrial production is still based on Mo layers.

#### 45.4.2.2 CIGS Absorber Layer

Because of a high absorption coefficient, a 2  $\mu\text{m}$  thick layer is sufficient for absorption of maximum incident radiation. CIGS layers can be grown with a variety of deposition methods (as described later). Although the grain size and morphology (surface roughness) depends on deposition methods, high efficiencies >13% have been achieved with most of the methods, which indicate that GBs in CIGS are benign and can be easily passivated. High-efficiency cells have p-type Cu(In,Ga)Se<sub>2</sub> bulk, while a defect-chalcopyrite Cu(In,Ga)<sub>3</sub>Se<sub>5</sub> phase in the form of thin layer segregates at the top surface that is n-type especially when doped by cation atoms diffusing from the buffer layer. It is believed that this inverted surface, leading to p–n homojunction in CIGS absorber, is crucial for high-efficiency cells.

#### 45.4.2.3 Buffer Layer

Several semiconductor compounds with n-type conductivity and bandgaps between 2.0 and 3.4 eV have been applied as a buffer to form a heterojunction in CIGS solar cells. However, CdS remains the most widely investigated buffer layer, as it has continuously yielded high-efficiency cells on different type of absorber layers. CdS for highest-efficiency CIGS cells is commonly grown by CBD, which is a low-cost, large-area process. However, its incompatibility with in-line vacuum-based production methods is a matter of concern. Although CBD-grown CdS serves as a reference for highest efficiency, physical vapor deposition (PVD)-grown CdS layers yield lower efficiency cells. Thin layers grown by PVD often do not show uniform coverage of CIGS and are less effective in chemically engineering the interface properties between the buffer and the absorber. The trend in buffer layers has been to substitute CdS with *Cd-free* wide-bandgap semiconductors and to replace the CBD technique with in-line-compatible processes. Alternative materials such as In<sub>2</sub>S<sub>3</sub>, ZnO, ZnS, ZnSe, etc. using different methods viz. PVD, RF sputtering, metal organic chemical vapor deposition (MOCVD), ALD, or a novel technique called ion layer gas reaction (ILGAR) have been explored (Bhattacharya and Ramanathan 2004; Chaisitsak et al. 2001; Ohtake et al. 1995; Olsen et al. 2002; Spiering et al. 2003). A record efficiency of 20.9% has been achieved for CBD-Zn(O,S) buffer layer by Solar Frontier (2014). Most industries are currently using CBD-CdS, but Solar Frontier has shown 17.8% efficiency on 819 cm<sup>2</sup> submodule developed with CBD-grown ZnS(O,OH) buffer layers (Nakamura et al. 2012).

#### 45.4.2.4 Front Electrical Contact

TCOs with bandgaps of above 3 eV are the most appropriate and have become the ultimate choice for front electrical contact due to their excellent optical transparency

(greater than 85%) and reasonably good electrical conductivity. Today, CIGS solar cells employ either ITO or, more frequently, RF-sputtered Al-doped ZnO. A combination of an intrinsic and a doped ZnO layer is commonly used. Although this double layer yields consistently higher efficiencies, the beneficial effect of intrinsic ZnO is still under discussion. Doping of the conducting ZnO layer is achieved by group III elements, particularly with aluminum. However, investigations show boron to be a feasible alternative because it yields a high mobility of charge carriers and a higher transmission in the long-wavelength spectral region, giving rise to higher currents. For high-efficiency cells, the TCO deposition temperature should be lower than 150°C in order to avoid the detrimental interdiffusion across CdS/CIGS interface. RF sputtering is not considered suitable for industrial production; therefore, alternative sputtering and CVD methods are investigated and used.

#### **45.4.2.5 Sodium Incorporation in CIGS**

One of the breakthrough in CIGS PV technology happened when the alumina or borosilicate glass substrate was replaced by soda-lime glass to match the thermal expansion coefficients, which resulted in substantial efficiency improvement (Hedström et al. 1993). It was subsequently realized that sodium (Na) plays an important role in high-efficiency CIGS solar cells because it affects the microstructure (grain size), and passivates the GBs, leading to changes in electronic conductivity by up to two orders of magnitude. The overall effect is efficiency improvement primarily because of an increase in the open circuit voltage ( $V_{oc}$ ) and fill-factor (FF) of the solar cells. Most commonly, Na is introduced into CIGS by diffusion from the soda-lime glass substrate during the absorber deposition. However, sodium incorporation from such an approach is neither controllable nor reliable; therefore, alternative methods to add Na from external sources are used either during or after the deposition of CIGS layers. These methods include the coevaporation or the deposition of a thin precursor of a Na compound such as NaF, Na<sub>2</sub>Se, or Na<sub>2</sub>S for CIGS on Na-free substrates, which include soda-lime glass covered with barrier layers Al<sub>2</sub>O<sub>3</sub>, Si<sub>3</sub>N<sub>4</sub>, etc. as used by Shell Solar (Kessler and Rudmann 2004). These barrier layers inhibit sodium diffusion from the glass substrate. CIGS on flexible substrates (metal and polyimide foils) also need controlled incorporation of sodium, which is provided from a precursor layer applied prior or after the CIGS growth as PDT.

#### **45.4.2.6 Potassium Incorporation in CIGS**

Another breakthrough in CIGS PV technology happened when potassium was introduced in a controlled manner. Results on enameled steel substrates, which contain a high amount of potassium, indicated a beneficial effect of potassium on the device performance (Wuerz et al. 2012). These observations inspired the development of a PDT where KF is evaporated onto the finished CIGS absorber layer in the presence of selenium, which led to a new record efficiency of 20.4% (Chirilă et al. 2013). Remarkably, this has been achieved with a low-temperature process on flexible polyimide substrate. The KF PDT induces a surface modification of the CIGS, resulting in a copper depletion and Cd enrichment. Introduced in the high-temperature process, the KF PDT enabled further efficiency improvement to 20.5% (Stolt 2014) and 20.8% (Jackson et al. 2014).

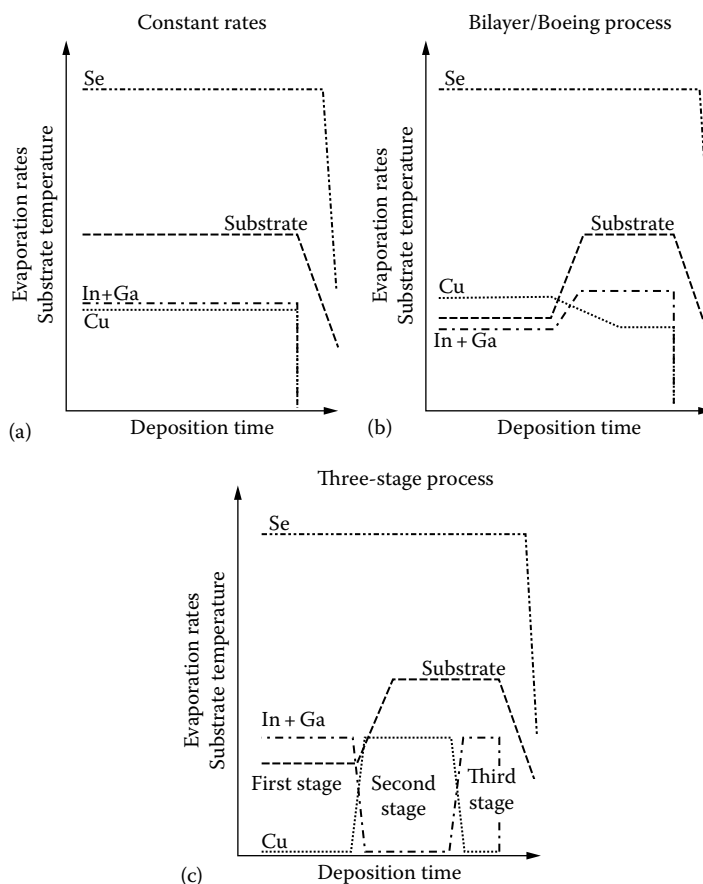

### 45.4.3 Deposition and Growth of CIGS Absorber

There are number of processes used for the deposition of the CIGS thin films, some of them are briefly described:

#### 45.4.3.1 Coevaporation Processes

As described earlier, vacuum evaporation is the most successful technique for deposition of CIGS absorber layers for highest-efficiency cells. Vacuum evaporation method involves simultaneous evaporation of the constituent elements from multiple sources in single or sequential processes during the whole absorber deposition process. While a variation of the In to Ga ratio during the deposition process leads to only minor changes in the growth kinetics, the variation of the Cu content strongly affects the film growth. Thus, different coevaporation growth procedures are classified by their Cu evaporation profile (Figure 45.13).

One variant of coevaporation is a bilayer process (also called the *Boeing process*), which originates from the work of Mickelsen and Chen (1982) and yields larger grain sizes

**FIGURE 45.13**

Diagram representing the recipes in the coevaporation processing steps in the deposition of  $\text{Cu(In,Ga)Se}_2$  used for (a) constant rate, (b) bilayer or Boeing, and (c) three-stage process.

compared to the constant rate (single stage) process. This is attributed to the formation of a  $\text{Cu}_x\text{Se}$  phase during the Cu-rich first stage that improves the mobility of group III atoms during growth.

The highest efficiencies in laboratories are achieved with the so-called *three-stage* process, introduced by NREL, United States (Gabor et al. 1994). With this process CIGS layer is obtained by starting the deposition of an  $(\text{In,Ga})_x\text{Se}_y$  precursor, followed by the codeposition of Cu and Se until Cu-rich overall composition is reached, and finally, the overall Cu concentration is readjusted by subsequent deposition of In, Ga, and Se. CIGS films prepared by the three-stage process exhibit a large-grained smooth surface, that reduces the junction area and is thereby expected to reduce the number of defects at the junction and yield high efficiency. Several groups worldwide have developed 16%–20.8% efficiency cells using CIGS grown with three-stage process.

#### 45.4.3.2 Selenization of Precursor Materials

This is another approach of obtaining CIGS thin films. This sequential process is favorable due to its suitability for large-area film deposition with good control of the composition and film thickness following the initial success of Arco Solar in 1987. Such processes consist of the deposition of a precursor material obtained by sputtering, evaporation, ED, paste printing, spray pyrolysis, etc. followed by thermal annealing in controlled reactive or inert atmosphere for optimum compound formation via the chalcogenization reaction as illustrated in Figure 45.14. The precursor materials are either stacked metal layers or a stack of their compound and alloys. Shell Solar, United States, and Solar Frontier (Showa Shell), Japan, use sputtering technique for precursor deposition and production of large-area solar modules up to  $60 \times 120 \text{ cm}^2$ , yielding maximum efficiencies of 13% on  $30 \times 30 \text{ cm}^2$  modules (Karg 2001; Kushiya et al. 2003; Palm et al. 2004).

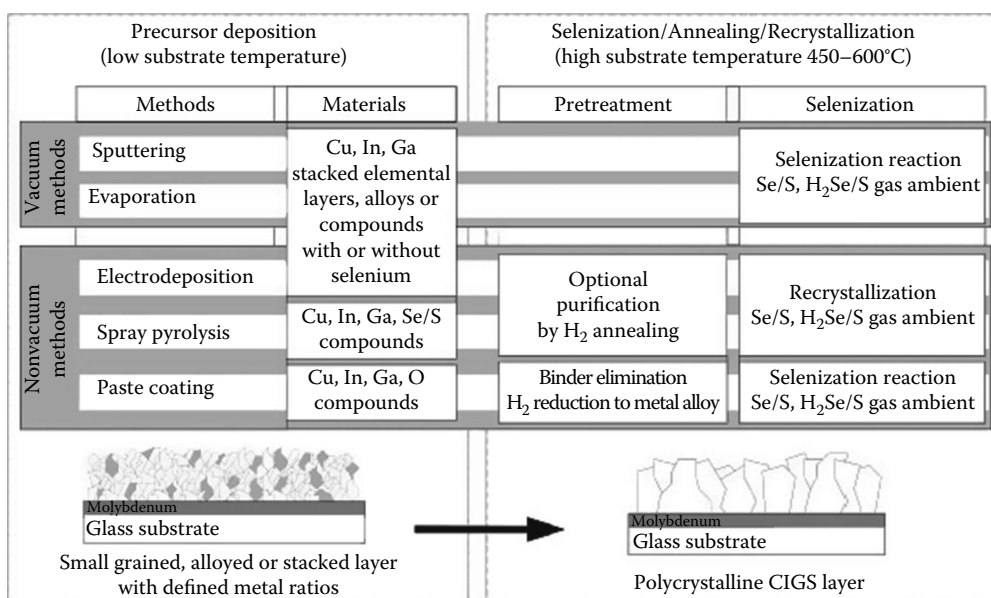

FIGURE 45.14

Schematic of the various processes for selenization of precursor materials.

#### 45.4.3.3 Alternative CIGS Growth Processes

There is a substantial interest to use nonvacuum methods for CIGS deposition. An innovative approach utilizes the stability of the oxides to produce nanosized precursor particles (Eberspacher et al. 2001; Kaelin et al. 2004; Kapur et al. 2001). Nanosized metal oxides are mixed in an ink suspension that allows low-cost, large-area deposition by doctor blading, SP, or spraying of the precursor. Such nonvacuum deposition of precursors allows a very efficient material utilization of almost 100% of the nonabundant metals indium and gallium. A selenization treatment converts precursor into CIGS layer, and solar cell efficiencies of over 13% have been achieved by ISET, United States. One of the drawbacks of the process is the toxicity of the  $\text{H}_2\text{Se}$  gas used for selenization. However, recent efforts are being made to selenize printed precursors with Se vapors (Kaelin et al. 2004).

The CIGS compound can also be formed directly by ED from a chemical bath (Hodes et al. 1986). Several groups including EDF-CNRS, France; CIS solar technologies, Germany; CISCuT, Germany, etc. have been using such approaches and obtained cells with efficiencies around or greater than 10% viz. 9.4% from single pot ED (Duchatelet et al. 2012) and 13.4% aperture efficiency on flexible foil achieved by Solo Power (Osborne 2012). Nexcis, France, reported an efficiency of 15.9% with ED followed by an RTP selenization treatment (Bermudez 2013).

The European consortium SCALENANO, which has received around EUR 7.5 million in EU funding, is scheduled to complete its work in July 2015. The consortium applies innovative process based on the ED of nanostructured precursors, as well as alternative processes with very high potential throughput and process rates. The researchers have demonstrated the scalability of ED-based processes for the synthesis of very homogeneous large areas of thin-film chalcogenide absorbers with medium-area solar modules with cell efficiency of 15.4% ([http://cordis.europa.eu/news/rcn/36210\\_en.html](http://cordis.europa.eu/news/rcn/36210_en.html)). With a hybrid approach that uses additional vacuum deposition on electrodeposited precursor layer, efficiencies as high as 15.4% have been achieved at NREL, United States.

#### 45.4.4 Flexible CIGS Solar Cells

Probably the ultimate advantage of thin-film technology is the application of roll-to-roll manufacturing for production of monolithically interconnected solar modules leading to low energy payback time because of high-throughput processing and low cost of overall system. A large number of activities on highly efficient, stable, and flexible thin-film modules based on CIGS have recently drawn much interest for flexible solar cells on metal and plastic foils. Apart from the expected high-efficiency and long-term stability for terrestrial applications, flexible CIGS has excellent potential for space application because of their space-radiation-tolerant properties, which are two to four times superior to the conventional Si and GaAs cells. Lightweight and rollable solar array structures will not only reduce the overall cost of space-deployable solar modules but also can substantially save on the launching cost of satellites.

Development and current status of flexible CIGS solar cells have been reviewed by Kessler and Rudmann (2004). Flexible CIGS cells can be grown on polyimide and on a variety of metals, for example, SS, Mo, Ti, etc. Therefore, the choice of substrate is important as there are some advantages and disadvantages: (1) The density of usable metals is four to eight times higher than polymer; therefore, cells on metals are heavier. (2) Metals are conducting and have rough surfaces; therefore, monolithic module development is difficult, which in contrast is easier on

polymer foils. (3) SS foils need an extra barrier layer against detrimental impurity (e.g., Fe) diffusion of the metal into the CIGS during deposition. (4) Metal foils can withstand high deposition temperatures (550–600°C), which leads to higher efficiency than on polymer foils, which are not suitable for processing temperature greater than 450°C.

High record efficiencies of flexible CIGS solar cells are 17.7% (Pianezzi et al. 2012) on SS, 18.6% on enameled steel (Powalla et al. 2014), and 20.4% on polymer foil (Chirilă et al. 2013). Several research groups and industries are involved in the development of flexible solar cells; a recent review of the technological status of CIGS-based PVs including activities on flexible substrate is given by (Reinhard et al. 2013) EMPA, Switzerland. The solar modules on SS foils are not monolithically connected; they are made by connecting individual cells into large-area cell with an overlap method. The basic schematic cross-section of a monolithic module on glass is shown in Figure 45.15 along with a flexible prototype minimodule developed on polymer foil by ZSW and ETH, Zurich (research group relocated to EMPA, Switzerland), within a European collaborative project.

Table 45.5 gives an overview of different flexible solar cell technologies, including the organic and TiO<sub>2</sub>-based dye-sensitized PV technologies. Because of the late start in R&D, flexible CIGS and CdTe solar cells are industrially less mature compared to a-Si cells. However, high cell efficiency and inherent stability advantages indicate promising potential for these technologies.

**FIGURE 45.15**

Flexible monolithic CIGS modules showing a prototype minimodule on a polymer foil (a) and schematic cross-section of the module (image taken from the website of ZSW) exhibiting the material component layers and their interconnect patterns (b).

**TABLE 45.5**

Overview of Different Flexible Solar Cell Technologies

	CIGS	CdTe	Amorphous Silicon	Organic and Titanium Oxide
Lab efficiency on plastic foil	20.4% (Single junction cell)	14% (Single junction cell)	9.8% (Single junction cells) <sup>a</sup> 8% <sup>a</sup> –12% <sup>a</sup> (multijunction cell)	5%–8%
Lab efficiency on metal foil	18.7% <sup>b</sup> (single junction cell)	11.5% (single junction cell)	14.6% / 13% (multijunction cell)	
Industrial efficiency (typical values)	10%–14%	Not yet demonstrated	4%–8% <sup>a</sup> (available on plastic and metal foils)	Not yet demonstrated
Stability under light	Material stable	Material stable	Degrades	Stability not proven

<sup>a</sup> Initial values measured before light-induced degradation of solar cells.

<sup>b</sup> Value not certified.

## 45.5 $\text{Cu}_2\text{ZnSn}(\text{S}, \text{Se})_4$ or CZTS Solar Cells

Currently, CdTe and CIGSSe technologies dominate the thin-film PV market with 1 GW/year production capacity barrier surpassed first time for CdTe devices in 2009 by First Solar (Wolden et al. 2011) and for CIGSSe in 2011 by Solar Frontier (Hering 2011). Despite the impressive growth rates in these technologies, two issues—absorber layer component abundance (scarcity of indium and tellurium) and toxicity (heavy metal cadmium)—represent potential road blocks for pervasive deployment of these thin-film chalcogenide-based PV technologies. For the aforementioned reasons, there has been strong motivation to find alternatives to the two leading thin-film chalcogenide absorbers that use low-cost, abundant elements. In this context, various absorbers that use earth-abundant metals such as SnS (Ramakrishna Reddy et al. 2006),  $\text{FeS}_2$  (pyrite) (Smestad et al. 1990),  $\text{Cu}_2\text{S}$  (Martinuzzi 1982), and  $\text{Cu}_2\text{ZnSn}(\text{S}, \text{Se})_4$  (CZTSSe) (Barkhouse et al. 2012) have been explored. The current status of CZTSSe technology and its development has been summarized by EMPA group in Switzerland (Fella et al. 2013). Among these, only  $\text{Cu}_2\text{S}$  and CZTSSe have exceeded the lower performance efficiency limit for commercial interest of 10% (Barkhouse et al. 2012; Hall et al. 1981) when compared with CIGSSe and CdTe, which have achieved 20.9% (Solar Frontier 2014) and 20.4% (First Solar 2014) efficiency values, respectively, for individual devices. However,  $\text{Cu}_2\text{S}$  technology was dropped from serious consideration in the 1980s owing to device instability arising from facile Cu diffusion into the semiconductor layers, leading to degradation of the device junction. Despite being in its infancy, CZTSSe technology can be considered a current favorite in terms of prospective Earth-abundant metal systems to supplement the existing CIGSSe and CdTe technologies, in the quest for more ubiquitous solar energy deployment.

### 45.5.1 Material and Properties

CZTSSe has a number of useful properties that could lead to its massive use as an abundant, nontoxic, and low-cost absorber for thin-film PV solar cells. It is a compound semiconductor whose intrinsic point defects lead to its p-type conductivity. It has a direct bandgap and has an absorption coefficient greater than  $\sim 10^4 \text{ cm}^{-1}$ , suitable for thin-film PVs applications (Chan et al. 2010; Ito and Nakazawa 1988; Xinkun et al. 2012). Its bandgap can be tuned to lay in the range 1.0 eV for  $\text{Cu}_2\text{ZnSnSe}_4$  and 1.5 eV for  $\text{Cu}_2\text{ZnSnS}_4$  (Chen et al. 2009; Timmo et al. 2010). The bandgap of CZTSSe can also be tuned by incorporation of Ge and Ge-containing materials having smaller bandgap than their Ge-free counterparts (Ford et al. 2011). This tenability is of particular interest for the manufacturing of absorbers with a bandgap between 1.1 and 1.5 eV, which allow theoretical efficiencies higher than 30% (Shockley and Queisser 1961). The knowledge gathered from CIGS solar cells fabrication could be tuned and adapted directly for CZTS solar cells. The GBs seem to have the same beneficial properties for CZTS as for CIGS, such as enhanced minority carrier collection taking place at the GB (Li et al. 2012).

### 45.5.2 CZTS Solar Cell Configuration

Since the CZTS solar cell configuration is similar to that of the CIGS (or CIGSSe) (already described in the previous sections), the present section would avoid going into the details about the same.

Although CZTS single crystals had been grown and analyzed in 1967 (Nische et al. 1967), however, the PV effect of the CZTS films was reported only in 1988 (Ito and Nakazawa 1988). The fabricated heterodiode consisted of a transparent cadmium-tin-oxide thin film and a CZTS thin film on an SS substrate. An open-circuit voltage of 165 mV was obtained with the device. In 1997, Friedlmeier et al. fabricated thin-film solar cells using a CZTS layer as the light absorber in contact with an n-CdS/ZnO window layer. The best energy conversion efficiency produced by the cells was 2.3%. This record was later broken by Katagiri's group in 1999 that produced a CZTS solar cell with 2.63% power conversion efficiency. In this cell, the CZTS film was deposited on a Mo-coated soda lime glass (SLG) substrate. By optimization of the sulfurization process, the efficiency of the solar cells was increased to 5.45% in 2003, and then to 6.7% in 2008. Two review papers regarding the efficiency milestones achieved in CZTS-based thin-film solar cells were reported by Katagiri (2005) and Katagiri et al. (2009a), respectively. Todorov et al. (2010) reported 9.6% efficient CZTS-based thin-film solar cells. In this cell, the CZTS thin film was partly selenized to have a broader spectral photoresponse. The current record value of 11.1% is reported by Barkhouse et al. (2012). Figure 45.16 gives the power conversion efficiency in the record CZTSSe thin-film devices versus year, showing constant progress in the technology.

CdS has been observed to have suitable band offset with CZTS, and until now, the most efficient solar cells were obtained with a CdS buffer layer (Nagoya et al. 2011). At the absorber/buffer interface, CZTS is Cu poor, similar to CIGS (Bär et al. 2011). Moreover, sodium incorporation seems to have the same effects on CZTS as in CIGS. It promotes the growth of larger grains, enhances conductivity, and has a significant effect on film morphology, as was demonstrated by SLG/borosilicate substrate comparison and dipping in Na<sub>2</sub>S (Hlaingo Oo et al. 2011; Prabhakar and Jampana 2011). However, Na diffusion in CIGS

**FIGURE 45.16**

Power conversion efficiency in the record CZTSSe thin-film devices versus year, showing consistent progress. Data for pure sulfur-containing materials (CZTS) are represented by circles, whereas data for kesterites in which Se has been introduced are represented by triangles. The laboratories responsible for each record are Nagaoka Nat. College of Technology (black), University of Stuttgart (white), and IBM Corp. (gray). The dotted arrow is a guide to the eye. (From Mitzi et al. 2013.)

is observed to be larger than in CZTS. It is interesting to note that oxidation of the CZTS absorber by dipping in deionized water (Katagiri et al. 2009a) or O<sub>2</sub> annealing (Repins et al. 2012) before deposition of CdS seems to improve efficiencies. As for CIGS, reducing the time between absorber synthesis and CdS deposition to the minimum is of utmost importance (Grenet et al. 2012).

### 45.5.3 Deposition and Growth of CZTS (CZTSSe) Absorber

The investigations on the phase equilibrium in the Cu<sub>2</sub>S-ZnS-SnS<sub>2</sub> system showed that single phase CZTS crystals is a challenge as it can only be grown in a very narrow region (Oleksyuk et al. 2004). Secondary phases such as ternary and quaternary compounds are much easier to form than CZTS. Therefore, it is quite challenging to deposit CZTS thin film without the significant presence of secondary phases. Moreover, in contrast to CIGS, the elements in CZTS synthesis are prone to evaporation and sublimation. Zn sublimates at 430°C (Teeter et al. 2011), SnSe at 350°C (Redinger et al. 2011a), and SnS at 370°C and Sn evaporates at 400°C (Weber et al. 2010; Yoo et al. 2012). Moreover, high temperatures promote CZTS decomposition that can be avoided by atmosphere control (Redinger et al. 2011b).

The possibility of replacing the rare In with readily available Zn and Sn while retaining key semiconductor properties, such as nearly identical bandgap to the highly successful chalcopyrite absorbers, makes CZTSSe particularly attractive for large-scale PV production. This potential has given significant research impetus not only toward the fabrication of higher performance CZTSSe devices with traditional vacuum deposition techniques such as sputtering and coevaporation but also to explore a variety of alternative lower-cost and high-throughput fabrication approaches. Some of these alternative methods include spray pyrolysis, ED, photochemical deposition, *monograin* deposition, and direct liquid-coating techniques, including pure-solution, particle-based, and hybrid slurry ink deposition. The details of these techniques have been covered in an extensive review article by Mitzi et al. (2013).

#### 45.5.3.1 Sputtering

Sputtering has been the first and one of the most extensively explored vacuum-based routes to CZTSSe film deposition (Ito and Nakazawa 1988). Katagiri et al. have investigated a series of sequential sputtering approaches comprising different stacked and cosputtered precursor configurations followed by high-temperature sulfurization anneals. The results from these studies laid the foundation for CZTSSe technology, establishing key process parameters such as optimal elemental ratios (generally, Cu-poor and Zn-rich relative to the ideal CZTSSe stoichiometry) (Katagiri et al. 2009b). After a series of improvements, including soaking in deionized water after film deposition to remove surface oxide impurities, a power conversion efficiency of 6.77% was achieved for a pure sulfide CZTS device (Katagiri et al. 2008). Recently, CZTSSe devices were prepared by cosputtering from compound targets of Cu<sub>x</sub>(S,Se)<sub>y</sub>, Zn<sub>x</sub>(S,Se)<sub>y</sub>, and Sn<sub>x</sub>(S,Se)<sub>y</sub> in an argon atmosphere, followed by annealing in an SnS and S<sub>2</sub> gas atmosphere, and devices with efficiencies of as high as 8% have been reported (Chawla and Clemens 2012).

#### 45.5.3.2 Coevaporation

In contrast to the CIGS technology, CZTSSe deposition using coevaporation has encountered significant challenges during especially in the classical configuration where the substrate is maintained at high temperature while delivering precisely controlled

elemental fluxes. In addition to the typically volatile Se and S in chalcopyrite absorbers, Sn re-evaporation also occurs during CZTSSe deposition (Friedlmeier et al. 1997). This issue was addressed by introducing a faster coevaporation process in which Sn loss could be mitigated. One way to go around this issue is by adding continuous Sn overpressure throughout the whole high-temperature process, including part of the cooling stage as indicated in a recent NREL report (Repins et al. 2011). Using this approach, device efficiencies of as high as 9.2% for pure selenide CZTSSe devices have been achieved (Repins et al. 2012). Currently, the best performing coevaporated CZTS (pure sulfide) devices have reached efficiencies of 8.4%, using a process developed at IBM that consists of coevaporation onto a low-temperature substrate followed by a short anneal at atmospheric pressure (Shin et al. 2011).

#### 45.5.3.3 Nonvacuum Deposition Approaches

From the early years of CZTSSe development, it was well understood that a combination of cheap readily available materials combined with a reliable low-cost fabrication approach could revolutionize the PV industry. Three approaches based on pure solutions, nanoparticles, or hybrid particle–solutions, respectively, have been particularly pursued. Of these, the third category of inks, comprising a combination of dissolved and solid active components, has so far been the most successful CZTSSe fabrication approach. It advantageously uses the binding action of dissolved metal chalcogenide species to produce dense, compact layers and additionally bypasses the solubility limitation of pure solution approaches by introducing particle components that further provide densification and crack-deflection benefits. Recently, Yang and coworkers (Hsu et al. 2012) studied the chemical pathways involved in the hydrazine-based deposition and heat treatment process. The precursor ink was dried at room temperature resulting in the integration of copper and tin chalcogenide complexes to form a bimetallic framework, with hydrazine and hydrazinium molecules as spacers. After mild thermal annealing, the spacers are removed and the  $\text{Cu}_2\text{Sn}(\text{Se},\text{S})_3 + \text{Zn}(\text{Se},\text{S}) \rightarrow \text{Cu}_2\text{ZnSn}(\text{Se},\text{S})_4$  reaction is triggered. The described reaction pathway contains fewer steps than most deposition processes, which typically start with elemental or binary chalcogenides (Hsu et al. 2012). By use of this hybrid solution–nanoparticle approach, a record efficiency of 9.7% was reported in 2010 by the IBM group (Todorov et al. 2010). The method was further refined to yield 10.1% power conversion efficiency in 2011 (Barkhouse et al. 2012) and most recently to the 11.1% level (Todorov et al. 2011), which represents the current world record for the kesterite-based system.

The efficiency improvement in the CZTS technology has been significant in a short span of time, and this gives a hope that this technology can provide alternatives to the material sustainable issues for In and Ga in CIGS. It may be noted that the In and Ga materials are the by-products of the Zn smelting factories, and so ramping up the production of CZTS technology will also enable the sustained supply of In and Ga, leading to sustained and regenerative production along with CZTS technology growth.

---

## 45.6 New-Generation Solar Cells

The beginning of 1990s has seen the emergence of new and disruptive technologies viz. dye-sensitized and later organic solar cells (Grätzel 2000), which followed completely different device approach of bulk-heterojunction formation in the nanometer length regime,

which can be referred to as new generation solar cells. DSSCs are nanocomposites of mesoporous  $\text{TiO}_2$  and inorganic dyes (typically ruthenium complexes); they created a breakthrough by achieving relatively high conversion efficiency  $\sim 10\%$  through the use of rather inexpensive and abundant materials (O'Regan and Grätzel 1991).

The solar cell action in the aforementioned device on the illumination of light is initiated by excitonic electron–hole pair generation and dissociation leading to a charge separation at the nanointerface. These devices are therefore termed as *excitonic* or *organic–inorganic* or *hybrid* solar cells. Unlike conventional p–n homojunction (c-Si) solar cells, the absorption of photons and electron transport is mediated via two dissimilar constituents, viz., dyes and n-type nanocrystalline  $\text{TiO}_2$ , respectively, while the holes are transported through a hole-transporting material (HTM), which could be a redox liquid electrolyte or ion-conducting polymeric electrolyte (quasisolid state) or quantum dot sensitized or hole-conducting conjugated polymer material or small molecules or perovskites (solid state).

Although the initial results had been remarkable, the liquid junction DSSC technology appears to have now reached a state of stagnation in the efficiency values, with an increase from about 10% to 12.3% only in the span of over 20 years. This technology had also suffered from the lack of sensitizer dyes with wider spectral coverage, atmospheric degradation, and engineering issues such as encapsulation and sealing of the liquid junction device, which had prevented this technology from making a mark in commercialization. Incidentally, there has been a breakthrough in an attempt to solve these issues with the development of solid-state DSSC, in the form of the mesoscopic perovskite solar cells developed in parallel by Michael Grätzel and coworkers at EPFL, Switzerland (Burschka et al. 2013), and Henry Snaith and coworkers at Oxford University (Lee et al. 2012) with efficiencies  $\sim 10\%$  and  $11\%$ , respectively, initially which had moved up to over  $17\%$  (Bennett 2014; Snaith 2014) toward the end of 2013. A comprehensive detail on these developments including liquid-, quasi-, and solid-state DSSCs (or perovskite cells) has been reported (Upadhyaya et al. 2013) and has been described briefly in the following section.

A significant achievement was made toward the development of DSSC/CIGS tandem (Liska et al. 2006) solar cell, which resulted then with over  $15\%$  efficient cells with  $1.42\text{ V}$  open circuit voltage (using a physical stack of DSSC and CIGS cells with 4 wired configuration with DSSC cell efficiency about  $8\%$  and CIGS efficiency about  $13\%$ ), bringing a step jump in efficiencies. The monolithic two-wire DSSC/CIGS tandem was not successful because of issues of corrosion caused by liquid electrolyte component (Wenger et al. 2009). However, with solid-state analogues of DSSC or perovskite solar cells available with higher efficiencies, it is anticipated that the tandem cells up to  $27\%$  efficiencies could be developed (Kim et al. 2013; Kranz et al. 2013).

#### 45.6.1 Perovskite Solar Cells

Apart from the aforementioned listed thin-film solar cells, there are a new generation of thin-film solar cells along with DSSCs and organic solar cells that have emerged recently. Attempts have been going on over many years to find an alternative to the liquid electrolytes and to obtain, thus, an improved DSSC, which will have ease of fabrication, less complication in the sealing and encapsulation of the device, possibility for monolithic interconnection of the cells within the module, and therefore also increased performance and lower cost. However, a class of solar cells based on perovskite structured

**FIGURE 45.17**

Comparing the rate of increase in perovskite solar cell efficiencies with the other thin-film PV technologies. (From Hodes, G., *Science*, 342, 317, 2013.)

semiconductors has emerged and rapidly reached conversion efficiencies of more than 15% (Figure 45.17), as listed in Table 45.2.

Most commonly,  $\text{CH}_3\text{NH}_3\text{PbI}_3$ -based organic–inorganic perovskite materials have been used in these types of solar cells, which are having high charge carrier mobility. High mobility is important because, together with high charge carrier lifetimes, it means that the light-generated electrons and holes can move large enough distances to be extracted as current, instead of losing their energy as heat within the cell (Hodes 2013). Moreover, the perovskite solar cells can be deposited by low-temperature methods such as solution process (spin coating) and thermal evaporation methods. The advantages of the solid-state DSSCs over the liquid DSSCs are obvious: less complications involved in the manufacturing equipment, easy possibility for producing monolithically interconnected modules, easier sealing, and encapsulation of the modules (similar to the processes employed for other thin-film solar cells). Although the efficiency values reached for small-size individual solar cells can be considered to be satisfactory, and should basically provide a great commercialization potential for this technology in the future, especially thanks to the fact that we have here a true solid-state device, the stability and longevity of the device is yet to be ascertained. Although the perovskites are cheaper than the conventional dyes and have wider spectral coverage, they are susceptible to temperature and humidity. Temperature around  $95^\circ\text{C}$  can bring structural transformation in the materials and also atmospheric moisture can lead to degradation as well. Thus, a strong barrier layer would be required for desired stability toward moisture ingress. In addition other variants of perovskites will have to be found out with intrinsic temperature stability issues. Besides, other critical issues of long-term stability of the devices are the stability of the organic spiro-OMeTAD layer, and the need for the perovskites with Pb-free compounds, to cover the environmental concerns.

### 45.7 Environmental Concerns and Cd Issue

The CdTe and CIGS thin-film technologies have demonstrated excellent potential for cost-effective production of solar electricity. However, these technologies, especially the CdTe, suffer from the perception of toxicity of constituent element Cd, which is used in the form of a stable compound in thin-film modules. Often raised issues such as the risks or hazards in handling CdTe technology are associated with the materials used during the processing and fabrication of CdTe/CdS and CdS/CIGS solar cells along with the risks associated during the cradle to grave operating lifetime of these modules. The environmental and health hazard (E&H) issues of CdTe solar modules have been extensively investigated by several independent agencies including the national laboratories in Europe and United States (Fthenakis and Zweibel 2003; Fthenakis et al. 1999, 2004). There are a number of reports now available, which support CdTe technology against any serious threat arising even under worst-case scenarios. Under extreme conditions like fire under basement and leaching from broken modules, the theoretical models show that even if all the Cd compounds were to be released, Cd concentrations within the near vicinity to the CdTe PV system are below human health screening levels (Beckmann and Mennenga 2011; Dutta et al. 2012; Sinha et al. 2011). An interesting report also provides a supporting argument in favor of CdTe technology analyzed during earthquakes or tsunami in Japan (Matsuno 2013). While First Solar program of module recycling is already available and supports their confidence (<http://www.firstsolar.com/en/technologies-and-capabilities/recycling-services>), the chance of Cd compounds and other potentially harmful materials getting into the ambient environment from the PV plant during its lifetime is also negligible. The current power generation technologies using coal have a large amount of Cd emitted in the environment in an uncontrolled manner, with the amount far exceeding the expected emission from CdTe modules even under exceptional conditions (e.g., fire). Even the dominant PV technologies based on Si solar cells have larger life cycle Cd emissions due to the embodied energy being larger for these devices (Fthenakis et al. 2008).

While CdTe technology has no chance to do away with Cd, there is some maneuverability in CIGS technology in the elimination of very thin (typically ~50 nm) CdS buffer layer, and so the quest for alternative buffer layer is being successfully pursued. Initial success has already been achieved as CIGS solar cells of 16%–18.8% and modules of 13.4% have been developed with alternative *Cd-free* buffers (Hedström et al. 1993; Kushiya 2004). Recently, coevaporation of CIGS in an inline single-stage process is used to fabricate solar cell devices with up to 18.6% conversion efficiency using a CdS buffer layer and 18.2% using a  $\text{Zn}_{1-x}\text{Sn}_x\text{O}_y$  (Cd-free) buffer layer. Furthermore, a 15.6 cm<sup>2</sup> minimodule, with 16.8% conversion efficiency, has been made with the same layer structure as the CdS baseline cells, showing the excellent uniformity. These cell results were externally verified (Lindahl et al. 2013).

Referring to the perception and concerns on Cd issues, V. Fthenakis (Sr. Chemical Engineer, Brookhaven national Laboratory) and K. Zweibel (Manager, Thin film partnership program, NREL, United States) had presented a detailed account of their studies during their presentations at the 2003 NCPV program review meeting in the United States (Fthenakis et al. 2004) that confirmed that CdTe panels would be almost benign with almost zero emission (0.01 g/GW h) as compared to its counterparts oil (44.3 g/GW h) and

coal (3.7 g/GW h), with no associated health hazards, and gave a clean chit to CdTe technology. The following points emerged out of the studies:

Cadmium is a by-product of zinc, lead, and copper mining. It constitutes only 0.25% of its main feedstock ZnS (sphalerite). Cadmium is released into the environment from phosphate fertilizers, burning fuels, mining and metal processing operations, cement production, and disposing of metal products. Releases from disposed Cd products, including Ni–Cd batteries, are minimum contributors to human exposure because Cd is encapsulated in the sealed structures. Most human cadmium exposure comes from ingestion and most of that stems from the uptake of cadmium by plants, through fertilizers, sewage sludge, manure, and atmospheric deposition. Although long-term exposure to elemental cadmium, a carcinogen, has detrimental effect on kidneys and bones, limited data exist in toxicology. However, CdTe compound is more stable and less soluble than Cd element and therefore likely to be much less toxic.

Considering the electrolytic refinery production of CdTe powders (from Cd wastes from Zn, iron, and steel industries), there would be an emission of 0.001% Cd gaseous emission. This would correspond to 0.01 g/GW h, which is significantly less as compared to the perceptions and hypes created by some who estimate it at 0.5 g/GW h based on other crude processes or unsubstantiated data. The only potential hazard that could come to any ones' mind would be the building fire. It has also been estimated quantitatively that the maximum temperature of a basement on fire is ~900°C, which is still less than the melting point of CdTe (1041°C). Besides, the vapor pressure at 800°C for CdTe is ~2.5 Torr (0.003 atmosphere), so this minimizes the risks further, and once sealed between glass plates, any Cd vapor emission is unlikely. The main conclusion of the studies was that the environmental risks associated with CdTe-based technology are minimal. Every energy source or product may present some direct or indirect environmental health and safety hazards and those of CdTe should by no means be considered a problem; the following conclusions were drawn:

- Cd is produced as a by-product of Zn and can either be put to beneficial uses or discharged to the environment posing another risk.
- CdTe in PV is much safer than other current Cd uses.
- CdTe PV uses Cd about 2500 times more efficient than Ni–Cd batteries.
- Occupational health risks are well managed.
- Absolutely no emission during PV operation.
- A risk from fire emission is minimal.
- CdTe technology and modules are safe and do not pose significant risks.

---

## 45.8 Conclusions

1. PV market is booming with a phenomenal surging growth rate of over 40% for more than a decade despite a downturn observed in the worldwide economy recently. The cumulative PV production capacity was ~140 GW by 2013, while 50 GW production is anticipated in 2014 alone. This is in contrary to the belief in the last decade

that high demand for cost-effective PV installations with more consumer-oriented choices can neither be met by the c-Si wafer technology nor is expected to achieve low production cost targets of below €1/W, which is a myth now.

2. An upsurge in the PV production and an artificial module price crisis created by Chinese manufacturers has brought a radical drop in the module prices well below \$0.6/Wp since 2011. This strategy has wiped away the PV industries in Europe and has caused a PV manufacturing base shift toward the Asia, with China, Taiwan, and Korea taking this opportunity and leading the show through their natural advantage of cheaper material supply and cheaper human resources available.
3. Thin-film PV has clearly demonstrated an excellent potential for cost-effective generation of solar electricity using CdTe technology by First Solar in the United States and CIGS technology by Solar Frontier in Japan currently aiming to produce 2 GW capacities annually. While the world record cell efficiencies of 20.4% for CdTe and 20.9% for CIGS have already matched/surpassed polycrystalline Si efficiency of 20.4%, the module efficiencies have also shown significant figures of 17% and 16.4% for CdTe and CIGS, respectively. In fact, thin-film PV market has gained stability from c-Si production and market leadership with almost 90% share. It is anticipated that a mix of c-Si and thin-film PV technologies will cater the market needs in near to midterm future, followed by the dominance of thin-film and other PV technologies in long term.
4. The a-Si technology has suffered a setback mainly because of the stagnancy and the low efficiency figures arising from the intrinsic light-dependent degradation issues. This has resulted in the bankruptcy of the United Solar company in 2013, which was the largest manufacturer of triple junction a-Si technology on steel foils. Efforts are underway in Japan through NEDO programs to overcome these barriers for a successful relaunching of this technology, which will have wider application in BIPV and BAPV sectors in the future.
5. Thin-film PV industries are growing fast; however, there are several issues:
  - a. Reducing the gap between lab efficiency and larger area industrial production efficiency. This is achievable with the design of better equipment with in situ diagnostics. Nonavailability of standard deposition system for thin-film PV has been a problem, so effort is needed to develop large-area equipment suitable for thin-film PV.
  - b. Unlike c-Si technology, which allows the process and equipment availability off the shelf, there is no availability of processing equipment and the optimized processes for thin-film PV technologies, which are only under the proprietary control of the companies involved. Although companies like Manz Solar (<http://www.manz.com/>) have taken initiatives in this direction, this is not enough to cover the entire promise.
  - c. To lower the cost, increase the throughput and the yield, efforts are needed for further simplification and increased robustness of the process and device structures.
  - d. If multi-giga and terawatt PV facilities are to be successful for a safer and prosperous world, further improvements in the device structures along with optimized material utilisation (low wastage) have to be achieved for attaining efficiencies greater than 25%.

**46.1 Introduction**

The current state of solar cell development is illustrated in [Figure 46.1](#). While single-junction silicon solar cells dominate today's solar industry, the rapid rise in efficiency versus time (experience curve) of the multijunction cells makes this a particularly attractive technology path. The high efficiency, in comparison with single junction cells, such as silicon, is obtained by stacking several junctions in series, electrically isolated by tunnel diodes, as explained in Chapter 44. These can be qualitatively viewed by adding the voltages of three junctions in series, while maintaining the current of a single junction (Figure 46.1).

Under concentrated sunlight, multijunction (GaInP/GaAs/GaInNAs) solar cells have demonstrated an efficiency of 44.4% within the lab, as compared to silicon cells' best efficiency of 25%. This means that, in sunny areas, a multijunction concentrator system can generate almost twice as much electricity as a silicon panel with the same area.

[Table 46.1](#) gives the efficiencies of CPV submodules achieved as of 2012.

The concentrating optics focus the light onto a small area of cells, reducing the area of the solar cells by a factor of, typically, 500–1000 times. The reduced cell area overcomes the increased cell cost. The cell cost is diminished in importance and is replaced by the cost of optics. Thus, in high direct insolation locations, the multijunction concentrator technology has the potential to reduce the cost of solar electricity. As a side benefit, the cells are more efficient under concentration, provided a reasonable cell temperature can be maintained. The technology has been extended to four junctions and could be extended to even five junctions if efficiency benefits justify added cost. The efficiency is a moving target; today's triple junction cell efficiency is nearly 45%. Thus, one may reasonably extrapolate that multijunction cells may reach 50% efficiency in the future. Using less cell material for a given

power output has attraction to cell manufacturers that are having trouble producing sufficient material to keep up with demand. It is worth mentioning that this technology was first developed and proven in the space program, where specific power (power/mass) is a more important consideration than cost.

## 46.2 CPV Technology

CPV technologies may use any concentrators developed for concentrating thermal technologies, including parabolic trough or parabolic dishes, compound parabolic concentrators (CPCs), or Fresnel concentrators. The concentrations achieved depend on the type of concentrators used. The CPV systems are classified as low, medium, or high concentrations, depending on the concentration ratio as shown in Table 46.2.

The most common type of concentrator is based on Fresnel concentrator as shown in Figure 46.2.

For low concentration CPV, silicon or even CdTe or CIGS panels may be used. However, for very high concentrations, triple junction cells of III–V compounds are used.

**TABLE 46.2**

CPV Concentration Classes

Class of CPV	Typical Concentration Ratio	Type of Converter
High concentration	>400×	Multijunction
Medium concentration	~3×–100×	Silicon or other cells
Low concentration	<3×	Silicon modules

**FIGURE 46.2**

Fresnel concentrator optics used in the most common CPV panels.

---

## 46.2 CPV Market

In 2004, less than 1 MW of concentrator PV systems was installed, out of a total world PV market of 1200 MW, and for some time, the market share of CPV remained extremely small. However, a dramatic reduction in cost of a CPV system from \$3.54/W in 2012 to \$2.62/W in 2013 increased the CPV installation to 160 MW in 2013 (Melkonyn 2013).

Amonix, Ind., of Torrance, California, spent more than 15 years developing five generations of CPV prototypes that led to a 35 kW CPV system installed in Arizona by Arizona Public Service (Amonix 2005). Since then, they have completed the largest CPV system of 30 MW in Alamosa, Colorado, in 2012. As of 2014, there are 54 companies developing or marketing CPV systems around the world. With reduction in the prices and increase in the efficiency, the global market for CPV is expected to grow at a very high rate (Mendelsohn et al. 2012).

---

## 46.4 Energy Payback

CPV system costs are much more sensitive to the price of steel than to the price of silicon. In this regard, CPV systems share similar concerns with the wind industry (McConnell 2002). Other technological similarities with wind systems include the low cost of production plants, suitability for distributed and large-scale utility generation, modularity, moving parts, and the need for a good resource, be it wind or solar.

Such observations suggest that CPV systems could follow in the footsteps of wind systems. It seems plausible that CPV system costs can approach wind system costs (typically U.S. 80¢/W today—or about the same as projected CPV costs) if only because

common materials (e.g., steel, glass, plastic) are dominant and because production plant costs are relatively low. Also consistent with these observations are recent estimates of energy payback for CPV technologies that are very close to values published for wind turbines at good wind sites. Specifically, the energy payback has been estimated at 8 months for a CPV system in a site having a good solar resource (Bett et al. 2005). More recently, the Fraunhofer Institute for Solar Energy in Freiburg, Germany, estimated the energy payback period for a CPV system in Italy as about 9 months (Fraunhofer ISE 2013).

---

## 46.5 Qualification Standards

Qualification standards help developers design their new products by identifying weaknesses before production and project installation. They give customers the confidence that their project investments will pay off. In short, they can contribute immensely to a technology's successful market entry.

Fortunately, the CPV industry thought about this situation in the 1990s. Standards take years to develop because the process is based on consensus. Companies do not want standards that are unnecessarily strict or require expensive test procedures. Customers want standards that ensure good product performance. So input from both groups—companies and customers—as well as from relatively objective research organizations leads to an accepted set of test procedures vital for successful CPV market. The first CPV standard (IEEE 2001) was published in 2001. This standard, however, was most suitable for US concentrator PV technologies using Fresnel lenses. The International Electrotechnical Commission (IEC) with input from engineers from more than 10 countries has been developing a standard suitable for concentrators using mirrors or lenses with solar concentration ratios ranging from a couple of suns to thousands of suns. The IEC issued their standard IEC 62108 in 2007 as a comprehensive CPV standard (IEC 2007). They are also working on new standards for solar trackers and safety.

### **47.1 Introduction**

One of the most serious issues facing urbanized areas today is development of cost-effective environmentally acceptable disposal of the community's solid waste. The solid waste generated in a community may be collected by private companies or governmental entities, or portions by both, but the assurance that the waste is ultimately disposed of in an environmentally safe manner is a governmental responsibility.

Solid waste management is a major issue in the United States, because of increasing concerns with environmental problems. One potential solution is to use municipal solid waste, which, for all practical purposes is a renewable commodity, for the generation of electricity. An analysis by Penner and Richards<sup>53</sup> showed that incineration of municipal waste, even after 30% of the waste was recycled, could provide as much electric power as eight large nuclear or coal generating stations. Their analysis further concluded that this could provide 1%–2% of the total electric energy needs in the United States at prices competitive with coal-fired base load power plants.

The basic technology for modern waste-to-energy combustion was developed in Europe during the 1960s and 1970s. This technology, which has been modified and improved since its development, has been widely implemented in the United States. However, despite the fact that incineration of solid waste can decrease its volume ninefold and ameliorate the final waste disposal into landfills, the full potential of utilizing solid waste for energy production is not being realized because of widespread fears regarding environmental pollution. In preparing this chapter, the realities of the situation have been taken into account and the discussion emphasizes the prevention of pollution as much or more than the production of power from waste. Waste-to-energy combustion in modern facilities with adequate environmental safeguards and careful monitoring has been shown to be a safe and cost-effective technology that is likely to increase in importance during the next decade.

Two conditions usually point to the use of combustion processes in treating municipal solid waste prior to ultimate disposal: the waste is collected in an urbanized area with little or no conveniently located land for siting of sanitary landfills (need for volume reduction); and markets exist for energy recovered from the combustion process, and possibly for reclaimed materials, with the energy attractively priced. Even some rural areas are currently considering waste to energy facilities.

Modern waste-to-energy (WTE) plants reflect significant advances that have been made in addressing the technical and practical difficulties of material handling, combustion control, and flue gas cleanup. In the early days of waste incineration, when air pollution regulations were undemanding or nonexistent, relatively simple, fixed-grate plants operating on a single- or two-shift basis were common. However, with increasingly stringent air pollution control regulations, more complex plants requiring continuous operation are now being built.

---

### **47.2 Waste Quantities and Characteristics**

Municipal solid waste (MSW) as used herein refers to solid waste collected from residences and commercial, light industrial and institutional waste. It does not include heavy industrial waste, which is another problem and varies widely in quantity and characteristics,

depending on the industry and specific industrial plant. Changes in packaging practices and improvements in the general standard of living have resulted in significant increases in the quantities of solid waste generated over the past 50 years. Additionally, increasing emphasis on and participation in the recycling of wastes by local communities has resulted in significant variations in quantity and characteristics of MSW at the local community level. All of these factors must be considered when planning a WTE facility. Chapter 48 gives more information on waste availability.

#### 47.2.1 Waste Quantities

In the United States approximately 120 million tons of MSW were generated in 1970, increasing to 220 million tons in 1998.<sup>23</sup> MSW generation is projected to increase to almost 260 million tons by the year 2015.<sup>25</sup> At the local level the quantity of solid waste generated varies geographically, daily, and seasonally, according to the effectiveness of the local recycling initiatives, and differences in socioeconomic conditions.<sup>60</sup>

Over the past 40 years, numerous studies by EPA,<sup>21</sup> APWA,<sup>54</sup> and others<sup>67</sup> have indicated that urbanized areas in this country generate approximately 2.0 lb/capita/day of MSW from residences and another 2.0 lb/capita/day from commercial and institutional facilities, on a national average basis. Thus, a typical community of 100,000 inhabitants would generate about 200 tons/day of gross MSW discards averaged over a 1-year time period.

These projections are subject to adjustments related to specific community characteristics. Thus, communities in the south, with longer active growing seasons than those in the north, tend to produce and collect more yard waste. Recent requirements for on-site disposal and/or composting of yard waste is changing this variable. Rural communities tend to produce less waste per capita than highly urbanized areas because of their greater potential for on-site waste disposal. In the past, the communities in the north tended to produce more waste in the winter due to the prevalence of heating of homes with solid fuels, which produced large quantities of ashes for disposal. Variations in yard wastes and ashes produced from home heating with solid fuels are also examples of variations in MSW quantities related to seasonal effects. Seasonal variations in MSW generation have been noted to range  $\pm 15\%$  from the average, while daily variations in waste collections may range up to  $\pm 50\%$  from the average, depending largely on number of collections per week. Daily variations in waste quantities are more important in designing certain plant components, while geographic and seasonal effects are more important in establishing plant size.

Waste quantities are also affected by the effectiveness of local recycling initiatives and by socioeconomic conditions. EPA studies have indicated an increase, nationally, in waste recycling from 6.6% in 1960–1970, to 16.2% in 1990,<sup>22</sup> and 28.2% in 1998.<sup>24</sup> The national recycling rate had increased to 34% and 87.2 million tons by 2013,<sup>25</sup> at which time it is expected to level off.\* A community in New England<sup>7</sup> projected a 14.0% drop in MSW generation between 1989 and 1991 due to recycling activities in the community, and a 6.0% drop due to the recession during this period in this region of the country. A 15% drop in MSW collections was noted in a Long Island community during a recessionary period in 1972. The impact of recycling on MSW generation should be considered in plant sizing, while the impact of recessionary periods on plant economics may require specific consideration during project planning.

---

### 47.2.2 Waste Characteristics

It is important in approaching the design of a WTE facility that one consider the potential variations in both physical and chemical composition of MSW. Historically, one of the most troublesome areas in WTE plants has been materials handling systems. To successfully select materials handling system components and design an integrated process, one must have adequate information on the variability and extremes of the physical size and shape the solid waste facility must handle, the bulk density and angle of repose of the material, and the variation in noncombustible content. This information generally is not available from published surveys and reports, and can only be secured through inspection of the MSW in the field. Materials handling equipment for refuse feeding and residue handling must be large enough and oriented properly to pass the largest bulky items in the MSW, and large enough and rugged enough to handle the quantities of materials required to meet plant design capacity, or the plant will experience expensive periods of down time and might have to be derated.

In the design of the furnace/boiler portion of WTE facilities, the refuse characteristics of interest are the calorific value, moisture content, proportion of noncombustibles, and other components (such as heavy metals, chlorine, and sulfur) whose presence during combustion will result in the need for flue gas cleanup. The capacity of a WTE furnace boiler is roughly inversely proportional to the calorific or heating value of the waste. Table 47.1 illustrates the variation in waste characteristics that has been observed in studies defining the average solid waste composition in the United States since 1960.

As indicated in Table 47.1, approximately 35%–40% of the combustible fraction of MSW is composed of cellulosic material such as paper and wood. This percentage has remained relatively constant over the past 20 years, even after taking into account the

**TABLE 47.1**

Generation, Materials Recovery, Composting, Combustion with Energy Recovery and Discards of MSW, 1960–2013 (in Millions of Tons)

Activity	1960	1970	1980	1990	2000	2005	2009	2011	2012	2013

Discards to landfill, other disposal <sup>c</sup>	82.5	112.6	134.4	145.3	140.3	142.3	133.0	131.7	132.2	134.3

Note: neg., negligible = less than 5000 tons or 0.05%.

<sup>a</sup> Composting of yard trimmings, food and other MSW organic material. Does not include backyard composting.

<sup>b</sup> Includes combustion of MSW in mass burn or refuse-derived fuel form, and combustion with energy recovery of source separated materials in MSW (e.g., wood pallets, tire-derived fuel).

<sup>c</sup> Discards after recovery minus combustion with energy recovery. Discards include combustion without energy recovery. Details might not add to totals due to rounding.

greater than fourfold increase in recycling percentage achieved over this period. The remainder of the combustible content is composed of various types of plastics, rubber, and leather. The heat released by burning cellulose is approximately 8000 Btu/lb (on a dry basis), while that released by plastics, rubber, and leather is significantly higher on a per pound, dry basis. Heat released by burning garbage (on a dry basis) is only slightly less than cellulose. However, the moisture content of garbage has been observed to range from 50% to 75%, by weight, while that of the cellulosic fraction of MSW usually ranges from 15% to 30%.

In recent years, it has been observed that the higher heating value (HHV) of the combustible portion of MSW (moisture and ash free) averages about 9400 Btu/lb. Considering the recent changes in MSW composition following recycling (increase in plastics while cellulosic material has remained relatively constant), this moisture and ash free HHV has probably increased to 9500 Btu/lb. Taking 9500 Btu/lb as the moisture and ash free heat content of MSW, Table 47.2 illustrates the variation in as-received heat content that one could expect in MSW with moisture content ranging from 20% to 50% by weight and non-combustible content ranging from 25% by weight (earliest period) to approximately 15% by weight (currently).

Moisture content is a highly important and also a highly variable characteristic of waste materials. The moisture content of MSW is generally around 25%, but has been observed to vary from 15% to 70%. This variation may be due, for example, to seasonal variations in precipitation, the nature of the waste (e.g., grass clippings vs. paper) and the method of storage and collection (e.g., open vs. closed containers/trucks). Thus, after a heavy rain, the moisture content of the solid waste may be so high that it may be difficult to sustain combustion. The combustion of solid waste usually can proceed without supplementary fuel when the heat value is greater than 3500–4000 Btu/lb (8140–9300 kJ/kg). This type of variation in MSW composition must be considered in the design of WTE facilities.

The ultimate or elemental analysis of the combustible portion of the MSW refers to the chemical analysis of the waste for carbon, hydrogen, oxygen, sulfur, chlorine, and nitrogen. This information is used to estimate the heat content of waste, moisture, and ash free; to predict the composition of the flue gases; and, from the last three elements (sulfur, chlorine, and nitrogen), to assess the possible impact of waste combustion on air pollution. A typical analysis of solid waste is presented in Table 47.3.

**TABLE 47.2**

Variation in Heat Content of MSW

Noncombustible (%)	15		25

## 47.3 Design of WTE Facilities

The primary function of a WTE facility is to reduce solid waste to an inert residue with minimum adverse impact on the environment. Thermal efficiency, in terms of maximizing the capture of energy liberated in the combustion process, is of secondary importance. WTE facilities are usually classified as mass-burn systems, or refuse-derived fuel (RDF) systems.

### 47.3.1 General Features

#### 47.3.1.1 Types of Facilities

Mass-burn systems are large facilities (usually over 200 tons/day) that burn, as-received, unprocessed MSW which is extremely heterogeneous. Most mass-burn systems burn the waste in a single combustion chamber under conditions of excess air (i.e., more than is needed to complete combustion) (see [Figure 47.1](#)). The waste is burned on a sloping, moving grate, which helps agitate the MSW and mixes it with combustion air. Many different proprietary grate systems exist.

In refuse-derived fuel (RDF) systems, usually large facilities, the MSW is first processed (see [Figure 47.2](#)) by mechanical means to produce a more homogeneous material prior to introduction into a furnace/boiler. Several types of RDF can be made—coarse, fluff, powder, and densified. These differ in complexity and horsepower requirements of the waste processing facilities, size of particle produced, and whether or not the

**FIGURE 47.1**

**FIGURE 47.2**

RDF processing system.

material is compacted under pressure into pellets, briquettes, or similar forms. The coarse type of RDF is the most common form produced at this time.

RDF can be burned in one of the two types of boilers. It can be used as the sole or primary fuel in dedicated boilers (see [Figure 47.3](#)) or it can be co-fired with conventional fossil fuels in existing industrial or utility boilers. One advantage of these systems is that RDF can be produced at one location for use at a nearby off-site boiler, allowing for flexibility in locating processing facilities. Also, some materials, such as steel and glass, can be recovered for recycling during the initial processing step.

**FIGURE 47.3**  
West Palm Beach, FL, RDF-fired boiler by the Babcock and Wilcox Company.

Mass-burn and RDF systems together account for 86 of the 98 currently operating waste-to-energy facilities and 98% of the waste combustion capacity. Modular units, described briefly later, account for the other 12 units and 2% of the waste combustion capacity.<sup>39</sup>

#### 47.3.1.2 Operation and Capacity

The capacity to be provided in a facility is a function of the area and population to be served; and the rate of refuse production for the population served. A small plant (100 tons/day) without energy recovery might not be operated on weekends. For capacities above 400 tons/day, or any plant with energy recovery, economic and/or equipment operating considerations usually dictate three-shift operation, 7 days/week.

If collection records, preferably by weight, are available for the community, forecasts for determining required plant capacity can be made with reasonable accuracy. If records are not available, refuse quantities for establishing plant size may be approximated by assuming a refuse generation rate of 4.0 lb/capita/day when there is little or no waste from industry. Of course, in planning for plant capacity, the impact of local recycling activities on both quantity and characteristics of MSW must be considered as discussed earlier.

Other factors must be taken into account in establishing the size or capacity of a facility. Should the facility serve only one community, or should it be regional and serve several communities? What are the possible benefits of economies of scale? What is the impact of the cost of hauling refuse to a central point on overall project economics? There is substantial evidence available at present to show that implementation becomes much more difficult as the number of separate political jurisdictions is increased. Imposition of regional plans on local jurisdictions to achieve economies of scale, where it cannot be conclusively demonstrated that such regional plans make sound economic sense based on the total cost of the solid waste management plan, including the cost of transporting the solid waste to the regional facility, is, at best, unwise. Economies of scale in these projects have tended to be illusory, while haul costs to gather sufficient waste together to achieve the economies of scale have tended to be ignored in developing total project economics.

#### **47.3.1.3 Siting**

One of the key issues to face in implementing a WTE project is locating a site for the facility. Since MSW is usually delivered to these plants by truck, inevitably there will be substantial truck traffic in the vicinity of the plants. The equipment and processes used in these plants are industrial in nature. They are generally noisy at the source and tend to produce dust and odors. These facts indicate that it is desirable to site such plants in industrial or commercial areas.<sup>45</sup> It has been contended, as cited in a 1989 OTA report<sup>68</sup> "that sites are sometimes selected to avoid middle- and higher-income neighborhoods that have sufficient resources to fight such development."

Plants should be located near major highways to minimize the impact from increased truck traffic. As shown by operating WTE plants in Europe and the United States, it is possible to control all nuisance conditions by proper attention to the details of plant design. The local impact of truck deliveries to the plant can be minimized by providing sufficient length of access road so that refuse truck queuing does not take place on public highways. Odors and noise can be confined to the plant building. Odors and fugitive dust can be destroyed by collecting plant air and using it for combustion air supply. Noise should be attenuated at the source to maintain healthful working conditions. In all cases, there is no need to adversely impact the surrounding neighborhood. Proper attention to architectural treatment can result in a structure that blends into its surroundings; if sited in industrial or commercially zoned areas.

Since considerable vertical distance is frequently required in the passage of MSW through a mass-burn WTE plant, there is an advantage in a sloping or hillside site. Collection trucks can deliver MSW at the higher elevation, while residue trucks operate at the lower elevation, requiring minimum site regrading. This consideration does not generally apply to RDF plants.

### 47.3.2 Fuel Handling

#### 47.3.2.1 Refuse Receipt, Processing, and Storage

Scales, preferably integrated into an automated record keeping system, should be provided to record the weight of MSW delivered to the WTE plant. Either the entire tipping area or individual tipping positions should be enclosed so as to control potential nuisance conditions in the vicinity of the plant, such as blowing papers, dust, and/or odors. The number of tipping positions provided should take into consideration the peak number of trucks expected per hour at the facility and should be located so the trucks have adequate time and room to maneuver to and from the dumping positions while minimizing queue time.

Collections usually are limited to one 8 h daily shift 5 days/week (sometimes with partial weekend collection) while burning will usually be continuous, so ample storage must be provided. This usually requires 2–3 days of refuse storage at most WTE plants. Seasonal and cyclic variations should also be a consideration in establishing plant storage requirements.

Refuse storage in large mass-burn plants is normally in long, relatively narrow, and deep pits extending along the front of the furnaces. It will generally be necessary to rehandle the refuse dumped from the trucks. In some mass-burn plants and in RDF plants, floor dumping and storage of the MSW either on the dump floor or in shallow, relatively wide pits is common practice.

When computing the dimensions required for storage of as-received MSW, the required volume may be determined based on an MSW bulk density of from 400 to 600 lb/yd<sup>3</sup> (240–360 kg/m<sup>3</sup>).<sup>54,61</sup> Other factors to consider in sizing and laying out refuse storage facilities in WTE plants is that refuse flows very poorly and can maintain an angle of repose greater than 90°. Thus, MSW is commonly stacked in storage facilities to maximize storage capacity.

Sizing a refuse storage pit requires the use of empirical data, judgment, site constraints, and knowledge of plant layout and operations. The pit should be at least long enough to provide sufficient truck tipping positions so that the trucks are not unduly delayed in discharging their waste (tipping) into the pit. It has been found in practice that it takes an average of 10 min for the truck to perform the tipping operation. This time may be shorter for packer trucks and longer for transfer vehicles. Each tipping position must provide at least 14 ft of unobstructed width for this operation. Ideally, 20 ft should be allowed for each tipping position to allow for convenient truck access and space for armored building support columns.

The pit should be capable of holding a minimum of 3 days' storage at the facility's maximum continuous rating. The desired volume should be based on a bulk density of about 500 lb/cycle of waste. The dimensions of the pit will be dependent on site constraints and the facility design. The pit is usually at least as long as the width of all the boilers it feeds. The depth will be dependent on groundwater conditions, but should be 30–45 ft deep if possible. The total volume of storage should equal the volume in the pit up to the tipping floor level plus the volume above the tipping floor assuming the waste is stacked at a 45° from the charging floor wall to the tipping floor. The remainder of the pit will be used for the grapple to move waste away from the tipping positions. After the waste has been stacked, the grapple can remove the material against the tipping floor wall and form a trench, since the waste will maintain a vertical face when stacked.

At most newer and more successful RDF plants, after receiving the MSW in a floor dump type of operation, the MSW is loaded onto conveyors that carry the material

to flail mills or trommels with bag-breaking blades. These facilities break apart the bags containing the waste, allowing glass and some metals to be separated from the remaining MSW. The separated MSW, primarily the light combustible fraction, is then reduced in size. Removal of the glass prior to the size reduction process alleviates the problem, experienced in earlier plants, of contamination of combustible material with glass shards.

Processes to produce powdered fuel or RDF fuel pellets, although interesting, have not been developed to a state of commercial availability. A process to produce RDF by “hydro-pulping” after being attempted in two full-scale plants, was not commercially successful.

#### **47.3.2.2 Refuse Feeding**

Batch feeding of MSW, practiced in the past in mass-burn plants, is undesirable and is not practiced in modern plants. In the larger mass-burn plants, the solid waste is usually moved from the storage pit to a charging hopper by a traveling bridge crane and an orange-peel type of grapple. The grapple size is established by a duty cycle analysis, taking into account the quantity of material that must be moved from the pit to the furnaces, the distances over which the material must be moved, allowable crane speeds, and the need to rehandle (mixing and/or stacking) material in the pit. Grapples can range in size from 1.5 to 8 yd<sup>3</sup> (1–6 m<sup>3</sup>) capacity and larger.

The crane used in this service should be capable of meeting the severest of duty requirements.<sup>52</sup> The load lifting capability is established by adding to the grapple weight, 1.5 times the volumetric capacity of the grapple times a density of MSW of 600–800 lb/yd<sup>3</sup> (360–480 kg/m<sup>3</sup>).<sup>37</sup> In the past, the crane has been operated from an air-conditioned cab mounted on the bridge. However, crane operation is now centralized in a fixed control room, usually located at the charging floor elevation and either over the tipping positions opposite the charging hoppers or in the vicinity of the charging hoppers.

In modern mass-burn plants, the MSW is deposited from the crane grapple into a charging hopper. The charging hopper, which is built large enough to prevent spillage on the charging floor and with slopes steep enough to prevent bridging, is placed on top of a vertical feed chute that discharges the MSW into the furnace. The feed chute may be constructed of water cooled steel plates or steel plates lined with smooth refractory material. The chute is normally at least 4 ft (1.2 m) wide, to pass large objects with a minimum of bridging, and the width of the furnace. It is kept full of refuse to prevent uncontrolled admission of air into the furnace. The refuse is fed from the bottom of the feed chute into the furnace by a portion of the mechanical grate, or by a ram. The ram generally provides better control of the rate of feed into the furnace than the older technique of using a portion of the mechanical grate for refuse feed.

In RDF plants, conveyors, live bottom bins, and pneumatic handling of the size-reduced MSW combustible material have been utilized. The fuel material is usually blown into these furnaces, where it is partially burned while in suspension, with combustion being completed on grates at the bottom of the furnace. These fuel feeding systems are generally more complex than the mass-burn systems.

#### **47.3.3 Combustion Principles**

Combustion is the rapid oxidation of combustible substances with release of heat. Oxygen is the sole supporter of combustion. Carbon and hydrogen are by far the most important of the combustible substances. These two elements occur either in a free or combined state

**TABLE 47.4**

Elements and Compounds Encountered in Combustion

Substance	Molecular Symbol	Molecular Weight	Form	Density (lb/ft <sup>3</sup> )
Carbon	C	12.0	Solid	—
Hydrogen	H <sub>2</sub>	2.0	Gas	0.0053
Sulfur	S	32.1	Solid	—
Carbon monoxide	CO	28.0	Gas	0.0780
Oxygen	O <sub>2</sub>	32.0	Gas	0.0846
Nitrogen	N <sub>2</sub>	28.0	Gas	0.0744
Nitrogen atmos.	N <sub>2atm</sub>	28.2	Gas	0.0748
Dry air		29.0	Gas	0.0766
Carbon dioxide	CO <sub>2</sub>	44.0	Gas	0.1170
Water	H <sub>2</sub> O	18.0	Gas/liquid	0.0476
Sulfur dioxide	SO <sub>2</sub>	64.1	Gas	0.1733
Oxides of nitrogen	NO <sub>x</sub>	—	Gas	—
Hydrogen chloride	HCl	36.5	Gas	0.1016

in all fuels—solid, liquid, and gaseous. Sulfur is the only other element considered to be combustible. In combustion of MSW, sulfur is a minor constituent with regard to heating value. However, it is a concern in design of the air pollution control equipment. The only source of oxygen considered here will be the oxygen in the air around us.

Table 47.4 displays the elements and compounds that play a part in the combustion process. The elemental and molecular weights displayed are approximate values which are sufficient for combustion calculations. Nitrogen is listed as chemical nitrogen N<sub>2</sub>, with a molecular weight of 28.0 and as atmospheric nitrogen, N<sub>2atm</sub>, which is a calculated figure to account for trace constituents of dry air. Water occurs as a vapor in air and in the products of combustion and as a liquid or vapor constituent of MSW fuel.

A U.S. standard atmosphere of dry air has been defined as a mechanical mixture of 20.947% O<sub>2</sub>, 78.086% N<sub>2</sub>, 0.934% Ar (argon), and 0.033% CO<sub>2</sub> by volume.<sup>43</sup> The percentages of argon and carbon dioxide in air can be combined with chemical nitrogen to develop the following compositions of dry air by volume and by weight that can be used for combustion calculations:

Constituent	% by Volume	% by Weight
Oxygen, O <sub>2</sub>	20.95	23.14
Atmospheric nitrogen, N <sub>2atm</sub>	79.05	76.86

Atmospheric air also contains some water vapor. The level of water vapor in air, or its humidity, is a function of atmospheric conditions. It is measured by wet and dry bulb thermometer readings and a psychrometric chart. If specific data are not known, the American Boiler Manufacturers Association recommends a standard of 0.013 lb of water per pound of dry air, which corresponds to 60% relative humidity and a dry bulb temperature of 80°F.

Table 47.5 displays the chemical reactions of combustion. These reactions result in complete combustion; that is, the elements and compounds unite with all the oxygen with which they are capable of entering into combination. In actuality, combustion is a more complex process in which heat in the combustion chamber causes intermediate

TABLE 47.5

Chemical Reactions of Combustion

Combustible	Reaction
Carbon	$C + O_2 = CO_2$
Hydrogen	$2H_2 + O_2 = 2H_2O$
Sulfur	$S + O_2 = SO_2$
Carbon monoxide	$2CO + O_2 = 2CO_2$
Nitrogen	$N_2 + O_2 = 2NO$
Nitrogen	$N_2 + 2O_2 = 2NO_2$
Nitrogen	$N_2 + 3O_2 = 2NO_3$
Chlorine	$4Cl + 2H_2O = 4HCl + O_2$

Source: From Hecklinger, R.S., Combustion, in: *The Engineering Handbook*, Dorf, R.C. (ed.), CRC Press, Inc., Boca Raton, FL, 1996.

reactions leading up to complete combustion. An example of intermediate steps to complete combustion would be when carbon reacts with oxygen to form carbon monoxide and, later in the combustion process, the carbon monoxide reacts with more oxygen to form carbon dioxide. The combined reaction produces precisely the same result as if an atom of carbon combined with a molecule of oxygen to form a molecule of carbon dioxide in the initial reaction. An effectively controlled combustion process results in well less than 0.01% of the carbon in the fuel leaving the combustion chamber as carbon monoxide; and the remaining 99.99% of the carbon in the fuel leaves the combustion process as carbon dioxide. It should also be noted with regard to Table 47.5 that some of the sulfur in a fuel may combust to  $SO_3$  rather than  $SO_2$  with a markedly higher release of heat. However, it is known that only a small portion of the sulfur will combust to  $SO_3$  and some of the sulfur in fuel may be in the form of pyrites ( $FeS_2$ ), which do not combust at all. Therefore, only the  $SO_2$  reaction is given. Also, some nitrogen is converted to oxides of nitrogen ( $NO_x$ ), and some chlorine is converted to hydrogen chloride in the presence of moisture in the flue gas. While these components do not factor into the combustion calculations, they are important for the purpose of establishing air pollution control requirements.

Factors directly affecting furnace design are the moisture and the combustible content of the solid waste to be burnt and the volatility of the material to be burnt. The means for temperature control and sizing of flues and other plant elements should be based on design parameters that result in large sizes. Combustion controls should provide satisfactory operation for loads below the maximum rated capacity of the units.

The combustible portion of MSW is composed largely of cellulose and similar materials originating from wood, mixed with appreciable amounts of plastics and rubber, as well as some fats, oils, and waxes. The heat released by burning dry cellulose is approximately 8,000 Btu/lb, while that released by certain plastics, rubber, fats, oils, and so on, may be as high as 17,000 Btu/lb. If MSW consists of five parts cellulose and one part plastics, rubber, oil, and fat, the heat content of the dry combustible matter only is approximately 9500 Btu/lb.

The heat released in combustion of basic combustible substances is displayed in Table 47.6. The heating value of a substance can be expressed either as higher (or gross) heating value or as lower (or net) heating value. The higher heating value takes into account the fact that water vapor formed or evaporated in the process of combustion includes the latent heat of vaporization, which could be recovered if the products of combustion are reduced in temperature sufficiently to condense the water vapor to liquid water.

**TABLE 47.6**

Heat of Combustion

Combustible	Molecular Symbol	Heating Value (Btu/lb)	
		Gross	Net
Carbon	C	14,100	14,100
Hydrogen	H <sub>2</sub>	61,100	51,600
Sulfur	S	3,980	3,980
Carbon monoxide	CO	4,350	4,350

Source: From Hecklinger, R.S., Combustion, in: *The Engineering Handbook*, Dorf, R.C. (ed.), CRC Press, Inc., Boca Raton, FL, 1996.

The lower heating value is predicated on the assumption that the latent heat of vaporization will not be recovered from the products of combustion.

The heat released during combustion may be determined in a bomb calorimeter, a device with a metal container (bomb) immersed in a water jacket. A 1 g MSW sample is burned with a known quantity of oxygen, and the heat released is determined by measuring the increase in temperature of the water in the water jacket. Since the bomb calorimeter is cooled to near ambient conditions, the heat recovery measured includes the latent heat of vaporization as the products of combustion are cooled and condensed in the bomb. That is, the bomb calorimeter inherently measures higher heating value (HHV). It has been customary in the United States to express heating value as HHV. In Europe and elsewhere, heating value is frequently expressed as the lower heating value (LHV).

Heating value can be converted from HHV to LHV if weight decimal percentages of moisture and hydrogen (other than the hydrogen in moisture) in the fuel are known, using the following formula:

$$\text{LHV}_{\text{Btu/lb}} = \text{HHV}_{\text{Btu/lb}} - [\% \text{H}_2\text{O} + (9 \times \% \text{H}_2)] \times (1050 \text{ Btu/lb}) \quad (47.1)$$

$$\text{LHV}_{\text{J/kg}} = \text{HHV}_{\text{J/kg}} - [(9 \times \% \text{H}_2) + \% \text{H}_2\text{O}] \times (2240 \text{ kJ/kg}) \quad (47.2)$$

For example (using data from [Table 47.9](#)),

$$\text{LHV}_{\text{Btu/lb}} = \text{HHV}_{\text{Btu/lb}} - [\% \text{H}_2\text{O} + (9 \times \% \text{H}_2)] \times 1050 \text{ Btu/lb}$$

$$\text{LHV}_{\text{Btu/lb}} = 4940 - [0.30 + (9 \times 0.047)] \times 1050$$

$$\text{LHV}_{\text{Btu/lb}} = 4940 - [0.30 + 0.42] \times 1050$$

$$\text{LHV}_{\text{Btu/lb}} = 4940 - 756 = 4184 \text{ Btu/lb}$$

Another method for determining the approximate higher heating value for MSW is to perform an ultimate analysis and then apply Dulong's formula:

$$\text{HHV}_{(\text{Btu/lb})} = 14,544 \text{ C} + 62,028 \left( \text{H}_2 - \frac{\text{O}_2}{8} \right) + 4,050 \text{ S} \quad (47.3)$$

where C, H<sub>2</sub>, O<sub>2</sub>, and S represent the decimal proportionate parts by weight of carbon, hydrogen, oxygen, and sulfur in the fuel. The term O<sub>2</sub>/8 is a correction used to account for hydrogen which is already combined with oxygen in the form of water. For example (using data from [Table 47.9](#))

$$\text{HHV}_{(\text{Btu/lb})} = 14,544 \text{ C} + 62,028 \left( \text{H}_2 - \frac{\text{O}_2}{8} \right) + 4,050 \text{ S}$$

$$\text{HHV} = 14,544 \times 0.257 + 62,028 \left( 0.048 - \frac{0.21}{8} \right) + 4,050 \times 0.001$$

$$\text{HHV} = 3,738 + 62,028(0.047 - 0.026) + 4.0$$

$$\text{HHV} = 3,738 + 62,028 \times 0.021 + 4.0$$

$$\text{HHV} = 3738 + 1303 + 4 = 5045 \text{ Btu/lb}$$

An alternate method of estimating the HHV is to multiply the approximate dry combustible HHV of 9500 Btu/lb by the weight fraction of combustibles:

$$\text{HHV} = 9500 \times (1 - \text{moisture} - \text{ash})$$

$$\text{HHV} = 9500 \times (1 - 0.30 - 0.18)$$

$$\text{HHV} = 9500 \times 0.52 = 4940 \text{ Btu/lb}$$

The American Society for Testing and Materials (ASTM) publishes methods for determining the ultimate analysis of solid fuels such as MSW. The ultimate analysis of a fuel is developed through measures of carbon, hydrogen, sulfur, nitrogen, ash, and moisture content. Oxygen is normally determined “by difference”; that is, once the percentages of the other components are measured, the remaining material is assumed to be oxygen. For solid fuels, such as MSW, it is frequently desirable to determine the proximate analysis of the fuel. The procedure for determining the proximate analysis is also prescribed by ASTM. The qualities of the fuel measured in percentage by weight are moisture, volatile matter, fixed carbon, and ash. This provides an indication of combustion characteristics of a solid fuel. As a solid fuel is heated to combustion, first the moisture in the fuel evaporates, then some of the combustible constituents volatilize (gasify) and combust as a gas with oxygen, and the remaining combustible constituents remain as fixed carbon in a solid state and combust with oxygen to form carbon dioxide. The material remaining after combustion is complete is the ash. MSW, with a high percentage of volatiles and a low percentage of fixed carbon, burns with much flame.

[Table 47.7](#) displays ignition temperatures for combustible substances in MSW. The ignition temperature is the temperature to which the combustible substance must be raised before it will unite in chemical combination with oxygen. Thus, the temperature must be reached and oxygen must be present for combustion to take place. Ignition temperatures are not fixed temperatures for a given substance. The actual ignition temperature is influenced by combustion chamber configuration, oxygen fuel ratio, and synergistic effect of

**TABLE 47.7**

## Ignition Temperatures

Combustible	Molecular Symbol	Ignition Temperature (°F)
Carbon (fixed)	C	650
Hydrogen	H <sub>2</sub>	1080
Sulfur	S	470
Carbon monoxide	CO	1170

multiple combustible substances. The ignition temperature of MSW is the ignition temperature of its fixed carbon component. The volatile components of MSW are gasified but not ignited before the ignition temperature is attained.

The oxygen, nitrogen, and air data displayed in Table 47.8 represent the weight of air theoretically required to completely combust one pound of a combustible substance. The weight of oxygen required is the ratio of molecular weight of oxygen to molecular weight of the combustion constituent as displayed in Table 47.5. The weights of nitrogen and air required are calculated from the percentage by weight constituents of dry air. In actuality, to achieve complete combustion, air in excess of the theoretical requirement is required for complete combustion to increase the likelihood that all of the combustible substances are joined with sufficient oxygen to complete combustion. The level of excess air required in the combustion of MSW depends on the configuration of the combustion chamber, the nature of the fuel firing equipment, and the effectiveness of mixing combustion air with the MSW. An excess air level of 80% is commonly associated with combustion of MSW in modern WTE facilities. Excess air is generally monitored using an oxygen analyzer at the economizer outlet. The type of analyzer used at waste-to-energy facilities generally reports percent wet oxygen. The dry oxygen can be estimated by assuming 15% moisture in the flue gas using the following equation:

$$\text{Dry oxygen} = (\text{wet oxygen}) / (1 - \text{percent moisture}/100), \text{ or } \text{dry oxygen} = (1.176)(\text{wet oxygen})$$

Excess air can be approximated by the following equation:

$$\text{Excess air} = 55.2 - 10.46 \times (\text{dry O}_2) + 1.4 \times (\text{dry O}_2)^2$$

where dry O<sub>2</sub> is the percentage dry oxygen in the flue gas.

Excess air serves to dilute and thereby reduce the temperature of the products of combustion. The reduction of temperature tends to reduce the heat energy available for useful work. Therefore, the actual excess air used in the combustion process is a balance between the desire to achieve complete combustion and the objective of maximizing the heat energy available for useful work.

It is frequently useful to know the temperature attained by combustion. The heat released during combustion heats the products of combustion to a calculable temperature. It must be understood that the calculation procedure presented here assumes complete combustion and that no heat is lost to the surrounding environment. Thus, it is a temperature that is useful to compare one combustion process with another. The heat available for heating the products of combustion is the lower heating value of the fuel. The increase in temperature is the lower heating value divided by the mean specific heat of the products of combustion. The mean specific heat is a function of the constituent products of combustion ( $W_{P.C.}$ ) and the temperature. To approximate the theoretical temperature attainable, one can use a specific heat of 0.55 Btu/lb/°F for water vapor ( $W_{H_2O}$ ) and 0.28 Btu/lb/°F for the other gaseous products of combustion ( $W_{P.C.} - W_{H_2O}$ ). Thus, the formula approximating the temperature attained during combustion is

$$T_{\text{comb}} = T + \frac{\text{LHV}_{\text{Btu/lb}}}{0.55W_{H_2O} + 0.28(W_{P.C.} - W_{H_2O})} \quad (47.4)$$

For example (using data from Table 47.9)

$$T_{\text{comb}} = T_{\text{ambient}} + \frac{\text{LHV}_{\text{Btu/lb}}}{0.55W_{H_2O} + 0.28(W_{P.C.} + W_{H_2O})}$$

If the ambient temperature is assumed to be 60°F, then

$$T_{\text{comb}} = 60 + \frac{4184}{0.55 \times 0.81 + 0.28(7.55 - 0.81)}$$

$$T_{\text{comb}} = 60 + \frac{4184}{0.45 + 1.89} = 60 + \frac{4184}{2.34}$$

$$T_{\text{comb}} = 1848 \cong 1850^\circ\text{F}$$

Typical combustion calculations are provided in Table 47.9 for MSW to determine the products of the combustion process. Each of the combustible substances combines and completely combusts with oxygen as displayed in Table 47.5. The weight ratio of oxygen to the combustible substance is the ratio of molecular weights. Table 47.8 displays the weight or volume of oxygen theoretically required for complete combustion of one pound of the combustible substance. Sulfur dioxide from combustion of sulfur in fuel is combined with  $\text{CO}_2$  in the sample calculation as a matter of convenience. If desired, a separate column can be prepared for sulfur dioxide in the products of combustion. Oxygen in the fuel combines with the combustible substances in the fuel, thereby reducing the quantity of air required to achieve complete combustion. The sample calculation uses the weight percentages of oxygen

**TABLE 47.9**

Sample Calculation for Municipal Solid Waste (MSW)

Air Calculations (80% Excess Air)				
Ultimate Analysis				
Substance	Fraction% by Weight	Oxygen Required for Combustion, lb/lb of Element	Theoretical Oxygen, lb/lb of Element	Theoretical Dry Air, lb/lb of Element
Carbon	0.279	2.67	0.745 <sup>a</sup>	3.218 <sup>b</sup>

Moisture from fuel			1.00	0.281 <sup>d</sup>
Moisture from air			0.084 <sup>g</sup>	
Total moisture			0.698 <sup>h</sup>	
Total			7.382	
LHV = 5100 – [0.281 + (9 × 0.037)] × 1050 = 4455 Btu/lb				
Temperature developed in combustion = 60 + 4455 / [(0.698 × 0.55 <sup>i</sup> ) + (7.382 – 0.698) × 0.28 <sup>j</sup> ] = 2035°F				
Check:				
Total products of combustion = 180% of theoretical air + moisture from air + fraction percent by weight of C, H, O, N, S, and moisture				
7.382 = 6.485 + 0.084 + 0.279 + 0.037 + 0.209 + 0.005 + 0.002 + 0.281 = 7.382				

<sup>a</sup> Weight percent of element times oxygen required for combustion.<sup>b</sup> Theoretical oxygen times 4.32.<sup>c</sup> Amount of theoretical air due to oxygen in fuel.<sup>d</sup> Weight percent of element times lb/lb of element.<sup>e</sup> Excess oxygen.<sup>f</sup> 180% of theoretical dry air times 0.7686 plus weight percent of nitrogen in fuel.<sup>g</sup> Moisture in combustion air = 0.013 times 180% of theoretical air (0.013 lb moisture per lb of dry air at 80°F and 60% relative humidity).<sup>h</sup> Total of moisture from combustion of hydrogen, moisture in fuel, and moisture from air.<sup>i</sup> Heat capacity of water vapor.<sup>j</sup> Heat capacity of dry flue gas.

to reduce the theoretical air requirements and the nitrogen in the products of combustion. The decimal percentage of excess air is multiplied by the total theoretical air requirement to establish the weight of excess air and the total air requirement including excess air.

#### 47.3.4 Furnaces

While the general principles of a modern waste combustor burning as-received MSW are common to all types, the specific solid waste combustion process is rather complex. The waste is heated by contact with hot combustion gases or preheated air, and by radiation from the furnace walls. Drying occurs in a temperature range of 122°F–302°F (50°C–150°C). At higher temperatures, volatile matter is formed by complicated thermal decomposition reactions. This volatile matter is generally combustible and, after ignition, produces flames. The remaining material is further degased and burns much more slowly. In an RDF furnace (see [Figure 47.3](#)), most of the volatile matter and some of the fixed carbon is burned in suspension while the remaining fixed carbon is combusted on a grate at the bottom of the furnace.

The complexity of the combustion of solid waste streams results from the nature of the decomposition and burning reactions and their association with heat transfer, air flow, and diffusion. In most waste combustors, combustion takes place while the solids are supported on and conveyed by a grate. Since the early 1960s, most MSW incinerators have incorporated one of a number of available proprietary grate systems that allow continuous feed of unscreened waste into and movement through furnaces with integral boiler facilities. The grate performs several functions: provides support for the refuse, admits underfire air through openings in the grate surface, transports the solid waste from feed mechanism to ash quench, agitates the bed, and serves to agitate and redistribute the burning mass.

The basic design factors which determine furnace capacity are grate area and furnace volume. Also, the available capacity and method of introducing both underfire and overfire air will influence, to a lesser extent, furnace capacity. Required grate area, in a conservative design, is normally determined by limiting the burning rate to between 60 and 70 lb/ft<sup>2</sup> h (290–340 kg/m<sup>2</sup> h) of grate area.<sup>54</sup> This is based on limiting the heat release rate loading on the grate to 250,000–300,000 Btu/ft<sup>2</sup> of grate per h (2.8–3.4 GJ/m<sup>2</sup>/h).

Furnace volume required is established by the rate of heat release from the fuel. Thus, furnace volume is generally established by using heat release rates ranging from 12,500 to 20,000 Btu/ft<sup>3</sup>/h (450–750 MJ/m<sup>3</sup>/h), with the lower heat release rate being more desirable from the standpoint of developing a conservative design. A conservative approach to design in this area is desirable because of probable periodic operation above design capacity to meet short-term higher than normal refuse collections and possible receipt of high heat-content waste.

Water wall units burning as-received MSW have been built as small as 75–100 tons/day (68–91 tons/day) capacity. However, the cost per ton of rated capacity of such units is relatively high. A more common unit size for both mass-burn and RDF furnaces is 250–1000 tons/day (225–900 tons/day), while water wall mass-fired units have been built as large as 750–1200 tons/day (675–1090 tons/day) capacity.<sup>5</sup>

The primary objective of a mechanical grate in a mass-burn furnace is to convey the refuse from the point of feed through the burning zone to the point of residue discharge with a proper depth of fuel and sufficient retention time to achieve complete combustion. The refuse bed should be agitated so as to enhance combustion. However, the agitation

should not be so pronounced that particulate emissions are unreasonably increased. The rate of movement of the grate or its parts should be adjustable to meet varying conditions or needs in the furnace.

In the United States over the past 20 years, several types of mechanical grates have been used in continuous feed furnaces burning as-received MSW. These include reciprocating grates (see Figure 47.4), rocking grates (see Figure 47.5), roller grates (see [Figure 47.6](#)),

**FIGURE 47.4**  
Reciprocating grates.

**FIGURE 47.5**  
Rocking grates.

**FIGURE 47.6**

Roller grate system by Covanta Energy Group.

and water wall rotary combustors for mass-burn units, and traveling grates for RDF units (see [Figure 47.3](#)). The reciprocating grates, rocking grates, and roller grates agitate and move the refuse material through the furnace by the movement of the grate elements and the incline of the grate bed. Additional agitation is obtained, particularly in the reciprocating grate, by drops in elevation between grate sections. The rotary combustor slowly rotates to tumble the refuse material, which is conveyed through the inside of the cylinder. The combustor is inclined from the horizontal so that gravity assists in moving the material through the unit. The traveling grate conveys the refuse through the furnace on the grate surface. Stirring is accomplished by building the grate in two or more sections, with a drop between sections to agitate the material.

Other grate systems have been developed in Europe for burning as-received MSW, some of which are currently being utilized in plants being constructed or in operation in the United States. The roller grate, or so-called Dusseldorf System (see [Figure 47.6](#)), uses a series of 5 or more rotating cylindrical grates, or drums, placed at a slope of about  $30^\circ$ .<sup>57</sup> The refuse is conveyed by the surface of the drums, which rotate in the direction of refuse flow, and is agitated as it tumbles from drum to drum. Underfire air is introduced through the surface of the drums. Both the Von Roll and the Martin grates use a reciprocating motion to push the refuse material through the furnace. However, in the Martin grate (see [Figure 47.7](#)), the grate surface slopes steeply down from the feed end of the furnace to the ash discharge end and the grate sections push the refuse uphill against the flow of waste, causing a gentle tumbling and agitation of the fuel bed.

Another variable feature in the various grate designs is the percentage of open area to allow for passage of underfire air.<sup>73</sup> These air openings vary from approximately 2% to 30%

**FIGURE 47.7**

Martin system. (From Braun, H., Metzger, M., and Vogg, H., *Zur Problematik der Quecksilber-Abscheidung aus Rauchgasen von Müllverbrennungsanlagen*, Vol. 1, Teil 2, 1985.)

of the grate surface area. The smaller air openings tend to limit the quantity of siftings dropping through the grates and create a pressure drop that assists in controlling the point of introduction of underfire air. RDF grates generally have a smaller percentage of air openings. Larger air openings make control of underfire air more difficult but allow for continuous removal of fine material, which could interfere with the combustion process, from the fuel bed.

Furnace configuration is largely dictated by the type of grate used. In the continuous feed mechanical grate system, the furnace is rectangular in plan and the height is dependent upon the volume required by the limiting rate of heat release cited earlier. An optimum furnace configuration would provide sufficient volume for retention of gases in the high-temperature zone of maximum fuel volatilization long enough to ensure complete combustion, and would be arranged so that the entire volume is effectively utilized. Temperatures are usually high enough with present-day refuse for proper combustion. Turbulence should be provided by a properly designed overfire air system.

With present-day mass-fired water wall furnaces, the use of refractories in furnace construction has been minimized but not eliminated. Refractory materials may be used to line charging chutes, provide a transition enclosure between the top of the grates and the bottom of the water walls, a protective coating on the water wall tubes, and an insulating layer between the hot gases and the metal walls of flues downstream of the primary combustion chamber. Refractory brick used in a charging chute must be able to withstand high temperatures, flame impingement, thermal shock, slagging, spalling, and abrasion. The protective coating on the water wall tubes must be

relatively dense castable material with a relatively high heat conductivity.<sup>74</sup> Insulating refractories used in flues downstream from the boilers, on the other hand, should have a low heat conductivity.

Refractories are generally classified according to their physical and chemical properties, such as resistance to chemical attack, hardness, strength, heat conductivity, porosity, and thermal expansion.<sup>49</sup> The material may be cast in brick in a variety of shapes and laid up with air-setting or thermal-setting mortar, or may be used in a moldable or plastic form. Material used in waste combustor construction includes “high duty” and “superduty” fireclay brick, phosphate-bonded alumina material, and silicon carbide, among others. In selecting the proper materials for application in this type of service, because the variety of materials is so great and the conditions of service so varied and severe,<sup>16</sup> advice of a recognized manufacturer should be sought.

As indicated in the section on combustion calculations, the combustion process requires oxygen to complete the reactions involved in the burning process. The air that must be delivered in the furnace to supply the exact amount of oxygen required for completion of combustion is called the stoichiometric air requirement. Additional air supplied to the furnace is called excess air and is usually expressed as a percentage of the stoichiometric requirements.

The total air supply capacity in a waste combustor must be greater than the stoichiometric requirement for combustion because of imperfect mixing and to assist in controlling temperatures, particularly with dry, high heat-content refuse. The total combustion air requirements can range from 6 to 8 lb of air/lb of refuse for mass-fired water wall furnaces, and slightly less for RDF facilities.

In the modern mass-burn mechanical grate furnace chamber, at least two blower systems should be provided to supply combustion air to the furnace—one for underfire or undergrate air and the other for overfire air. Underfire air, admitted to the furnace from under the grates and through the fuel bed, is used to supply primary air to the combustion process and to cool the grates.

Overfire air may be introduced in two levels. Air introduced at the first level, called secondary air, immediately above the fuel bed, is used to promote turbulence and mixing, and to complete the combustion of volatile gases driven off the bed of burning solid waste. The second row of nozzles, which are generally located higher in the furnace wall, allow the introduction of air, called tertiary air, into the furnace to promote additional mixing of gases and for temperature control.

Blower capacities should be divided so that the underfire air blower is capable of furnishing half to two-thirds of the total calculated combustion air requirements, while the overfire blower should have a capacity of about half of the total calculated air requirements. Setting these capacities requires some judgment related to assessing how great a variation is anticipated in refuse heat contents during plant operation. Variable frequency drivers on the fan motors or dampers on fan inlets and air distribution ducts should be provided for control purposes.

Pressures on underfire air systems in mass-burn units for most U.S. types of grates will normally range from 2 to 5 in. of water. European grates frequently require a higher pressure. The pressure on the overfire air should be high enough that the air, when introduced into the furnace, produces adequate turbulence without impinging on the opposite wall. This is normally accomplished by the use of numerous relatively small (1½–3 in. in diameter) nozzles at pressures of 20 in. of water or higher.

Recirculated flue gas is sometimes used in part for underfire air and tempering air. Using recirculated flue gas as combustion air reduces the quantity of fresh air needed,

thereby increasing thermal efficiency and minimizing thermal  $\text{NO}_x$  formation. It can also be used as tempering air to control the temperature of the flue gas entering the boiler.<sup>13</sup> The duct work for recirculated flue gas is highly susceptible to corrosion due to the presence of acid gases. For this reason, it is critical that the recirculated gas be taken from the system after the pollution control devices.

In an RDF-fired, spreader-stoker type of unit, the combustible material is generally introduced through several air-swept spouts in the front water wall, is partially burned in suspension, and then falls onto a grate on which combustion is completed as the partially burned material is conveyed to the residue discharge under the front water wall face of the furnace. Densified RDF can also be burned in such units. The RDF can furnish all the combustible input to the system, or it may be co-fired with a fossil fuel, generally coal.

Some combustion air in RDF-fired units is introduced with the fuel through the air-swept feed spouts to distribute the fuel on the grate. Additional air is introduced into the furnace higher in the water wall area to enhance turbulence and mixing in the unit and/or to control temperatures. This additional combustion air supply is similar to the tertiary air utilized in the mass-burn units.

#### **47.3.5 Boilers**

Substantial quantities of heat energy may be recovered during the thermal destruction of the combustible portions of MSW. Systems that have been successfully used to recover this energy include mass-fired refractory combustion chambers followed by a convection boiler section; a mass-fired water wall unit where the water wall furnace enclosure forms an integral part of the boiler system and an RDF semisuspension-fired spreader-stoker/boiler unit. Each system has apparent advantages and disadvantages.

##### ***47.3.5.1 Refractory Furnace with Waste Heat Boiler***

In a refractory furnace waste heat boiler unit, energy extraction efficiencies are generally lower, assuming the same boiler outlet temperatures, than with the other systems. Approximately 50%–65% of the heat generated in the combustion process may be recovered with such systems. These units can produce approximately 2–3 lb steam/lb of normal MSW (heat content = 4500 Btu/lb), versus 3 or more lb/lb MSW in mass-fired water wall units. This lower efficiency of steam generation is caused by larger heat losses due to higher excess air quantities needed with such units to control furnace temperatures so that furnace refractories are not damaged. However, the boilers in such units, if properly designed and operated, generally are less susceptible to boiler tube metal wastage problems than the other systems listed earlier.

##### ***47.3.5.2 Mass-Fired Water Wall Units***

Mass-fired water wall units are the most widely utilized type of heat recovery unit in this field today. In this type of unit, the primary combustion chamber is fabricated from closely spaced steel tubes through which water circulates. This water wall lined, primary combustion chamber incorporated into the overall boiler system is followed by a convection type of boiler surface. It has been found desirable in these plants to coat a substantial height of the primary combustion chamber, subject to higher temperatures and flame impingement, with a thin coating of a silicon carbide type of refractory material

or inconel and to limit average gas velocities to under 15 ft/s (4.5 m/s) in this portion of the furnace. Gas velocities entering the boiler convection bank should be less than 30 ft/s (9.0 m/s).<sup>74</sup> Efficiency of heat recovery in such units has been found to range generally from 65% to 75%, with steam production usually above 3 lb of steam/lb of normal as-received MSW. Water table studies have been used occasionally in some larger units to check on combinations of furnace configuration and location of overfire combustion of air nozzles.<sup>27</sup>

#### **47.3.5.3 RDF-Fired Water Wall Units**

As pointed out earlier, RDF may be burned in a semisuspension-fired spreader-stoker/boiler unit where the RDF is introduced through several air-swept spouts in the front water wall, partially burns in suspension, and then falls on a grate on which combustion is completed. In this type of unit, the water wall lined primary combustion enclosure (furnace) may be followed by a superheater (usually), a convection boiler heat transfer surface, and (sometimes) an economizer surface.

Efficiencies of RDF-fired boilers generally range from 65% to 80% of the heat input from the RDF. Steam production from RDF would normally be expected to be somewhat greater than 3 lb of steam/lb of RDF. However, when one takes into account the combustible material lost in the processing of as-received MSW to produce the RDF, steam production normally will fall to about 3 lb of steam/lb of as-received MSW.<sup>35</sup>

If the energy recovered from the combustion of as-received MSW or RDF is to be used to produce electricity, some superheating is desirable, if not necessary. Since boiler tube metal wastage in these plants is, at least partially, a function of tube metal temperature<sup>10</sup> and steam is a less efficient cooling medium than water, superheater surface is more prone to metal wastage problems than other areas of boiler tubing. Tube metal temperatures, above which metal wastage can be a significant operational problem, are generally thought to range from 650°F to 850°F (345°C–455°C). These temperatures are lower than those for maximum efficiency of electrical generation by steam driven turbines. It is desirable to consider this in facility design to reduce plant downtime and minimize maintenance costs.

In the 1980s and early 1990s a so-called full-suspension combustion concept was attempted in which finely shredded combustible material from MSW was blown into the furnace through nozzles located one-half to two-thirds up the height of the water wall furnace enclosure. In this type of unit most of the RDF, usually composed of smaller sized particles than in the semisuspension-fired unit was supposed to burn in suspension. This concept was not successful due to problems related to the additional handling of the RDF and greater power required to achieve a finer shred. Also, some boilers seemed to experience a greater tendency for slag formation in the boiler. While the concept initially anticipated that the RDF would completely burn in suspension, experience indicated that this does not occur. Accordingly, dump grates became a necessity in such furnace boiler units to allow for completion of combustion prior to water quenching of the residue. This concept has been abandoned.

#### **47.3.6 Residue Handling and Disposal**

The residue from a well-designed, well-operated mass-fired incinerator burning as-received refuse will include the noncombustible material in the MSW and usually somewhat less than 3% of the combustibles. The nature of this material will vary from relatively

fine, light ash, burned tin cans, and partly melted glass to large, bulky items such as lawn mowers and bicycles.

In most modern WTE plants bottom ash residue is discharged from the end of the furnace grate through a chute into a trough filled with water. Removal from the trough may be either by a ram discharger onto a conveyor or by a flight conveyor to an elevated storage hopper from which it is discharged to a truck. If a water-filled trough with a flight conveyor is used, normally two troughs are provided, arranged so that the residue can be discharged through either trough. The second trough serves as a standby. Fly ash, residue collected in the air pollution control equipment downstream of the furnace/boiler, is usually returned back to and mixed with the bottom ash.

A key feature in the design of ash discharge facilities is provision for sealing the discharge end of the furnace to prevent uncontrollable admission of air. This seal is usually provided by carrying the ash discharge chute at least 6 in. (15 cm) below the water surface in the receiving trough. In the design of the conveyor mechanism, the proportions should be large because the material frequently contains bulky metal items and wire, potential causes of jamming. Also, the residue material tends to be extremely abrasive. A grizzly screen is often used to remove oversized bulky materials from the residue prior to its being loaded onto trucks for delivery to the landfill.

Residue is usually taken to a landfill for final disposal. Many modern facilities dispose of their residue at monofills (landfills that accept WTE plant residue only). The volume of material remaining for ultimate disposal will range from 5% to 15% of that received at the plant. Many plants currently operating in the United States that weigh MSW received at the plant and residue discharged from the furnaces, indicate that the weight of MSW is only reduced by from 40% to 50%. However, as much as one-third of the residue weight in these plants may be attributed to incomplete drainage of the material prior to its discharge into the final transportation container. The ram-type ash discharger used in European and most large U.S. plants generally achieves much better dewatering of residues than older water-filled trough, ash drag residue handling systems. These systems can achieve 65%–75% weight reduction.

The main components of ash are inert materials of low solubility, such as silicates, clay, and sand. Aluminum, calcium, chlorine, iron, selenium, sodium, and zinc are major elements in all particles and, along with carbon, can comprise over 10% by weight of the ash.<sup>20</sup>

A broad range of trace metals and organic compounds may be found in fly and bottom ash. Data on ash composition are difficult to compare, however, because they reflect different types and sizes of facilities, unknown sample collection methodology and sample size at each facility, interlab variation in testing procedures (even using the same test), and the heterogeneous nature of MSW itself. In addition, the presence of a substance in ash does not mean that it will enter the environment. Its fate depends on its solubility, how the ash is managed, and whether the ash is subject to conditions that cause leaching.<sup>47</sup>

Metals tend to be distributed differently in fly and bottom ash. Most volatile and semi-volatile metals, such as arsenic, mercury, lead, cadmium, and zinc, tend to be more concentrated or “enriched” in fly ash.<sup>59,70</sup> Less volatile metals, such as aluminum, chromium, iron, nickel, and tin, typically are concentrated in bottom ash.<sup>58,59</sup>

Organic chemicals also exhibit differing distributions. Dioxin/furan and polychlorinated biphenyls (PCBs) tend to be enriched in fly ash, while other chemicals such as polycyclic-aromatic hydrocarbons (PAHs) and phthalates tend to be concentrated in bottom ash.<sup>70</sup> Concentrations of dioxins/furans in fly ash exhibit a wide range, but they are significantly lower in ash from modern facilities than in ash from older incinerators.<sup>32,71,79</sup>

From a regulatory standpoint, a number of different testing procedures have been developed and utilized by regulatory agencies over the past several years in an attempt to predict the behavior of MSW residues deposited in landfills. Most of these methods were developed to predict leaching characteristics of residues deposited in landfills with raw or as-received MSW. Test results using these methods have been quite variable. However, as pointed out earlier, most modern WTE facilities dispose of their residue in monofills.<sup>68</sup> Tests of leachate from such monofills indicate metals concentrations below extraction procedure (EP) toxicity limits, and in most cases below U.S. drinking water standards.<sup>68</sup> Most test data show little or no leaching of organic chemicals.<sup>33,68</sup>

Following a court decision in the mid-1990s that ash residue from combustion of MSW is not exempt from the rules and regulations for hazardous waste, regulators have required testing of ash residues as they are discharged from the plant, i.e., separately if bottom ash and fly ash are discharged separately, and combined if they are combined prior to discharge from the plant. Bottom ash is alkaline and usually tests as nonhazardous, while fly ash is acidic and frequently tests as hazardous. When the fly ash is mixed with bottom ash prior to discharge from the plant, the alkaline bottom ash neutralizes the smaller quantities of acidic fly ash. The mixture tests as nonhazardous and can be disposed of in the normal monofill.

#### 47.3.7 Other Plant Facilities

The balance of the plant equipment is similar to that used in fossil fuel-fired boiler facilities. However, there are differences. Thus, the combustion of MSW produces a highly corrosive environment for boiler tube materials. Metal chlorides are believed to be primarily responsible for boiler tube corrosion problems.<sup>40</sup> The most important factors in high temperature corrosion are metal temperature, gas temperature, temperature gradient between gas temperature and metal temperature, deposit characteristics, and temperature fluctuations.<sup>1</sup> For this reason, boiler tubes are generally fabricated using corrosion-resistant alloys. Boiler tube shields or weld overlay cladding of boiler tubes with inconel are also used in highly corrosive/erosive areas.<sup>40</sup>

Some waste-to-energy facilities incorporate an air heater to preheat combustion air. Finned tubes plug quickly due to the large quantity of flyash in the flue gas. These air heaters are always of the bare tube design.

Since thermal efficiency is not an overriding concern in waste-to-energy facilities, many plants have one, or at most two, feedwater heaters. Some have only a deaerator for feedwater heating, unlike conventional power plants which have several stages of feedwater heaters.

---

#### 47.4 Air Pollution Control Facilities

Potential emissions from the combustion of MSW may be broadly classified into particulates, gaseous emissions, organic compounds, and trace metals. The concern is to reduce emissions so as to adequately protect public health. This is achieved using good combustion practice and equipment specially designed to remove the targeted pollutants.

During the 1980s and 1990s, the emission requirements for air pollution control equipment became more stringent as the USEPA promulgated new standards. The most recent standards were published in the December 19, 1995 Federal Register as 40 CFR Part 60 Subpart Cb.<sup>4,72</sup> These standards established emission limits for large (over 248 tons/day

**TABLE 47.10**

Emission Limits for Large Combustor Units

Parameter	Limit	Conditions
Particulates	27 mg/DSCM	Corrected to 7% oxygen
Opacity	10%	6 min average
Cadmium	0.04 mg/DSCM	Corrected to 7% oxygen
Lead	0.49 mg/DSCM	Corrected to 7% oxygen
Mercury	Lesser of 0.08 mg/DSCM or 85% removal	Corrected to 7% oxygen
SO <sub>2</sub>	Lesser of 31 ppmv or 75% removal	Corrected to 7% oxygen 24 h geometric mean
HCl	Lesser of 31 ppmv or 95% removal	Corrected to 7% oxygen
Dioxin/furans	60 ng/DSCM-ESP	Corrected to 7% oxygen
	30 ng/DSCM—all others	
NO <sub>x</sub>	220 ppmv—water wall	Corrected to 7% oxygen
	250 ppmv—rotary water wall	Corrected to 7% oxygen
	250 ppmv—RDF	Corrected to 7% oxygen
	240-fluidized bed	Corrected to 7% oxygen

**TABLE 47.11**

Emission Limits for Small Combustor Units

Parameter	Limit	Conditions
Particulates	70 mg/DSCM	Corrected to 7% oxygen
Opacity	10%	6-min average
Cadmium	0.10 mg/DSCM	Corrected to 7% oxygen
Lead	1.6 mg/DSCM	Corrected to 7% oxygen
Mercury	Lesser of 0.08 mg/DSCM or 85% removal	Corrected to 7% oxygen
SO <sub>2</sub>	Lesser of 80 ppmv or 50% removal	Corrected to 7% oxygen 24 h geometric mean
HCl	Lesser of 250 ppmv or 50% removal	Corrected to 7% oxygen
Dioxin/furans	125 ng/DSCM	Corrected to 7% oxygen
NO <sub>x</sub>	No limit	Corrected to 7% oxygen

[225 Mg/day]) and small (under 248 tons/day [225 Mg/day]) combustor units. Tables 47.10 and 47.11 contain a summary of those standards.

#### 47.4.1 Particulate Control

Particulates have been a matter of concern and regulatory agency attention for some time. The initial concern was from the standpoint of reducing gross particulate emissions that were both an aesthetic and a potential public health problem. Current interest and concern is directed toward better control of submicron-size particles<sup>75</sup> and other pollutants.

Electrostatic precipitators were the most commonly used gas cleaning device for particulate emission control in municipal waste combustors in the 1970s and early 1980s. They were designed to achieve high collection efficiencies (99% or higher) and meet the air emissions standards at the time. As emission standards became more stringent for particulates, fabric filters became more prevalent. Many electrostatic precipitators were replaced with fabric filters due to the 1995 regulations.

Fabric filters can operate at high efficiency, even in the submicron particle size range. They became widely used in the late 1980s because of the increasing emphasis of regulatory agencies on acid gas control and lower particulate emission levels. Baghouses are more effective than electrostatic precipitators for acid gas scrubbing when preceded by a spray dryer. The original bags used in these facilities had a limited life at high temperatures. Experiments using different materials of construction have led to longer bag life.

The scrubber/fabric filter control systems have been shown to be capable of operating at a particulate emission level of 20 mg/Nm<sup>3</sup> (0.009 gr/dscf) and lower (see Table 47.12). The material selected for the filter bags can have an important effect on filtering efficiency and the emission level thus achieved. In general, test results to date for the scrubber/fabric indicate lower particulate emissions than those for electrostatic precipitators on WTE plants. However, in general, electrostatic precipitators have not been designed to meet emission levels as low as those specified for fabric filter installations. Electrostatic precipitators following spray drying absorbers in Europe have been tested at particulate emission levels of 1–8 mg/Nm<sup>3</sup> (0.00045–0.0036 gr/dscf). The reliability and overall economics of the various control processes must be considered when making a selection of equipment to meet these very low emission control requirements. Data are available<sup>68</sup> on emission levels for approximately 30 different specific elements, many of them heavy metals. Elements found to occur in stack emission from municipal waste combustors are lead, chromium, cadmium, arsenic, zinc, antimony, mercury, molybdenum, calcium, vanadium, aluminum, magnesium, barium, potassium, strontium, sodium, manganese, cobalt, copper, silver, iron, titanium, boron, phosphorus, tin, and others.

Since the condensation point for metals such as lead, cadmium, chromium, and zinc is above 570°F (300°C), the removal efficiency for such metals is highly dependent on the particulate removal efficiency. Some metal compounds, particularly chlorides such as AsCl<sub>3</sub> at 252°F (122°C) and SnCl<sub>4</sub> at 212°F (100°C), have condensation points below 300°C. For such compounds, particulate collection temperatures will be a factor in collection efficiency. High removal (over 99%) has been observed for most metals for highly efficient (over 99%) particulate removal systems operating at appropriate temperatures.

#### 47.4.2 Gaseous Emission Control

Gaseous emissions such as SO<sub>2</sub>, HCl, CO, NO<sub>x</sub> and hydrocarbons have recently become a concern in municipal waste combustors and their emissions are now regulated. Acid gas emissions are controlled by scrubbing devices. Carbon monoxide, NO<sub>x</sub>, and hydrocarbons are controlled by good combustion practice. Oxides of nitrogen in some cases also require control equipment in the form of selective noncatalytic reduction (SNCR) to reduce NO<sub>x</sub> to acceptable levels.

Common gaseous emission factors, based on tests at a number of waste-to-energy plants, are shown in Table 47.13. High carbon monoxide and hydrocarbon emissions are caused by incomplete combustion and/or upsets in combustion conditions. High nitrogen oxide emissions are generally caused by high combustion temperatures. Hydrogen chloride (and hydrogen fluoride) and sulfur oxides, on the other hand, are directly a function of the chlorine (fluorine) and sulfur content in the fuel. The highest emissions, cited in Table 47.13, are from older, poorly controlled plants without significant pollution control equipment. Hydrogen chloride (and hydrogen fluoride) and sulfur oxides are best removed by acid gas scrubbing devices using chemical treatment. Initial efforts at acid gas control used wet collectors. However, this type of flue gas cleaning equipment is subject to problems such as corrosion, erosion, generation of acidic waste water, wet plumes, and, not least, high operating cost. Because of these problems, various semiwet and dry methods of cleaning flue gases have been developed and installed. These methods of gas treatment are based on the injection of slurried or powdered lime, limestone, or dolomite; adsorption; and absorption; followed by chemical conversion.<sup>68</sup> Since the reactivity of these lime materials is rather low, a multiple of the stoichiometric quantity is normally required to obtain a satisfactory cleaning effect. High removal efficiencies can be achieved for HCl, but reduction of SO<sub>2</sub> and SO<sub>3</sub> is more difficult to achieve and maintain. Slaked lime is highly reactive and stoichiometric ratios of 1.2–1.7 have been used for 97%–99% HCl removals and 60%–90%

**TABLE 47.13**

Gaseous Emission Factors for Municipal Waste Combustors (lb/ton)

	New York Incinerators	Test Results U.S. Plants	Martin Plants	EPA Data Base Tests through 1988	
	1968–1969	1971–1978	1984–1986	Mass-Burn	RDF
Carbon monoxide	—	3.7–9.3	0.2	0.06–16.2	1.0–5.2
Nitrogen oxides	—	0.5–2.2	5.0–6.0	0.5–4.5	2.5–3.2

SO<sub>2</sub> reductions, depending on operating conditions and particulate collector (fabric filters having demonstrated higher removal efficiencies than electrostatic precipitators).

Lime injection into a scrubber/fabric filter system has resulted in removal efficiencies of 90%–99% for HCl and 70%–90% SO<sub>2</sub>, provided that the flue gas temperature and the stoichiometric ratio for lime addition are suitable. This combination of processes has reduced HCl levels below 20 ppm and SO<sub>2</sub> to levels below 30 ppm for MSW waste-to-energy plants. This technology has also been extensively used in other applications for acid gas removal. The scrubber/electrostatic precipitator combination has been shown to provide about 90% HCl removal, but typically less SO<sub>2</sub> removal (about 50%). Since this removal efficiency does not meet the most recent regulations, many electrostatic precipitators have been replaced with baghouses. Lime injection into the furnace has also been tested with some success (about 50%–70% efficiency), but fails to meet the most recent regulations.

Some sampling to determine HF removal has been reported. In general, HF removal normally follows HCl removal (i.e., is usually over 90%–95%).

Carbon monoxide and hydrocarbon emissions are best controlled by maintaining proper combustion conditions. Nitrogen oxide emissions are controlled by ammonia injection or by use of combustion control techniques such as limitation of combustion temperatures or recirculation of flue gases. Note in the last column of [Table 47.13](#) that attempts to limit hydrocarbon emissions by improving combustion conditions and raising furnace operating temperatures seem to have resulted in increasing the level of NO<sub>x</sub> emissions.

Selective noncatalytic reduction (SNCR) appears to be the most practical method of reducing NO<sub>x</sub> emissions for most municipal waste combustors. SNCR involves the use of ammonia to reduce NO<sub>x</sub> to nitrogen and water. The SNCR reaction occurs at a temperature of 1600°F–2100°F. At lower temperatures, a catalyst is required to promote the reaction (selective catalytic reduction, or SCR). SCR is not used on municipal waste combustors. Tests conducted at a municipal waste combustor demonstrated that NO<sub>x</sub> emission levels of 150 ppmv (45%–55% reduction) can be achieved with SNCR.<sup>4</sup>

Thermodynamic equilibrium considerations indicate that under excess air conditions and with temperatures of 1472°F (800°C) and higher, maintained in a completely mixed reactor for a suitable period of time, emissions of organic or hydrocarbon compounds should be at nondetectable levels. However, measurements at operating plants, particularly those constructed prior to the early to mid-1980s, indicated significant emissions of trace organic or hydrocarbon compounds, some of which are toxic. These tests indicated that the basic objective of combustion control, thorough mixing of combustion products with oxygen at a temperature that is sufficiently high to provide for the rapid destruction of all organic or hydrocarbon compounds, had not been achieved in these early WTE plants.

If the fuel, or the gas driven off of the fuel bed, is not adequately mixed with air, fuel-rich pockets will exist containing relatively high levels of hydrocarbons, which then can be carried out of the combustion system. Kinetic considerations indicate that such hydrocarbons can be destroyed rapidly in the presence of oxygen at elevated temperatures. Also, if too much combustion air is introduced into the combustion chamber, either in total or in a particular area of the chamber, temperatures will be reduced, combustion reactions can be quenched, and hydrocarbons carried out of the combustion system. Achieving the goal of proper combustion control, destruction of all hydrocarbon compounds to form carbon dioxide and water, will minimize emission of potentially toxic substances as well as other compounds that may be precursors and capable of forming toxic compounds downstream in cooler regions of the boiler.

Table 47.13 shows that the hydrocarbons can vary significantly, frequently over relatively short periods of time, based on measurements at older municipal waste combustors.

The highest levels shown in this table occurred in one of the older plants and no doubt indicate very poor combustion conditions. Tests at modern WTE plants indicate consistently low levels of hydrocarbons, which are indicative of good combustion control. In modern, well-designed and -operated plants, photochemical oxidants and PAH are in concentrations too low to cause any known adverse health effects. Tests<sup>55,66</sup> for other substances that might be of concern, such as polychlorinated biphenyls (PCBs), generally have found levels discharged to the atmosphere to be so low as to have a negligible impact on the environment.

#### **47.4.3 Organic Compound Control**

Organic compounds for which emission data are available include polychlorinated dibenzodioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), chlorobenzenes (CBs), chlorophenols (CPs), polycyclic aromatic hydrocarbons (PAHs), and PCBs. A number of other organic compounds, including aldehydes, chlorinated alkanes, and phthalic acid esters, have also been identified in specific testing programs. Since dioxin/furan emissions have generated the most interest over the past several years, there are more data for these compounds, in particular for the tetrahomologues, and especially the 2,3,7,8-substituted isomers. The other compounds have been less frequently reported in the literature. The reason for this emphasis is the toxicity of dioxin/furan to laboratory animals and the perceived risk to humans.

Upset conditions in energy-from-waste plants can lead to local air-deficient conditions resulting in the emission of organic compounds. PAHs are formed during fuel-rich combustion as a consequence of free radical reactions in the high temperature flame zone. In addition, it is found that in the presence of water cooled surfaces, such as found in oil-fired home-heating furnaces, a high fraction of the polycyclic compounds are oxygenated. Similar free radical reactions probably take place in fuel-rich zones of incinerator flames yielding PAH, oxygenated compounds such as phenols, and, in the presence of chlorine, some dioxin/furan. The argument for the synthesis of dioxin/furan at temperatures of 400°F–800°F is supported by the increase in the concentration of these pollutants across a heat recovery boiler downstream of the refractory lined combustion chamber of a waste combustor.

This free radical mechanism appears to be the dominant source of dioxin/furan in municipal waste combustors. These compounds may also be present as contaminants in a number of chemicals, most notably chlorinated phenols and polychlorinated biphenyls (PCBs). Their presence in MSW results from the use of these chemicals, discontinued in some cases, as fungicides and bactericides for the phenol derivatives, or the use of PCBs as heat exchanger and capacitor fluids. These compounds are expected to survive in a furnace combustion chamber only if large excesses in the local air flow cool the gases to below the decomposition or reaction temperature. Dioxin/furan can also be produced by condensation reactions involving the chlorinated phenols and biphenyls. The observed formation of dioxin/furan when fly ash from MSW incinerators is heated to temperatures of 480°F (250°C) suggest such catalyzed condensation reactions of chlorinated phenols. PCBs are precursors to furan, and pyrolysis of PCBs in laboratory reactors at elevated temperatures for a few seconds has yielded furan.

The available test data clearly show that dioxin/furan exit the boilers and, depending on the emission control devices employed, some fraction enters the atmosphere either as gases or adsorbed onto particulates. In addition, the solids remaining behind in the form of fly ash and bottom ash contain most of the same compounds, and these become another potential source of discharge to the environment.

Emission data for total dioxin/furan generally fall into three main categories:

1. Low emissions, in the range of 20–130 ng/Nm<sup>3</sup>
2. Medium emissions, from 130 to 1000 ng/Nm<sup>3</sup>
3. High emissions, over 1000 ng/Nm<sup>3</sup>

Average dioxin/furan emission from older plants ranges from about 500 to 1000 ng/Nm<sup>3</sup>. The lower emission levels tend to be associated with newer, well-operated mass-fired facilities such as water wall plants, and with modular, starved or controlled air types of incinerators (see Table 47.14). In most test programs, adequate operating data were not collected to correlate emissions with operations. Researchers in the field theorize that combustion conditions can play a role in minimizing emissions, and several studies<sup>63,68,69</sup> were conducted in Canada and the United States to define that role more exactly.

Emissions from MSW combustion contain small amounts of many different dioxin/furan isomers. While individual dioxin/furan isomers have widely differing toxicities, the 2,3,7,7-TCDD isomer, present as a small proportion of the total dioxin/furan, is of greatest known toxicological concern. Based on animal studies it has been generally concluded that other 2,3,7,8-substituted dioxin/furan isomers, in addition to the 2,3,7,8-TCDD, are also likely to be of toxicological concern. A method for expressing the relative overall toxicological impact of all dioxin/furan isomers, as so-called “2,3,7,8-TCDD toxic equivalents,” was developed in the mid-1980s<sup>2</sup> and has been used by the EPA intermittently in its regulatory efforts since this time.

In this method, emissions are sampled, extracted, and analyzed for all constituent isomers of dioxin/furan. A system of toxicity weighting factors from the existing toxicological data (based almost entirely on animal studies) is applied to each constituent dioxin/furan isomer and the results are summed to arrive at the 2,3,7,8-TCDD toxic equivalent. An example of dioxin/furan test results expressed as 2,3,7,8-TCDD toxic equivalents, using three different systems of weighting factors, is shown in Table 47.15.

Emission control systems consisting of a scrubber/fabric filter have been evaluated for dioxin emissions.<sup>34</sup> Recently dioxin removal efficiencies exceeding 99% were obtained, which resulted in dioxin concentrations at the stack that approach the detection limit of the sampling and analytical equipment currently available. Emissions of furan followed a similar range of values as dioxin with the scrubber/high efficiency particulate removal

combination reducing furan to very low or nondetectable levels. Additional reductions of over 50% can be achieved by activated carbon injection.<sup>4</sup>

Some limited data on emissions of CB, CP, PCB, and PAH are available. Most sampling programs for dioxin/furan have unfortunately neglected to analyze for these compounds. Maximum levels from Canadian studies<sup>34</sup> are as included in Table 47.16 along with some data from tests on U.S. plants.<sup>33</sup> The scrubber/fabric filter technology generally demonstrated removal rates of 80%–99% for these compounds in these studies.

Very few studies report on other organic products in the flue gas. Some data from tests on older plants have been reported for aldehydes and certain other volatile hydrocarbons.<sup>3</sup> Such data are not available for newer plants.

The conventional combustion gas measurements include CO, total hydrocarbons (THCs), CO<sub>2</sub>, and H<sub>2</sub>O. Both CO and THC have been of interest as potential surrogates for dioxin/furan emissions; however, no strong correlations have been found in previous studies. In fact, very few studies have attempted to determine CO and dioxin/furan

emission data for several operating conditions on the same combustor to develop a correlation. On the other hand, several authors have attempted to correlate CO and dioxin/furan data obtained from several different facilities. From such comparisons, it appears that low CO levels (below 100 ppm) are associated with low dioxin/furan emissions.<sup>38</sup> High CO levels of several 100 ppm and even over 1000 ppm have been associated with high dioxin/furan emissions. During poor or upset combustion conditions, CO levels of several thousand ppm have been observed and THC levels have risen from a typical 1–5 ppm to 100 ppm and more. Since one of the measures available to combustor operators to optimize combustion control is to minimize CO production, one would assume from these general correlations that this would also tend to minimize dioxin/furan emissions, along with emissions of other trace chlorinated hydrocarbons. THC is not as useful as CO as an indicator of proper combustion because of problems in sampling to consistently obtain a representative sample for analysis at the analytical instrument.

Table 47.17 shows operating results achieved using dry and semidry lime injection followed by a baghouse for removal of trace organic pollutants from waste combustor emissions.

#### 47.4.4 Trace Metals

Trace metals are not destroyed during combustion, and the composition of wastes therefore provides, on a statistical basis, the measure of the total inorganic residue. The distribution of trace metals between bottom ash and ash carried over to the air pollution control device is dependent upon the design and operation of the combustor and the composition of the feed. The amount of ash carried up and with the flue gases discharged from a burning refuse bed increases with increasing underfire air rate and with bed agitation. Modular incinerators (described later in Section 47.7) with low underfire air flow rates tend to have lower particulate emissions than conventional mass-burn units and RDF units for this reason. In addition, the amount of ash carried from the combustion chamber will be influenced by the particle size of the inorganic content of the MSW.

The distribution of trace metals between the different components of refuse has a strong influence on the fate of the trace metals. For example, TiO<sub>2</sub> used as a pigment in paper products, has a particle size of about 0.2 µm and will tend to be carried off by the flue gases passing through the refuse bed, whereas TiO<sub>2</sub> present in glass will remain with the glass in the bottom ash. Up to 20% of the inorganic content of the waste will be entrained from burning refuse beds to form fly ash particles. The remainder will end up in the residue.

Volatile metals and their compounds, usually present in trace amounts in the feed, will vaporize from the refuse and condense in the cooler portions of a furnace either as an ultra fine aerosol (size less than 1  $\mu\text{m}$ ) or on the surface of the fly ash, preferentially on the surface of the finer ash particles. A large fraction of certain elements in the feed, such as mercury, will be volatilized.

Since mercury is a very volatile metal, it exists in vapor phase at temperatures as low as 68°F–122°F (20°C–50°C). Several studies have indicated that sufficient cooling of the flue gas (typically below 140°C, based on test results conducted to date) and a highly efficient particulate removal system to remove the particles on which the mercury has been adsorbed<sup>6,8,80</sup> are both required to achieve high mercury removal. High mercury removal has been obtained for the scrubber/fabric filter system, provided that the flue gas is adequately cooled (see Table 47.18).

Test results with carbon injection at two municipal waste combustors demonstrated that the EPA emission guidelines of 80 mg/dscm or 85% reduction in mercury emissions can be achieved with a spray dryer, fabric filter and carbon injection.<sup>4</sup>

Elements such as sodium (Na), lead (Pb), zinc (Zn), and cadmium (Cd), will be distributed between the volatiles and the residue in amounts that depend on the chemical and physical form in which the elements are present. For example, sodium in glass will be retained in the residue but that in common salt will partially disassociate and be discharged with the emission gases.

Some of the data on metal emissions that are available from tests on resource recovery plants is shown in Table 47.19. Note that the emission of trace metals can be dramatically limited at WTE plants by the use of high-efficiency particulate control devices that are installed on modern facilities.

While sampling for metal emissions is fairly well established, in order to obtain enough sample to analyze at highly controlled sources, samples times are extremely long, sometimes over 8 h using the U.S. EPA Method 5 sample train (relatively low sample rate). Several studies<sup>28,29,41</sup> of waste combustor emissions in the United States in the 1970s concluded that “municipal incinerators can be major sources of Cd, Zn, Sb and possibly Sn....” This conclusion is based on the relative concentration of these materials in the total suspended particulate catch. However, two of the three plants tested in these studies utilized inefficient air pollution control facilities. Thus, particulate emissions in these plants were relatively high when compared to the German and Japanese plant

<sup>a</sup> Total on particulate and vapor phase.

data in Table 47.19, which is similar to emission data from most modern mass-burn and RDF waste-to-energy plants in the United States.<sup>68</sup> Note also in Table 47.19 that, as the efficiency of particulate control improves, trace metal emissions generally decrease, and in most cases decrease significantly. Even though there is ample evidence from test data<sup>17</sup> to indicate that heavy metals tend to concentrate on the finer particulates, there is also evidence from test results to show that at high particulate removal efficiency (99%  $\pm$ ), high trace metal removal (99%  $\pm$ ) is achieved. Thus, the conclusion in these studies of waste combustors quoted earlier is not valid for WTE plants utilizing efficient air pollution control devices.

The important operating parameters for such equipment are flue gas temperature and composition, contact time, relative velocity of particles and gas stream, and possible activation of particles. See Tables 47.18 and 47.20 for operating results achieved using dry and semidry lime injection followed by a baghouse for removal of heavy metal pollutants from waste combustor emissions.

## 47.5 Performance

Mass burning of MSW is the most highly developed and commercially proven combustion process presently available for reducing the volume of MSW prior to ultimate disposal of residuals on the land, and for extracting energy from the waste.<sup>70</sup> Hundreds of such plants, incorporating various grate systems and boiler concepts, which differ in details of design, construction, and quality of operation, have been built throughout the world since the mid-1960s. Mass-burn systems are generally furnished with a guaranteed availability of 85%, while in practice availabilities of 90%–95% have been achieved.<sup>68</sup> Availability cannot approach 100% because standard maintenance practice requires periodic shutdowns. The newest mass-burn facilities seem capable of achieving high reliability, based on their performance in Europe, Japan, and the United States.

Refuse-derived fuel (RDF) facilities became popular during the 1970s. The early plants were generally designed with the intent to remove and recycle metals, glass, and other marketable materials, with the remaining fraction, RDF, to be burned in an existing boiler as a replacement fuel. Those types of facilities all failed and are no longer in operation. The main reasons for failure were that the recycled materials were highly contaminated with waste and were not marketable, and the boilers were not designed to handle the inconsistent RDF that was being fed to them.

The RDF approach quickly evolved to produce a fuel with a known specification to be burned in a dedicated boiler designed specifically to burn that fuel. The materials which were removed were sold, if possible, or landfilled. The primary difference in philosophy between the two types of RDF plants was that the early ones treated the RDF as the “waste” that contaminated the recovered materials, and the newer generation treated the recovered materials as the “waste” that contaminated the RDF. The newer generation RDF facilities which were designed in this manner have been successful.

Fluidized bed technology has been used outside the United States to combust solid waste for several years. One advantage of fluidized bed combustion is that the boiler is more efficient than those in mass-burn or spreader-stoker facilities. Also, fluidized bed combustion produces lower  $\text{NO}_x$  emissions than other incineration methods. Although lower, these  $\text{NO}_x$  emissions must still be controlled with additional air pollution control equipment, as with other combustion facilities. Fluidized bed combustion also has the advantage of

being able to add limestone with the sand in the bed to assist in acid gas removal. However, a scrubber is still needed to reduce emissions to permitted levels.<sup>46</sup>

The major disadvantage to a fluidized bed facility is that it does not have a long-term proven track record in the United States. Also, the size of the units are small when compared to the size needed for typical U.S. waste-to-energy facilities.<sup>46</sup>

---

## 47.6 Costs

It is extremely difficult to obtain accurate, consistent, and comparable WTE plant construction cost data from which to develop information which might be useful in predicting a planned new plant's construction cost during the study stage of a project. However, a 1988 study<sup>56</sup> has developed such data (appropriate for the time frame of mid-1987), which is confirmed in general by this author's personal experience. This study indicates that for the upper 90% confidence limit for the smallest facility, and the largest facility, the construction costs would range as indicated below:

1. A small modular combustion unit with a waste heat boiler and a capacity of less than 250 TPD—\$68,000 and \$40,000 per ton of daily MSW processing capability. (In most instances, such plants don't incorporate the same degree of equipment redundancy, and/or the same quality of equipment as the larger plants.)
2. A small refractory wall furnace with waste heat boiler and dry scrubbers of between 200 and 500 TPD capacity—\$90,000 and \$70,000 per ton of daily MSW processing capability.
3. A small, field erected, water wall congeneration or electric generation facility with dry scrubbers of between 500 and 1,500 TPD capacity—\$112,000 and \$85,000 per ton of daily MSW processing capability.
4. A large, field erected, water wall congeneration or electric generation facility with a dry scrubber between 2,000 and 3,000 TPD capacity—\$129,000 and \$112,000 per ton of daily MSW processing capability.

In this study,<sup>56</sup> the construction costs were said to include the vendor quote for construction plus contingency, utility interconnection expenses, and any identified allowances clearly associated with the construction price. All other costs, such as land acquisition, interest during construction, development costs, and management fees were not considered or included, where known, due to their highly project specific nature.

The following specific observations were made by the authors at the conclusion of this study:<sup>56</sup>

1. Capital construction price decreases with increasing size within size ranges and increases with a higher-value energy product.
2. Price is also affected by the construction, procurement, and air pollution control methods employed.
3. Refuse-derived fuel and mass burning water wall facilities are competitively priced with each other.

The effect of plant capacity on capital costs or mass-burn plants is shown in [Figure 47.8](#). Capital costs for other types of plants are similar.

**FIGURE 47.8**

Effect of plant capacity on capital costs for mass-burn facilities (electricity only), excluding costs associated with collection (e.g., trucks).

**FIGURE 47.9**

Effect of plant capacity on O&M costs for mass-burn facilities (electricity producing only), excluding costs associated with collection (e.g., trucks).

With respect to operating costs and/or tipping fees, information is even more difficult to obtain from which to develop costs for planning purposes. Costs cited in the literature from 1989 through 1994 range from \$40 to \$80 per ton of daily rated MSW processing capability.<sup>18,42,41,77,78</sup> Tipping fees on Long Island, which has generally high labor rates, high power costs, and very long hauls for residue disposal, have been noted to range up to \$110 per ton of daily rated MSW processing capability.<sup>26</sup> Plants in other parts of the country where plant operating cost elements are significantly lower have been found to have tipping fees closer to \$40 per ton.<sup>7</sup> Thus, tipping fees for a specific facility would have to be developed based on cost factors for that specific plant.

The effect of plant capacity on O&M costs for mass-burn plants is shown in [Figure 47.9](#). Information is so limited on other types of plants, and the costs are so dependent on local conditions that we do not feel that curves developed for other types of plants would be useful.

---

## 47.7 Status of Other Technologies

Several other technologies have been used to a small extent to burn MSW and beneficially use the energy produced in the combustion process. Their use in the future depends on numerous factors, perhaps the most important of which is full-scale demonstration of successful, reliable operation, after which total operational costs are shown to be competitive with mass-burn and/or RDF combustion costs.

### 47.7.1 Modular Systems

Modular systems, generally utilized in smaller plants, are assemblies of factory-prefabricated major components joined together in the field to form a total operational system. They have been built in individual unit sizes up to just over 100 tons/day capacity, combined into plants of just over 400 tons/day capacity. Modular systems are similar to mass-burn systems in that they combust unprocessed MSW, but they feature two combustion chambers, and the MSW is charged into the system with a hydraulic ram and combustion takes place on a series of stationary hearths. MSW is pushed from one hearth to the next by hydraulic rams. Two types of modular systems have been built and operated: starved air and excess air.

The primary chamber of a starved air modular system is usually operated in a slightly oxygen-deficient ("starved air") environment. The volatile portion of the MSW is vaporized in this chamber and the resulting gases flow into the secondary chamber. The secondary chamber operates in an excess air condition, and combustion of the gases driven off the MSW is essentially completed in this chamber. An excess air modular system operates in a manner similar to a field erected boiler system, with excess air injected into the primary chamber.

One advantage of these units, as indicated in the section on costs, is low cost. Another advantage is that factory prefabrication of major system components can result in shortening of the field construction time. One disadvantage of the two-chamber modular system is that waste burn out in the residue is not always complete, which increases ash quantities and reduces the efficiency of energy recovery.<sup>69</sup> Energy recovery efficiency is also reduced

due to generally higher “excess air” levels carried in these units. Also, combustion control is generally less effective in this type of unit, increasing the possibility of discharge of trace organic emissions. As pointed out earlier, these types of units generally utilize a lower quality of equipment and include less redundancy than larger mass-fired water wall and RDF WTE plants. Modular plants are responsible for about 2% of the total MSW burned at this time in the United States.

### **47.7.2 Fluidized Beds**

Fluidized bed combustion (FBC) differs from mass-burn and RDF combustion in that the fuel is burned in “fluid suspension”—entrained along with particles of sand in an upward flow of turbulent air at a temperature controlled to 1500°F–1600°F (816°C–971°C). To date, it has been used primarily to burn sewage sludge, industrial waste, and coal and has been used to combust RDF in one facility in the U.S. Fluidized bed combustion of MSW is more commonly used in some European countries.

“Bubbling” FBC designs retain the material near the bottom of the furnace, while “circulating” designs allow bed material to move upward and then be returned near the bottom of the bed for further combustion. The reason for the interest in this combustion technique to burn RDF is the potential for these designs to provide more consistent combustion because of the extreme turbulence and the proximity of the RDF waste particles to the hot sand particles.<sup>46</sup> Such systems also require lower combustion temperatures than mass-burn and current RDF systems.

### **47.7.3 Pyrolysis and Gasification**

Pyrolysis is the chemical decomposition of a substance by heat in the absence of oxygen. It generally occurs at relatively low temperatures (900°F–1100°F, compared with 1800°F for mass-burn). The heterogeneous nature of MSW makes pyrolysis reactions complex and difficult to control. Besides producing larger quantities of solid residues that must be managed for ultimate disposal, pyrolysis produces liquid tar and/or gases that are potentially marketable energy forms. The quality of the fuel products depends on the material fed into the reactor (e.g., moisture, ash, cellulose, trace constituent content) and operating conditions (e.g., temperature and particle size).<sup>68</sup>

Gasification is similar to pyrolysis in that it is the chemical decomposition of the substance by heat in the absence of oxygen. However, gasification occurs at temperatures of approximately 2200°F (1200°C). The reaction produces a synthetic gas with a heat content of approximately 250 Btu/cf. The approximate composition by volume on a dry basis is 25%–42% carbon monoxide, 25%–42% hydrogen, 10%–25% carbon dioxide, and 3%–4% nitrogen and other constituents. The synthetic gas is then cooled rapidly to reduce formation of dioxins and cleaned.<sup>62</sup>

Several prototype pyrolysis facilities were built in the 1970s with grants from EPA. These facilities were unable to produce quality fuels in substantial quantities. No one in the United States has yet successfully developed and applied the pyrolysis or gasification technology to MSW combustion. However, the use of pyrolysis and gasification for MSW management still attracts attention in other countries. Additional reading for pyrolysis and gasification technologies is available.<sup>9,44</sup>

---

## 47.8 Future Issues and Trends

It has been demonstrated by actual experience that modern mass-burn and RDF-fired MSW WTE plants can be designed and operated with reasonable assurance of continuous service and without adversely affecting nearby neighborhood property values. Allegations that WTE plant sites are situated adjacent to neighborhoods of low-income, disadvantaged, or minority populations ignore the specific technical siting criteria outlined earlier (i.e., adjacent to major highways, low land cost, industrial type area, etc.) which are generally followed in siting such facilities. Such areas frequently are closer to low-income neighborhoods than to middle- and higher-income neighborhoods.<sup>68</sup>

In 1994 the Supreme Court found that a local community could not force the MSW from that community to be taken to a specific facility such as a WTE plant.<sup>24</sup> This court decision was a major blow to the WTE industry bringing most planning and construction of new facilities to a halt in the mid-1990s. Many communities, when considering solid waste disposal options, have opted for low cost landfill disposal because of concern over impacts of higher cost WTE alternatives on taxes. At some point in the not too distant future, as the current landfills are rapidly filled, WTE technology will have to be utilized to solve the solid waste disposal problem. Some signs of this new interest in WTE technology are already occurring.

Another issue facing WTE plants is the uncertain future of regulatory requirements, both from the standpoint of legislation and from that of the regulatory agencies. In the past, legislation has been passed by Congress calling for Best Available Control Technology (BACT), then Lowest Achievable Emission Requirements (LAER), and then, most recently, Maximum Achievable Control Technology (MACT). The impact of this legislation, each calling for significant reductions in allowable emissions (absent any indication of the existence of a significant public health problem or benefit), has been to require extensive retrofits of existing plants and addition of equipment to proposed new plants, all at substantial expense without proven benefit and, in many cases, without prior proof of operational viability. Most facilities have opted to upgrade the air pollution control equipment and continue to operate.

Several positive actions are occurring in the field. Thus, most project developers have recognized the desirability of implementing a proactive program early in the project planning process to involve the public, particularly those in the vicinity of the proposed facility.<sup>60</sup> Also, the potential for materials recycling, which had been overenthusiastically embraced a number of years ago (state recycling goals as high as 70%, with some local communities projecting that their entire quantity of MSW could be managed through recycling), is gradually being recognized.<sup>45</sup> Franklin Associates<sup>23</sup> projects an increase in the recycling rate of from 22% in 1993 to 30% by the year 2000. Much of this increase in recycling is to come from increases in recovery of paper materials and diversion of yard wastes to composting. The impact of these changes in waste composition on energy available at WTE plants will be minimal, with the reduction in moisture content due to diversion of yard wastes being a positive factor.

The need to generate electric energy and safely manage the MSW generated by modern civilization, particularly in the vicinity of major metropolitan areas, together with the proven performance of modern WTE plants, indicate that this technology will be utilized to dispose of a portion of this country's solid waste and provide electricity.

Transformation of waste materials into energy can generally be accomplished through biological (i.e., anaerobic digestion), thermal, and chemical processes. The energy produced from these processes can be in the form of heat, gas, or liquid fuel.

---

## 48.1 Introduction

The anaerobic digestion (AD) process, carried out in the absence of oxygen, involves the use of microorganisms for the conversion of biodegradable biomass material into energy, in the form of methane gas and a stable humus material. AD can occur under controlled conditions in specially designed vessels (reactors), semicontrolled conditions such as in a landfill, or under uncontrolled conditions as it does in the environment. The focus in this chapter is on the controlled AD process. It should be noted that AD is differentiated from anaerobic fermentation, which is the term usually applied to processes employing anaerobic microbes for the production of fermentation products such as alcohol or lactic acid.

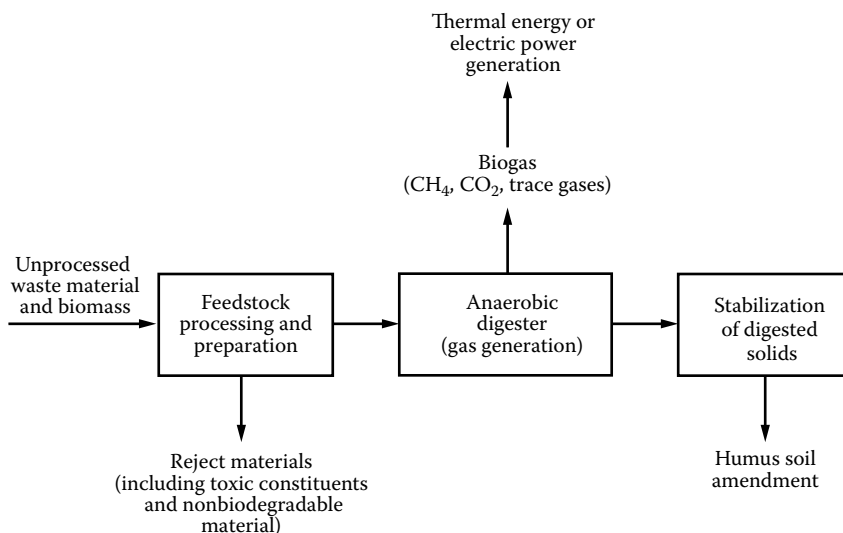

To describe anaerobic conversion of the biodegradable organic fraction of waste materials into energy, the following topics are presented in this chapter: (1) organic wastes and

biomass used as feedstocks in AD process, (2) issue of organic waste biodegradability, (3) fundamental of AD process, (4) monitoring of AD process, (5) reactor types used for AD, (6) modes of operation for AD, (7) utilization of the AD process by-products, and (8) full-scale application of the AD technologies.

## 48.2 Organic Wastes and Biomass Used as Feedstocks in Anaerobic Digestion Process

The general scheme for a controlled AD process is shown in Figure 48.1. As shown, the recovery of energy involves feedstock preparation, methane gas generation, stabilization of digested solids, and the utilization of digester gas and humus as a source of energy and soil amendment, respectively. Major sources of waste materials considered as a feedstock for AD process are (1) biodegradable organic fraction of municipal solid waste (BOFMSW); (2) agricultural waste including animal waste, crop residues, biomass, and energy crops; (3) food processing waste; and (4) wastewater treatment plant sludge or biosolids (WWTPS or WWTPBS). The typical distribution of the biodegradable and inert fractions of municipal solid waste (MSW) in the United States is shown in Figure 48.2. The composition of MSW may vary greatly by season, geographical area, and community socioeconomic level. The extrapolation of results from one location to another, therefore, may not be valid and should be done with caution.

As shown in Figure 48.2, paper, yard waste, and food waste are the principal biodegradable organic fractions. The biodegradability of these waste materials varies substantially as reported in Table 48.1. The issue of biodegradability is discussed further in the following section.

**FIGURE 48.1**  
General flow diagram of bioenergy recovery system.

**FIGURE 48.2**

Typical distribution of the biodegradable and inert fraction of MSW in the United States. It should be noted that the relative distribution of these fractions may vary greatly depending on the season, geographical area, and community socioeconomic level.

**TABLE 48.1**

Weight Distribution and Biodegradability of the Organic Fraction of MSW Found in the United States

Component	Percent by Wet Weight		Biodegradability		
	Range	Typical	Low <sup>a</sup>	Medium <sup>b</sup>	High <sup>c</sup>
Cardboard	3–10	10		x	
Magazines	2–8	6	x		
Newspaper	4–10	8	x		
Waxed cartoons	5–20	12		x	
Mixed paper	<1–5	3		x	
Food waste	6–18	9			x
Yard wastes	5–20	15			x
Wood waste	1–4	1.5	x		

<sup>a</sup> Low-biodegradable materials are classified as having a biodegradability of less than 30%.

<sup>b</sup> Medium-biodegradable materials are classified as having a biodegradability greater than 30% but lower than 75%.

<sup>c</sup> High-biodegradable materials are classified as having a biodegradability greater than 75%.

As illustrated in Figure 48.1, some waste material must be preprocessed to (1) remove toxic constituents, (2) remove nonbiodegradable materials, and (3) prepare a balanced feed-stock in terms of nutrient availability for methane recovery. Most livestock wastes and treatment plant sludge are relatively homogeneous and biologically active and contain sufficient nutrients. Therefore, little or no preprocessing of feedstock may be needed. Also, because dairy and pig wastes contain a variety of anaerobic microorganisms, methane gas will be produced when proper conditions are provided. Thus, for the AD of organic

wastes other than livestock wastes, the addition of dairy or pig manure is used commonly. The addition of livestock waste to activate a biological process is commonly known as "inoculation."

### 48.3 Issue of Biodegradability

While each organic waste may contain a constant ultimate biodegradable fraction, practical biodegradability can be quite variable. Factors such as particle size, time, and environmental conditions (i.e., temperature, nutrient requirements) will influence the final outcome of biodegradation. For example, because favorable conditions do not exist in most landfills, the biodegradability estimated from analytical test will usually be greater than the actual biodegradation that occurs in landfills. For practical purposes, the discussion in this section deals with the biodegradability of the organic fraction of waste materials used in AD processes. Substrate biodegradability is of special importance in an AD processes, where the production of energy is of concern.<sup>1,2</sup>

#### 48.3.1 Biodegradable Volatile Solids of an Organic Substrate

Dry organic substrates consist of volatile solids (VS) and ash. Taken together, these two components comprise the total solids (TS) of a substrate, as illustrated in Figure 48.3. The fraction of ash typically depends on the nature of the organic substrate. VS is measured as loss on ignition. Only the biodegradable volatile solids (BVS) fraction of the VS has the potential for bioconversion largely because of the presence of refractory volatile solids (RVS) which, in most digester feedstocks, is mostly lignin. Lignin is a complex organic material that is difficult for anaerobic bacteria to degrade and normally requires a long period of time for complete degradation. It is clear from Figure 48.3 that organic substrates with high RVS and ash contents have a low biodegradability.

The RVS in the organic fraction of MSW consists of the lignin content (LC) that is associated with cellulose in plant materials and thermoplastic materials. LC of an unsorted

**FIGURE 48.3**  
Characterization of a typical organic substrate.

organic fraction of MSW will fluctuate as the percentage of cellulose and thermoplastic materials will vary with season, socioeconomic conditions, and geographical locations. Knowing the BVS fraction of VS in the individual organic fractions of MSW will allow the biodegradability of any composite BOFMSW to be estimated.

### 48.3.2 Methods to Estimate Biodegradability

Several methods can be used to estimate the BVS fraction of an organic substrate, including (1) long-term batch digestion studies, (2) measurement of LC, and (3) chemostat studies. These methods are described briefly as follows.

#### 48.3.2.1 Long-Term Batch Digestion

Batch digestion studies, designed to simulate a specific AD process, can be used to predict the biodegradable fraction of an organic substrate. One method involves graphical analysis of weight loss over time and is used commonly to predict the ultimate biodegradability of energy crops and agricultural wastes.<sup>3</sup> This method is based on a linear regression plot of the remaining VS concentration as the retention time approaches infinity. Regular weight measurements of the batch digester throughout the course of the study are required to apply this method.

An alternative method for determining the biodegradable fraction of an organic substrate, using batch digesters, is to determine and compare the initial and final dry masses. Initial measurements are made of the mass and the percent TS of active reactor mass of each mixture to be tested. Each mixture includes a percentage of seed, that is, material taken from an active digester to provide suitable microorganisms. One batch mixture is always 100% seed. At the end of the batch study, the dry mass in each individual reactor is measured. The mass loss in each unit, corrected for seed biodegradation, is due to the conversion of the biodegradable portion of the substrate to biogas. The results of BOFMSW based on long-term batch digestion studies are shown in Table 48.2.

#### 48.3.2.2 Measurement of Lignin Content

An analytical method commonly used for determining the BVS fraction of an organic substrate is based on the measurement of the crude LC of the VS. Chandler et al.<sup>1</sup> correlated the

**TABLE 48.2**

Estimated Biodegradable Fraction of Organic Waste Components of MSW Based on Long-Term Batch Studies

Organic Substrate	BVS Fraction, %VS		
	Reactor 1	Reactor 2	Average
Newspaper	22.5	24.8	23.7
Office paper	83.5	81.8	82.7
Food waste	83.0	82.5	82.8
Yard waste	73.0	70.5	71.8
Mix blend <sup>a</sup>	70.5	69.5	69.8 <sup>b</sup>

<sup>a</sup> Mixed blend consists of 19% newsprint, 53% office paper, 15% yard waste, and 13% food waste (dry basis).

<sup>b</sup> The value reported for mixed blend is based on the actual organic waste, not the value that can be computed from each individual components.

**TABLE 48.3**Estimated Biodegradable Fraction of Organic Waste Components of MSW Based on LC<sup>a</sup>

Organic Substrate	LC Range, %VS <sup>a</sup>	Average BVS Fraction
Newspaper	20–23	22
Office paper	0.2–1	82
Yard waste	4–10	72
Food waste	0.1–0.7	82
Mixed blend <sup>b</sup>	4–7	67.6

<sup>a</sup> Computed using Equation 48.1.<sup>b</sup> Mixed blend consists of 19% newsprint, 53% office paper, 15% yard waste, and 13% food waste (dry basis).

biodegradability of various agricultural residues and newsprint, as determined by long-term batch digestion studies, with the LC of the substrate, as determined by sequential fiber analysis, developed by Robertson and Van Soest.<sup>4</sup> The following empirical relationship was developed to estimate the biodegradable fraction of an organic substrate from lignin test results:

$$\text{Biodegradable fraction} = 0.83 - 0.028\text{LC} \quad (48.1)$$

where the biodegradable fraction is expressed as a fraction of the VS and LC expressed as a percentage of the VS. The results of biodegradable fraction for BOFMSW based on the LC are shown in Table 48.3.

#### 48.3.2.3 Chemostat Studies

The BVS fraction of an organic substrate can also be estimated using chemostat techniques. The true digestible organic matter (TDOM) technique, developed by animal scientists, is used to assess the digestibility of animal feeds.<sup>5</sup> The test involves the digestion of a sample in vitro in rumen fluid for 48 h. A second chemostat technique, the biochemical methane potential (BMP) assay, is used to characterize the BMP and biodegradability of many organic substrates.<sup>6</sup> In the BMP assay, the substrate biodegradability is determined by monitoring the cumulative methane production from a slurry sample that is incubated anaerobically (typically for 30 days at 35°C) in a chemically defined media and inocula.

The biodegradability of energy crops as estimated using the BMP assay tends to be 3%–10% higher than the corresponding BVS value as estimated using the TDOM technique.<sup>7,8</sup> The BMP assay appears to be more suitable for determining the ultimate biodegradability.

#### 48.3.3 Biodegradability of Various Organic Waste Materials

The estimates of BVS, as a percentage of VS, of a typical organic fraction of MSW based on long-term batch studies, LC, and a pilot study are compared in Figure 48.4. As can be seen, the average BVS fractions calculated using either the LC or the long-term batch study are essentially the same. The BVS fraction obtained from the pilot study, using a complete-mix reactor and mass retention time (MRT) of 30 days, is about 83% and 81% of the estimated values obtained from the LC and the batch study, respectively. Similarly, Richards

**FIGURE 48.4**

Comparison of the BVS fraction of a typical mixed BOFMSW obtained using three methods of analysis.

et al.<sup>7,8</sup> were able to remove only 83% of BVS of sorghum, using a thermophilic, high-rate, high-solids reactor with an MRT of 45 days.

The values of biodegradable fraction for various organic substrates using different methods are compared in Table 48.4. It is important to note that the estimated BVS values based on field operations are normally about 80%–85% of the values estimated by chemostat studies. Thus, the use of BMP values would result in an overestimation of biogas production rate that can be achieved in actual practice. It is important to note

**TABLE 48.4**

Biodegradability of Various Organic Substrate Using Batch Digestion, Chemostat, and Field Operation Methods

Substrate	Methods Used to Estimate Biodegradability

BOFMSW	69.8			57 (30)	Kayhanian and Tchobanoglous [9]

<sup>a</sup> All field operations were conducted in a thermophilic, high-rate, high-solids reactor.

<sup>b</sup> Numbers in parentheses are nominal MRT value in days.

that complete removal of BVS as estimated from batch digestion and analytical or a chemostat method at a practical range of MRT (20–40 days) is not possible. For an in-vessel high-solids AD process, BVS can be defined as that fraction of VS that can be biodegraded under optimum environmental and nutritional conditions in a period of 20–40 days.

#### 48.3.4 Impact of BVS on Process Design and Performance

The common use of TS or VS both in describing the organic loading rate and feedstock carbon-to-nitrogen (C/N) ratio and in estimating gas production from the BOFMSW is misleading, as some of the organic compounds are low in biodegradability. The use of BVS instead allows meaningful comparisons to be made between the different AD processes reported in the literature. The impact of BVS on the organic loading rate, the computation of C/N ratio, and the prediction of biogas production are discussed as follows.

Traditionally, the loading rates for biological processes have been based on the VS content of the substrate feedstock. When handling substrates with variable biodegradabilities, estimates of the methane production potential and digester performance cannot be made accurately using a VS loading rate. Loading rates based on the BVS fraction of the substrate should be used to estimate the conversion of organic wastes to methane. The BVS organic loading rate can be expressed as the input BVS mass per active reactor mass per day. The BVS mass of an organic substrate can be computed using total inflow VS mass multiplied by the BVS fraction of VS.

Customarily, the C/N ratio is determined based on the total dry mass of the organic matter and the corresponding percentage concentrations of carbon and nitrogen. This method of determining the C/N ratio may not be appropriate for the BOFMSW because not all the organic carbon is biodegradable and/or available for biological decomposition. However, it appears that almost all the nitrogen in the organic material is available for conversion to ammonia via microbial metabolism.<sup>10</sup> Because the available nitrogen in the organic feedstock can be converted to ammonia, the C/N ratio should be based on the nitrogen content of the total organic mass and the carbon content of the BVS mass.<sup>11</sup>

A more accurate biogas volume production can be made from the BVS mass, rather than the TS or VS mass. However, not all the BVS mass computed using the LC or the results of long-term batch studies will be converted into biogas in field operation. For design purpose, a correction factor of about 0.82, derived from lignin test or long-term batch digestion, must be used when using the BVS mass as a basis for theoretical gas production. Computation of BVS fraction of the biodegradable fraction of MSW is illustrated in the following example calculation.

##### 48.3.4.1 Example BVS Calculation of MSW

Estimate the total BVS weight (mass) of a 100 ton/day MSW material recovery facility.

Use the following information:

1. Assume the composition of a typical MSW waste stream given in [Figure 48.2](#) is valid.

## 2. Typical characteristics of MSW subfractions:

Waste Material	TS, %	VS, %TS	LC
Yard waste	40	88	6.43
Food waste	30	90	0.36
Paper	94	98	9.29

**Solution**

## 1. Start from the typical composition of MSW, and prepare a table:

Waste Material	Weight, lb/day	
	Wet	Dry <sup>a</sup>
Yard waste	38,000	15,200
Food waste	18,000	5,400
Paper	80,000	75,200
Metal	42,000	42,000
Plastic	22,000	22,000

<sup>a</sup> Calculated using % TS.

## 2. Calculate the biodegradable organic fraction of MSW being serviced by the sorting facility:

$$\text{BOFMSW per day} = (0.68)(100 \text{ ton MSW/day}) = 68 \text{ ton}$$

## 3. Compute the total weight of BVS. To compute the BVS content of a substrate,

$$\text{VS weight} = \text{dry weight} \times \text{VS}\%$$

$$\text{BVS weight} = \text{VS weight} \times \text{BF}$$

where

$$\text{BF} = 0.83 - (0.028 \times \text{LC})$$

LC is the LC.

## 4. Prepare a table of the values calculated:

Biodegradable Waste	Dry Wt., lb/day	VS, %TS	VS Wt., lb/day <sup>a</sup>	BF, %VS <sup>b</sup>	BVS Wt., lb/day <sup>c</sup>
Yard waste	15,200	88	13,376	0.65	8,694
Food waste	5,400	90	4,860	0.82	3,985
Paper (mixed)	75,200	98	73,696	0.57	42,005
Total	95,800	00	91,932	00	54,684

<sup>a</sup> The values in this column are calculated as VS = dry weight  $\times$  VS%.<sup>b</sup> The biodegradable fraction (BF) is computed using Equation 48.1 and the LC or using the biodegradability value determined by a long-term batch study.<sup>c</sup> The values in this column are calculated as BVS = VS weight  $\times$  BF.**Comment**

It is important to note that the BVS weight is about 27% of the total wet weight of MSW, 40% of the total wet weight of BOFMSW, and 60% of the total VS fraction of the TS.

## 48.4 Fundamental of Anaerobic Digestion Process

The purpose of this section is to familiarize the reader with the basic microbiology related to an AD process. Topics discussed include (1) an introduction to anaerobic bacteria, (2) nutrient requirements for the anaerobic bacteria, (3) physical and chemical parameters affecting anaerobic bacteria, (4) basic biochemical reaction in AD process, and (5) pathway of complex organic substrate in AD process.

### 48.4.1 Anaerobic Bacteria

Effective anaerobic degradation of complex organic waste is a result of the combined and coordinated metabolic activity of the digester microbial population. This population of microorganisms is composed of several major trophic groups. At present, as reported in Table 48.5, four different groups of anaerobic bacteria are recognizable. With respect to methane recovery, the anaerobic bacteria are generally grouped as (1) hydrolysis (hydrolyzing bacteria), (2) acidogens (acid-forming bacteria), (3) acetogens (acid-forming bacteria), and (4) methanogens (methane-forming bacteria).

Methane bacteria are among the most strictly anaerobic microorganisms known and occur naturally in the rumen of cows, marshes, and brackish waters, as well as in wastewater treatment plant digesters. Methanogenic bacteria have been isolated from anaerobic digesters, together with other obligate anaerobes, such as the *Propionibacter*, *Butyrobacter*, and *Lactobacillus*. The true methane bacteria include the following identified genera: *Methanococcus*, *Methanobacterium*, *Methanosarcina*, *Methanospirillum*, and *Methanobacillus*. The main groups of methane bacteria along with some of their morphological and growth characteristics are given in Table 48.6.

As reported in Table 48.6, methane bacteria are rod, cocci, or sarcinate in shape. As a group, methane bacteria are nearly always Gram positive (a stain used to identify bacterial types) and usually not motile. Many methane bacteria are pleomorphic; that is, they exhibit variable morphology when viewed under the microscope, which makes their identification very difficult. Their length can vary between 2 and 15  $\mu\text{m}$ . Nutritionally, the methanogenic bacteria are said to be chemoheterotrophs (or chemotrophic heterotrophs), which means that they can build up their cell structures from either carbonate or organic compounds. Morphologically, methanogens are a diverse group; however, physiologically, they are quite similar as all share the common metabolic capacity to produce methane. The methanogens are possibly the most important group of anaerobic bacteria. They have scientific significance in their exclusive and distinctive properties among the bacteria.

**TABLE 48.5**

Four Major Groups of Anaerobic Bacteria and Their Function

Bacterial Group	Function
Hydrolytic bacteria	Convert saccharides, protein, lipids, and other minor chemical constituents of biomass to soluble compounds such as fatty acids, amino acids, and monosaccharides
Acidogenic bacteria (fermentation)	Convert products from hydrolysis reaction and other soluble compounds to compounds such as acetate, propionate, butyrate, $\text{CO}_2$ , and $\text{H}_2$
Acetogenic bacteria	Convert unicarbon compounds or $\text{HCOOH}$ or hydrolyze multicarbon compounds to acetic acid, $\text{H}_2$ , and $\text{CO}_2$
Methanogenic bacteria	Convert the by-products of acidogenesis and acetogenesis to methane and carbon dioxide

**TABLE 48.6**

Morphological Characteristics of Methane Bacteria

Organism	Morphology	Length, $\mu\text{m}$	pH Optimum	Electron Donor
<i>Methanobacterium formicium</i>	Rods, single pairs or chains	2–15		Hydrogen and formate
<i>Methanobacterium</i> strain MOH	Rods, single pairs or chains	2–4		Hydrogen
<i>Methanobacterium arborphilicum</i>	Rods, single pairs or chains	2–3.5	7.5–8	Hydrogen
<i>Methanobacterium</i> strain AZ	Rods, single pairs or chains	2–3	6.8–7.2	Hydrogen
<i>Methanosarcina barkeri</i>	Sarcina	1.5–5	7	Methanol and hydrogen
<i>Methanobacterium ruminantium</i>	Coccus chains	1–2 diameter	6.8–7.2	Hydrogen and formate
<i>Methanococcus vannielii</i>	Coccus	0.5–4 diameter	7.4–9.2	Formate
<i>Methanobacterium mobile</i>	Rod			Hydrogen and formate
<i>Methanobacterium thermoautotrophium</i>	Rod	5–10		Hydrogen
<i>Methanobacterium hungatii</i>	Spiral rods	50		Hydrogen and formate

#### 48.4.2 Nutrient Requirements for Anaerobic Bacteria

To operate a high-solids AD process at a commercial level, attention must be focused on process stability. Successful operational parameters have been established for the high-solids process studies conducted at the University of California, Davis (UC Davis).<sup>9</sup> However, in the AD of BOFMSW, bacterial nutritional requirements have often been overlooked. Nutritional deficiencies may result in reactor instability and incomplete bioconversion of the organic substrates. When the AD process is applied to the biodegradable organic fraction of MSW, bacterial nutritional requirements must be addressed, and nutrient supplementation may be required.<sup>13,14</sup>

Methanogenic bacteria have a variety of mineral nutrient requirements for robust growth.<sup>15,16</sup> For a proper bacterial metabolism, a variety of nutrients must be present in the substrate. The nutrient requirements for anaerobic bacteria can generally be categorized as macro- and micronutrient. For a stable AD process, these nutrients must be present in the substrate in the correct ratios and concentrations. Based on studies conducted at UC Davis, it was found that typical BOFMSW used as a feedstock for the AD process is deficient in many essential nutrients.<sup>17</sup> To overcome feedstock nutrient deficiencies, supplementary nutrients must be added to stimulate the digestion process. The range of nutrient concentrations needed to stimulate the anaerobic treatment of BOFMSW for gas production is not well known. The nutrient values reported in [Table 48.7](#) are based on 3 years of experience at the UC Davis high-solids biogasification project.

#### 48.4.3 Physical and Chemical Parameters Affecting Anaerobic Bacteria

The alteration of several physical and chemical environmental parameters in anaerobic digesters can influence microbial populations and digester performance.

**TABLE 48.7**

Representative Feedstock Nutrient Concentrations Required for the Robust Anaerobic Bioconversion of BOFMSW

Nutrient	Unit	Average Value (Dry Basis)	
		Range	Typical
C/N	Ratio	20–30	25
C/P	Ratio	150–300	180
C/K	Ratio	40–100	70
Co	mg/kg	<1–5	2
Fe	mg/kg	100–5000	1000
Mo	mg/kg	<1–5	2
Ni	mg/kg	5–20	10
Se	mg/kg	0–0.05	0.03
W	mg/kg	0.05–1	0.1

Source: Kayhanian, M. and Rich, D., *Biomass and Bioenergy*, 8, 433, 1995.

Note: C/N, C/P, and C/K ratios are based on biodegradable organic carbon and total nitrogen, phosphorus, and potassium.

**TABLE 48.8**

Physical and Chemical Effectors of Bacterial Populations in Anaerobic Digesters

Parameter	Population Response	Influence of Methanogenesis
Temperature (e.g., change to 65°C from 35°C)	Enrichment of thermophilic	Increase
pH (e.g., change to pH 5 from pH 7)	Enrichment of acidophiles	Decrease
Organic substrate composition (e.g., change soluble substrate [glucose] for particulate [lignoglucose])	Enrichment of biopolymer decomposers	Decrease
Substrate feed rate (e.g., change from slow to high glucose feed)	Enrichment of hydrolytic bacteria	Decrease
Inorganic composition (e.g., addition of excess sulfate)	Enrichment of sulfate reducers	Decrease

Source: Holland, K.T. et al., *Anaerobic Bacteria*, Chapman & Hall, New York, 1987.

Major environmental factors are summarized and shown in Table 48.8. Changing temperature from the mesophilic range (i.e., below 45°C) to the thermophilic range (i.e., above 55°C) increases organic mineralization and establishes a different species composition (i.e., thermophilic bacteria). Zeikus<sup>18</sup> found that thermophilic bacteria have a limited species composition, but they possess all the major nutritional categories and metabolize the same substrate as mesophilic bacteria. The ability to proliferate at growth temperature optima well above 60°C is associated with extremely thermostable macromolecules. As a consequence of growth at high temperatures and unique micromolecular properties, thermophilic bacteria can possess high metabolic rates, physically and chemically stable enzymes, and lower growth but higher end-product yields than similar mesophilic species. Thermophilic digesters are generally digest substrates within shorter retention time than mesophilic digesters.

Values of pH well below neutral are indicative of digester failure. The pH ranges for growth of many bacterial species inherent to anaerobic methane digester are not known and may vary considerably. Nevertheless, important hydrogen-producing (e.g., *Clostridium thermocellum*) and hydrogen-consuming (e.g., *Methanobacterium thermoautotrophium*) anaerobes do not grow at pH value below 6. Digester imbalances that favor more rapid growth

of nonmethanogens (e.g., high feed rate or chemical composition of feed) can lead to low pH and inhabitation of methanogenesis. Low pH values favor proton reduction to hydrogen, but not hydrogen oxidation to protons. Thus, methanogens may not function at low pH because they employ oxidoreductases for hydrogen oxidation and establishment of proton gradients during the catabolism of one carbon compound and acetate.

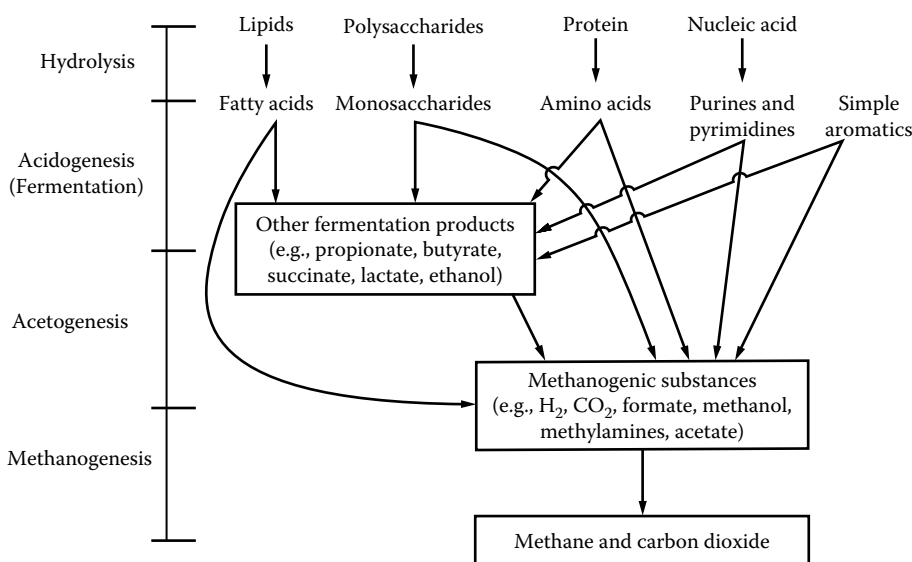

The organic composition of digester wastes affects species composition and methane yield. Most notably, methane yields from municipal wastes and animal manures are often limited by polymeric lignin surrounding cellulose and retarding its fermentation. High-molecular-weight lignin is not metabolized significantly by anaerobic bacteria. However, methane yield from digestion of lignocellulosics can be enhanced greatly by physico-chemical pretreatment that separates lignin from cellulose and/or solubilize lignin into anaerobically digestible substrates. To accomplish lignin solubilization, an adaptation period is required to obtain an active microbial population from untreated waste digesters that metabolized soluble chemical hydrolysis products of lignin. The organic composition modification caused by waste pretreatment is considered to be associated with change in species compositional change.

The most significant parameter affecting methanogenesis during AD processes is sulfate inhabitation. The addition of high levels of sulfate to decomposing organic matter can result in nearly complete inhabitation of methane formation as a result of species compositional change. The basis for this inhabitation is that carbon and electron flow during organic mineralization is diverted from methane formation to hydrogen sulfide production. The response of sulfide on many methanogens is concentration dependent. Sulfide is required by many methanogens as a sulfur source for growth. The addition of low sulfide concentrations often stimulates mixed culture methanogenesis, whereas addition of high concentrations can be inhibitory.

#### **48.4.4 Pathway of a Complex Organic Substrate in Anaerobic Digestion Process**

A generalized scheme for the AD of complex organic substrate is shown in [Figure 48.5](#). AD is generally considered to take place in four more or less distinct stages. The four stages have been described as (1) hydrolysis, (2) acidogenesis (often identified as fermentation in the literature), (3) acetogenesis, and (4) methanogenesis. Each of the four stages has distinct bacterial groups, and chemical reactions, as described previously, and the overall process proceeds in an assembly-line fashion.<sup>12</sup> In many literature references, acidogenesis (fermentation) and acetogenesis are considered to be one process termed “acidogenesis.”

Methane bacteria can only use limited range of substrates for growth and energy production. During AD, a varied mixture of complex compounds is converted to a very narrow range of simple compounds, mainly methane and carbon dioxide. The ecology of the system is much more complicated and involves an interacting succession of microbes, which influences each others' growth and metabolism. Nearly all anaerobic bacteria can use hydrogen and carbon dioxide, and most can use formate, a few acetate, and fewer still methanol and methylamines. However, in the mixed population and with many organisms, the range of fermentation products is restricted. The restriction is due to the phenomenon of interspecies hydrogen transfer by which methanogens utilize hydrogen and thus benefit other organisms. Hydrogen removal is helpful as it allows some organisms to dispose of more electrons via hydrogen rather than via the production of more-reduced carbon compounds, such as ethanol or butyrate. In general, fatty acids are the “key” intermediate products of the anaerobic fermentation of

**FIGURE 48.5**

Stages of AD. (From Tchobanoglous, G. et al., *Integrated Solid Waste Management: Engineering Principles and Management Issues*, McGraw-Hill Book Company, New York, 1993.)

organic compounds prior to methane formation. Acetate is by far the predominant fatty acid in normally operated systems, being responsible for about 70% of the fatty acid present. The VFA measurements are usually expressed in mg/L, therefore, as being acetate equivalent.

#### 48.4.5 Basic Biochemical Reaction in Anaerobic Digestion Process

The anaerobic bacteria described in previous sections are responsible for biochemical transformation of a wide variety of waste materials. These transformations are involved in the breakdown of complex polymers, such as cellulose, fats, and proteins, to long- and short-chain fatty acids and finally methane, carbon dioxide, and water. The basic biochemical reactions affected by anaerobic microbial population are oxidation/reduction reactions, where a number of organic compounds are oxidized by the removal of hydrogen. Carbon dioxide, is thereby, reduced in providing an oxidant for the methane bacteria. The hydrogen produced can be replaced by some of the organic acids and alcohols as direct reductants of carbon dioxide. The basic biochemical reactions utilizing hydrogen, carbon dioxide, carbon monoxide, alcohols, organic acids, methylamines, and other protein derivative compounds as a substrate are summarized in the energy-yielding equations given in [Table 48.9](#).

The general anaerobic transformation of the biodegradable organic fraction of waste materials can be described by the following equation<sup>19</sup>:

**TABLE 48.9**

Summary of Most Common Biochemical Reactions in AD Process

Substrate	Biochemical Reactions
Hydrogen and carbon dioxide	$4\text{H}_2 + \text{CO}_2 \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$
Carbon monoxide	$4\text{CO} + 2\text{H}_2\text{O} \rightarrow \text{CH}_4 + 3\text{CO}_2$
	$4\text{CH}_3\text{OH} \rightarrow 3\text{CH}_4 + \text{CO}_2 + 2\text{H}_2\text{O}$
Alcohols	$\text{CH}_3\text{OH} + \text{H}_2 \rightarrow \text{CH}_4 + \text{H}_2\text{O}$
Fatty acids	$4\text{HCOO}^- + 2\text{H}^+ \rightarrow \text{CH}_4 + \text{CO}_2 + 2\text{HCO}_3^-$
	$\text{HCOO}^- + 3\text{H}_2 + \text{H}^+ \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$
	$\text{CH}_3\text{COO}^- + \text{H}_2\text{O} \rightarrow \text{CH}_4 + \text{HCO}_3^-$
Methylamines and other protein derivative compounds	$4\text{CH}_2\text{NH}_2 + 2\text{H}_2\text{O} + 4\text{H}^+ \rightarrow 3\text{CH}_4 + \text{CO}_2 + 4\text{NH}_4^+$
	$2(\text{CH}_3)_2\text{NH} + 2\text{H}_2\text{O} + 2\text{H}^+ \rightarrow 3\text{CH}_4 + \text{CO}_2 + 2\text{NH}_4^+$
	$4(\text{CH}_3)_3\text{N} + 6\text{H}_2\text{O} + 4\text{H}^+ \rightarrow 9\text{CH}_4 + 3\text{CO}_2 + 4\text{NH}_4^+$
	$2\text{CH}_3\text{CH}_2\text{-N}(\text{CH}_3)_2 + 2\text{H}_2\text{O} \rightarrow 3\text{CH}_4 + \text{CO}_2 + 2\text{CH}_3\text{CH}_2\text{NH}_2$

For practical purposes, the overall conversion of the biodegradable organic fraction of waste materials to methane, carbon dioxide, and ammonia can be represented with the following equation (Tchobanoglous et al.<sup>19</sup>):

where

$$s = a - nw - m$$

$$r = c - ny - 2s$$

The terms  $\text{C}_a\text{H}_b\text{O}_c\text{N}_d$  and  $\text{C}_w\text{H}_x\text{O}_y\text{N}_z$  are used to represent (on a molar basis) the composition of the organic material present at the start and the end of the process, respectively. If it is assumed that the organic wastes are stabilized completely, the corresponding expression is

This relationship can be used to estimate the theoretical biogas volume and composition. Estimation of the amount of gas produced by the complete anaerobic stabilization of the BVS fraction of MSW is illustrated in the following example calculation.

#### 48.4.5.1 Example Estimation of Theoretical Gas Production

Estimate the total theoretical amount of gas that could be produced from MSW under anaerobic conditions in an in-vessel AD process. Assume that 78% by weight of the MSW is organic material including moisture. Further assume the moisture content is 20%, the VS are 83.5% of the total organic solids, the BVS are 75% of the VS and only 90% of the BVS will be converted to biogas. The overall chemical formula for the biodegradable organic material is  $\text{C}_{60}\text{H}_{94.3}\text{O}_{37.8}\text{N}$ .

**Solution**

1. Determine the BVS:

$$\text{BVS} = 78 \times (1 - 0.2) \times 0.835 \times 0.75 = 39.1 \text{ lb}$$

2. Determine the total amount BVS that will be converted to gas:

$$\text{BVS}_{\text{gas}} = 39.1 \times 0.9 = 35.2$$

3. Using the chemical formula  $\text{C}_{60}\text{H}_{94.3}\text{O}_{37.8}\text{N}$ , estimate the amount of methane and carbon dioxide that can be produced using Equation 48.4:

For the given chemical formula,  $a = 60$ ,  $b = 94.3$ ,  $c = 37.8$ , and  $d = 1$ .

The resulting equation is

4. Determine the weight of methane and carbon dioxide from the equation derived in step 3 and the data from step 2:

$$\text{Methane} = \left( \frac{512}{1437} \right) (35.2 \text{ lb}) = 12.5 \text{ lb} (5.7 \text{ kg})$$

$$\text{Carbon dioxide} = \left( \frac{1232}{1437} \right) (35.2 \text{ lb}) = 30.2 \text{ lb} (13.7 \text{ kg})$$

5. Convert the weight of gases, determined in step 4, to volume, assuming that the densities of methane and carbon dioxide are 0.0448 and 0.1235 lb/ft<sup>3</sup>, respectively:

$$\text{Methane} = \frac{12.5 \text{ lb}}{(0.0448 \text{ lb/ft}^3)} = 279 \text{ ft}^3 (7.9 \text{ m}^3)$$

$$\text{Carbon dioxide} = \frac{30.2 \text{ lb}}{(0.1235 \text{ lb/ft}^3)} = 244 \text{ ft}^3 (6.9 \text{ m}^3)$$

6. Determine the percentage composition of the resulting gas mixture using the gas volume determined in step 5:

$$\text{Methane (\%)} = \left[ \frac{279}{(279 + 244)} \right] \times 100 = 53.35\% \approx 53\%$$

$$\text{Carbon dioxide (\%)} = 100\% - 53.35\% = 46.65\% \approx 47\%$$

7. Determine the total theoretical amount of gas generated per unit weight of dry BVS as determined in step 1 and per ton of MSW:

$$\frac{(279 + 244)}{(39.1)} = 13.4 \text{ ft}^3/\text{lb BVS} \left( 1.48 \text{ m}^3/\text{kg BVS} \right)$$

$$\begin{aligned} \text{Biogas/ton of MSW} &= (13.4 \text{ ft}^3/\text{lb})(2,000 \text{ lb/ton})(0.78)(0.8)(0.835)(0.75) \\ &= 10,470 \text{ ft}^3/\text{ton MSW} \end{aligned}$$

### Comment

The theoretical gas production value determined earlier has been achieved with the high-solids anaerobic decomposition process (see Section 48.7.2).

## 48.5 Monitoring of the Anaerobic Digestion Process

Although the high-solids AD process is generally robust, care must be taken to ensure balanced operation. To aid the prevention of unbalanced digester operation and to prevent digester failure, proper methods of monitoring the high-solids AD process are described, and possible operational problems are identified along with suggested remedial actions to be taken when these problems arise.

### 48.5.1 Balanced Digestion

A balanced digester is one in which AD proceeds with a minimum of control. Balanced operation means that the environmental parameters of the system remain within their optimum range, with only occasional fluctuations. When an imbalance does occur, the two main problems are (1) identifying the beginning of an unbalanced condition and (2) identifying the cause of the imbalance. Unfortunately, there is no single parameter that will always indicate the commencement of an unhealthy anaerobic process. The parameters shown in Table 48.10 must all be monitored daily. None of these parameters can be used individually as a positive indicator of the development of digester imbalance.

**TABLE 48.10**

Indicators of Unbalanced Operation of the AD Process

Parameter	Warning Condition
Ammonia concentration	Increases
Percent CH <sub>4</sub> in biogas	Decreases
Percent of CO <sub>2</sub> in biogas	Increases
Reactor pH	Decreases
Total gas production	Decreases
VFA concentration	Increases
Waste stabilization	Decreases

**TABLE 48.11**

Summary of the Most Common Problems Associated with the AD Process and Suggested Actions to Cure the Problems

Major Problem	Suggested Action
Free ammonia toxicity	1. Start feeding organic waste with higher C/N ratio. 2. Dilute the active reactor mass with freshwater.
Nutrient deficiency	1. Add chemical nutrients. 2. Add organic materials rich in the needed nutrients.
Organic overloading	1. Do not feed. 2. Add strong base to neutralize acids. 3. Resume feeding at lower organic loading rate when pH reaches at least 6.8.
TS buildup	1. Add water.
Toxic overloading	1. Identify and remove the toxic element from the feedstock. 2. If the population of methanogens is reduced ( $\text{CH}_4$ concentration decreased), add proper methanogen seed. 3. If pH decreases below 6.8, add strong base to neutralize acids. 4. Resume feeding at lower organic loading rate when pH reaches at least 6.8.

The most immediate indication of impending operational problems is a significant decrease in the rate of gas production. If the growth of the microorganisms is being inhibited by one or more factors, it will be reflected in the total gas production. However, a decrease in the gas production rate may also be caused by a decrease in either the digester temperature or the rate at which the feed material is being added to the digester.

The most significant single indicator of a digester problem is a gradual decrease in pH. In an operating system, a decrease in pH is associated with an increase in organic acid concentration. Measurement of the increase in organic acids is also a good control parameter; however, proper laboratory facilities, equipment, and trained personnel are required to monitor this and most of the other control parameters affecting the anaerobic process. Gas production rate and pH are simple, quick measurements and are performed easily.

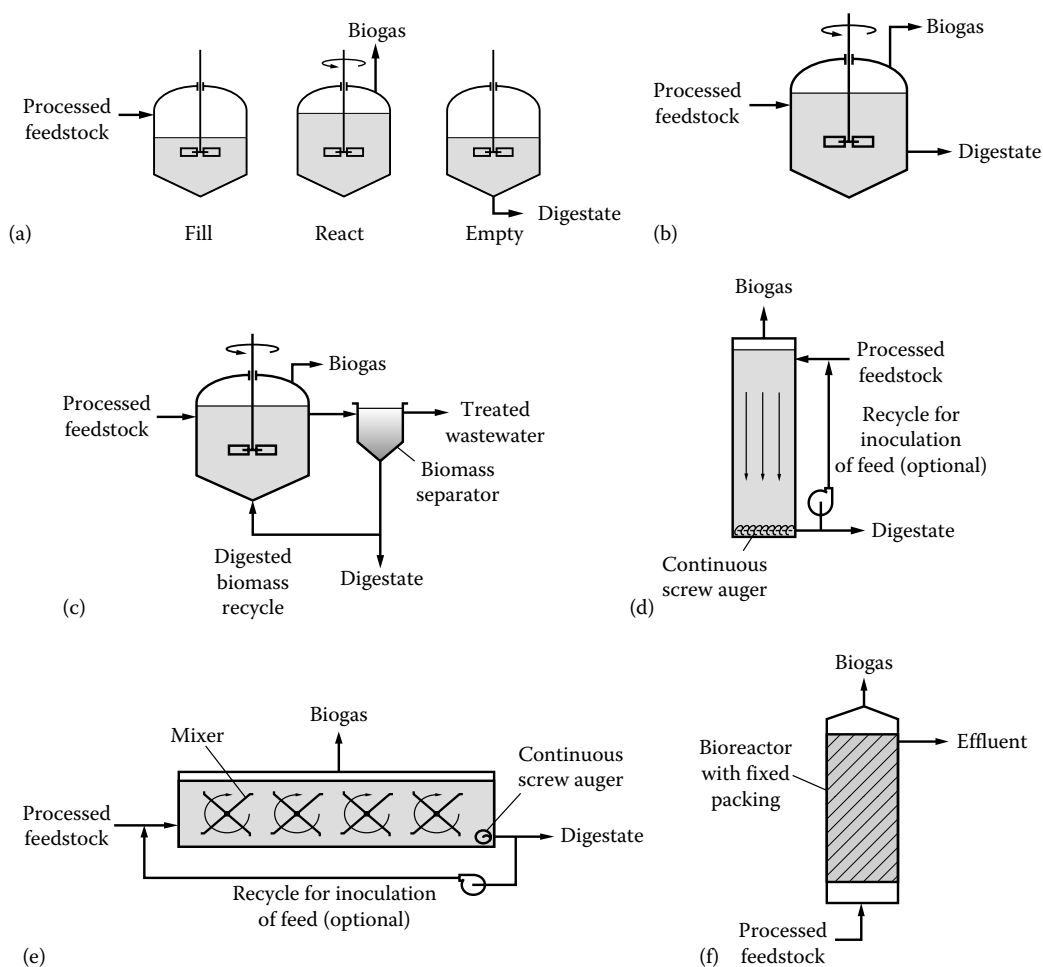

#### 48.5.2 Common Problems and Solutions to Stabilize Digester Operation

In general, there are five major problems associated with the AD process: (1) increase in TS concentration, (2) organic overloading, (3) toxic overloading, (4) free ammonia toxicity, and (5) nutrient deficiency. Possible actions to cure these problems are summarized in Table 48.11.

### 48.6 Reactor Types Used for Anaerobic Digestion

In the past 50 years, a wide variety of full-scale AD processes and reactors have been used for both waste stabilization and energy recovery. The AD is used most commonly in wastewater treatment plants for sludge stabilization with and without methane gas recovery plants.<sup>20</sup>

Full-scale digesters (including anaerobic lagoons [ANLs]) have also been used by dairy and hog farmers to stabilize their waste as well as to produce methane gas for the production of electrical power to offset their power consumption during pick hours and on

**FIGURE 48.6**

Typical reactor types used for AD (a) batch reactor, (b) complete-mix continuous flow reactor, (c) anaerobic contact reactor, (d) vertical plug-flow reactor, (e) horizontal plug-flow reactor, and (f) attached growth reactor.

annual basis.<sup>21,22</sup> AD is also commonly used for treatment and energy production from food processing industries. The principal types of AD reactor designs that can be used for waste stabilization as well as methane recovery for energy production are shown in Figure 48.6 and described briefly in the following. Other reactor designs, which incorporate features of the reactors shown in Figure 48.6, are described in Section 48.6.7.

#### 48.6.1 Batch Reactor

A batch reactor is fed once, and then the biotransformation is allowed to proceed until completion before any material is added or removed. A simplified diagram of a batch digestion is shown in Figure 48.6a. The evolution of compounds in the reactor can be monitored, and a similar level of decomposition can be achieved by all the material in the reactor at one time. Additionally, the systems are generally simple, with less support equipment than continuous fed reactors (see later). Batch processes are necessary when the

biotransformation being performed requires a long reaction time. Solids that are treated undiluted are often treated with batch reactors.

Usually, batch processes require more operator labor, for feeding and unloading, than continuous feed processes, and especially so for liquids and slurries, which are easily piped and pumped. For solids, the material handling needs are more similar for the two processes. Storage facilities are needed to contain waste received between batches. The need for storage can be inconvenient for large-scale, continuously produced wastes.

#### 48.6.2 Complete-Mix Continuous Flow Reactor

A reactor to which a waste stream is fed and a treated effluent stream is withdrawn continuously is known as a continuous flow reactor. A simplified diagram of a complete-mix reactor is shown in [Figure 48.6b](#). Most municipal wastewater sludge treatment processes are continuous feed processes, as municipal sludge is produced continually. A process can be designed to fit the expected maximum inflow rate, although fluctuations in flow rate and process upsets may interfere with operation. If alternate storage is not available, discharge of untreated or partially treated wastes can occur.

The average residence time of material in a continuous feed reactor can be determined using the following equation:

$$t = \frac{V}{Q} \quad (48.5)$$

where

$t$  is the residence time

$V$  is the reactor volume

$Q$  is the flow rate (vol/time)

Reactors that are fed liquids or slurries continuously require less operator labor than batch reactors. Because storage space is not necessary to contain continuously produced wastes between batches, continuous feed processes are used commonly for industrial or municipal wastes. There are two types of reactors that are intermediate between continuous feed and batch processes. A reactor that is fed once a day is a semicontinuous feed reactor. Also, a reactor that is fed continually, but only emptied when waste stabilization has been achieved, is a semibatch reactor.

In a complete-mix reactor, the reactor contents are blended to homogeneity with a mixing device. The effluent leaving the reactor is exactly the same as the material in every part of the reactor. If fed continuously, the input waste is considered to be immediately mixed completely with the reactor contents. These reactors can also be described as well-mixed or as continuous stirred-tank reactors (CSTRs). One advantage of a complete-mix process is that fluctuations in feed concentration or composition are diluted into the larger reactor mass. Because dilution and the concentration of waste nutrient determines the rate of waste decomposition, complete-mix reactors have a slower decomposition rate.

#### 48.6.3 Anaerobic Contact Reactor

The anaerobic contact process (ACP) is used to overcome the disadvantages of the complete-mix reactor without recycle. To enhance the rate of treatment, biomass is separated from the effluent and returned to the reactor. Biomass recycle can be used to reduce the

reactor size and cost. A simplified ACP is shown in [Figure 48.6c](#). Hydraulic retention times as low as a half-day have been achieved resulting in a significant reduction in plant size. ACP has been applied successfully for the treatment of meat-packing waste, where a retention time of several hours was measured. ACP is also used for the treatment of a high-strength waste material and is usually operated under low solids (TS less than 8%).

#### 48.6.4 Plug-Flow Reactor

All plug-flow reactors are continuously or semicontinuously fed. In a plug-flow reactor, material passes through, ideally, without interacting with the material fed in before or after it. These reactors can be thought of as tubes through which independent batches of reacting material pass. The reactor can be either vertical or horizontal flow as shown in [Figure 48.6d](#) and [e](#), respectively.

The retention time for a plug-flow reactor is the length of time it takes a mass introduced at the beginning of the reactor to pass through and be removed from the other end (see also [Equation 48.5](#)). Most horizontal plug-flow digesters are operated under low solids (usually with TS of less than 10%). Because the incoming, high-nutrient wastes are not diluted into the rest of the digester contents, the plug-flow digesters are more susceptible to system upsets due to sudden increases in waste concentration, called shock loadings. Fortunately, a certain degree of back mixing is unavoidable throughout the reactor due to longitudinal dispersion.

#### 48.6.5 Anaerobic Attached Growth Reactor

Anaerobic attached growth reactors are used to prevent the depletion of the bacterial population within the reactor and, thus, improve digester efficiency. A simplified anaerobic filtration process is shown in [Figure 48.6f](#). The retention of bacteria within the reactor is achieved by introducing some type of packing material on which the bacteria can grow. Various materials such as stone granules, wood chips, and plastic materials of various shapes and sizes have been used as packing material. The bacteria adhering to the filter particles bring about the treatment of the liquid as it passes through the reactor. Excess biomass dies and/or sloughs off and passes out as sludge. The anaerobic filtration process is usually used for the treatment of a high-strength waste material and usually operated under low solids (TS less than 8%).

#### 48.6.6 Reactors with Recycle Flow

Often, it is advantageous to recycle and mix effluent from an anaerobic reactor (digestate) with the inflowing waste stream (see [Figure 48.6c](#) through [e](#)). Recycling is especially advantageous when it is necessary to inoculate the incoming waste with bacteria that have acclimated to the system. Recycling of biomass can also be used to increase average residence time in the reactor and to dilute high-concentration wastes. Recycling a portion of the biomass can also be used for process control, allowing the reactor to respond to fluctuations in the waste stream. Recycling systems, however, add costs, both capital and operational, to a system. Hence, unless it is necessary, the use of a simpler, unrecycled system is typically favored.

#### 48.6.7 Other Reactor Types and Processes

Over the years, numerous anaerobic processes employing a variety of other reactor types, different than those described earlier, have been developed and are in use. Four of these other reactor types and processes are illustrated in [Figure 48.7](#) and described

**FIGURE 48.7**

Alternative types of reactors used for AD: (a) excavated and lined ANL, (b) UASB-IC, (c) anaerobic hybrid process (ANMBP), and (d) anaerobic membrane process (ANMBR). (Adapted from Tchobanoglous, G. et al., *Wastewater Engineering: Treatment and Resource Recovery*, 5th edn., Metcalf & Eddy Inc., AECOM, McGraw-Hill Book Company, New York, 2014.)

briefly in the following. It is important to note that there are many more reactor designs in use and that new reactor configurations are being developed continuously; including all of them in this chapter at present time is beyond the scope of this book.

#### 48.6.7.1 Anaerobic Lagoon

This is generally an unmixed reactor system, typically below ground, employing suspended/flocculating anaerobic biomass and settled anaerobic solids with hydraulic retention times of 20–50 days and average MRTs of 50–100 days (see Figure 48.7a). ANLs are often classified as arbitrary-flow reactors as the flow regime is neither complete mix nor plug flow. ANLs can be covered with synthetic membranes for gas collection. Uncovered and covered, ANLs handle a wider range of wastes including solids and soluble wastewaters and are by far the most common anaerobic processes in use today, especially for farm wastes.

#### 48.6.7.2 Upflow Anaerobic Sludge Blanket with Internal Circulation

An upflow anaerobic sludge blanket with internal circulation (UASB-IC) reactor consists of two stacked UASB reactors in series, each with a gas separator at the top (see Figure 48.7b). The system uses a down comer pipe from a top chamber to the bottom inlet and a riser pipe from the first gas separator to induce recirculation and high upflow velocities in the lower granular sludge blanket reactor. Gas produced from the lower reactor is captured in the first separator and creates a gas lift for water and biosolids in the riser pipe. The gas is separated (released) from the biosolids in the chamber above the second reactor gas separator.

#### **48.6.7.3 Anaerobic Hybrid Process**

A combination of stand-alone anaerobic technologies (see [Figure 48.7c](#)) employing a combination of an UASB reactor and anaerobic filter to provide a high biomass concentration and high volumetric organic removal rates in the lower portion and further removal of volatile fatty acids and capture of suspended solids in the upper anaerobic filter portion.

#### **48.6.7.4 Anaerobic Membrane Process**

A mixed reactor system (see [Figure 48.7d](#)) employing suspended/flocculating anaerobic biomass and a synthetic membrane solid–liquid separation with solids recycle to provide a long SRT with the short hydraulic retention time.

---

### **48.7 Modes of Operation for Anaerobic Digestion**

To design a full-scale AD for the recovery of energy from waste materials, several parameters must be specified. These parameters may influence the physical characteristics of the reactor, the mode of operation, and the performance of a digestion system. Several modes of operation are discussed in the following.

#### **48.7.1 Low-Solids Digestion**

AD systems for municipal wastewater operate under low-solids conditions; that is, the concentration of solids in the waste substrate is typically less than 10%. This mode of operation is appropriate because both municipal wastewater and the sludge collected for disposal from aerobic wastewater treatment processes are intrinsically low solids. The waste substrate in a low-solids system can be pumped and piped easily as it behaves like water. A low-solids system is also more able to handle feed composition fluctuations and higher ammonia levels, because the large volume of water serves to dilute the incoming waste compounds. Dilution of waste compounds also means dilution of nutrients, unfortunately, so that low-solids digestions can require more retention time if the nutrient level is too low. Also, the high dilution means that larger-sized tanks are required to accommodate wastes.

It is possible to digest substrates other than wastewater treatment sludge, however, and many of these waste substrates have higher solids content. High-solids AD has recently been developed to accommodate these wastes. Originally developed to dispose of agricultural wastes, particularly manures, high-solids AD can be used to degrade food industry wastes, BOFMSW, agricultural and forestry residues, and other high-solids wastes.

#### **48.7.2 High-Solids Digestion**

High-solids AD operates at solids contents from 20% to 32%. Typically, high-solids wastes, such as BOFMSW, must be mixed with water or a low-solids waste, such as wastewater treatment sludge, to dilute the solids content to within the operating range. A high-solids system can operate with tanks that are up to 75% smaller than a low-solids system, for the same dry weight of waste. Because the nutrient in a high-solids reactor is more concentrated, the conversion rate is higher. Additionally, the high-solids process produces an end product that requires less dewatering to convert it into a landfillable waste or a usable compost material. High-solids AD systems are, however, more sensitive to micronutrient

deficiencies and toxic inhibition, since there is more mass to digest and is diluted with less moisture. Especially, thermophilic systems are critically dependent on the maintenance of a proper C/N ratio, as explained in the following.

#### 48.7.3 Thermophilic Digestion

Process in which the waste substrate is heated to between 120°F and 135°F is characterized as thermophilic. Although heating the reactor adds additional equipment and energy costs, thermophilic process has higher reaction rates as compared with ambient processes. Because bacterial metabolism is greater at the higher temperatures, a wider range of bacteria can colonize the reactor. Due to a decrease in water solubilization with increased temperature, thermophilic processes can be more vulnerable to inhibition effects due to the presence of some soluble compounds. Thermophilic methanogenic systems, for example, are more sensitive to high ammonia concentrations than are similar mesophilic systems.

#### 48.7.4 Mesophilic Digestion

Processes in which the waste substrate has a temperature of between 68°F and 98°F are characterized as mesophilic. Often, no heating equipment at all is used. Although less costly than thermophilic systems, the time necessary for bioconversion may be significantly longer. If heating equipment is not used, the efficiency of the process will also depend on the weather.

#### 48.7.5 Two-Stage Digestion

As discussed in the previous sections, AD is principally carried out by four microbial populations under four, more or less, distinct and interconnected stages. In the second and third (acidogenesis and acetogenesis) stage of the digestion process, soluble wastes are converted to organic acids, CO<sub>2</sub> and H<sub>2</sub>, and, finally, in the fourth stage, methane bacteria convert organic acids to methane and carbon dioxide. Acid-forming (acidogenic and acetogenic) and methane (methanogenic) bacteria are distinct from each other in several features. These features include their physiology, nutrient requirements, growth capabilities, and sensitivity to environmental stress. A single-stage digester can be most efficient only when a compromise is achieved between the relatively fast-growing acidogenic and acetogenic bacteria and the slower, more sensitive methanogenic bacteria.

A two-stage digester (see [Figure 48.8](#)) is designed to isolate the hydrolytic, acidogenic, and acetogenic bacteria from the methane bacteria into separate reactors and, thus, optimize each environment for maximum efficiency. Distinct features of two-stage reactor are overall greater efficiency and system stability, and substantial reductions in total reactor volume. Several methods can be used to separate the nonmethanogenic and methanogenic bacteria:

1. Various inhibitors may be introduced into the acid digester to prevent methanogenesis:
  - a. Adding chloroform
  - b. Adding carbon tetrachloride
  - c. Limiting oxygenation
  - d. Adjusting redox potential
2. Dialysis of methane bacteria by filtering the acids.
3. Adjusting the dilution rate and recycling of cell mass to each phase.

**FIGURE 48.8**  
Two-stage AD.

#### 48.7.6 Codigestion of Wastewater Treatment Sludge and BOFMSW

The codigestion of WWTPS and BOFMSW have been investigated by numerous researchers.<sup>24–29</sup> Most of these early studies concluded that high-quality source-separated MSW could be digested without nutrient supplementation up to organic loading rates of about 2.6 kg VS/m<sup>3</sup> day. They also reported that under conditions of nutrient addition, gas production could be enhanced, and a more stable process could be achieved. Other studies conducted by Rivard et al.<sup>13,14</sup>, Babbitt et al.<sup>30</sup>, and Cecchi et al.<sup>31</sup> confirmed the stabilizing effect of sludge to the digestion of MSW, with sludge comprising between 8% and 20% of feedstock VS.

One large-scale codigestion of MSW and wastewater sludge has been demonstrated in the United States by the Refuse Conversion to Methane (REFCOM) project in Tampa, Florida. The REFCOM system was based on a conventional low-solids digester design and operated as part of a total resource recovery process. The successful operation of the REFCOM process for mixed MSW at a rate of 50 ton/day or greater has confirmed the technical feasibility of the AD process. Reliable gas production was achieved in this facility for more than a year, indicating that MSW with wastewater sludge as a cosubstrate can support an anaerobic biological conversion process.

Most codigestion studies conducted prior to 1990 were low-solids processes, typically at a TS of 4%–8%. Only recently has the high-solids AD process been utilized for the codigestion of MSW and WWTPS.<sup>13,14,32</sup> In these high-solids digestion studies, the sludge was used mainly to provide sufficient nutrients for microbial growth and metabolism. Nearly 22 years ago, the technical feasibility of the anaerobic composting process was demonstrated for comanagement of BOFMSW and WWTPS at UC Davis, as described in the following.<sup>33</sup>

#### 48.7.7 Two-Stage Anaerobic Composting

In anaerobic composting, the focus is twofold: (1) production of methane as a source of energy and (2) complete waste stabilization to produce humus-like material. AD normally occurs at much higher solids content (e.g., 25%–32%). When a high-solids AD process is combined with a second stage aerobic biodryer, the two-stage process is termed “anaerobic composting.”<sup>34,35</sup> The principal differences between the conventional aerobic and anaerobic composting processes are summarized in Table 48.12. The process flow diagram, physical characteristics of the reactors, and the energy recovery and volume reduction achieved are described as follows.

**TABLE 48.12**

Comparison of Aerobic and Anaerobic Composting Processes

Characteristic	Aerobic Process	Anaerobic Process
Energy use	Net energy consumer	Net energy producer
End products	Humus, CO <sub>2</sub> , H <sub>2</sub> O	Sludge, CO <sub>2</sub> , CH <sub>4</sub>
Volume reduction	Up to 50%	Up to 50%
Processing time	21–30 days	20–40 days
Primary goal	Volume reduction	Energy production
Secondary goal	Compost production, waste stabilization	Volume reduction, waste stabilization

#### 48.7.7.1 Process Flow Diagram

The process flow diagram for the anaerobic composting process studied at the UC Davis is illustrated in Figure 48.9. As shown in Figure 48.9, the process involves two separate stages. The first stage of the two-stage process involves the high-solids AD of the biodegradable organic fraction of MSW to produce a gas, composed principally of CH<sub>4</sub> and CO<sub>2</sub>, and digested solids. The second stage of the two-stage process is used to decrease the moisture content of the anaerobically digested solids. Typically, the solids content of the digested solids is increased from 25% to about 65%. Because the second stage aerobic process is used to dry the digested solids, the term biodryer is also used to describe the process. The physical and operational characteristics of the pilot anaerobic composting facilities used at UC Davis are briefly described in the following.

#### 48.7.7.2 Physical Characteristics

The physical characteristics of the pilot-scale anaerobic composting facilities are summarized in Table 48.14. As reported in Table 48.13, both the anaerobic digester and the biodryer are designed to operate as complete-mix reactors. Additionally, both units are

**FIGURE 48.9**

Flow diagram of the two-stage anaerobic composting process studied at UC Davis. The platform scale was used to obtain data for the preparation of materials mass balances.

**TABLE 48.13**

Summary of the Physical Characteristics of the UC Davis Pilot-Scale High-Solids AD/Aerobic Biodrying Processing Units

Item	Unit	Description/Value
<i>Anaerobic Digester</i>		
Reactor type		Complete mix
Mixing mechanism		Mechanical
Heating mechanism		Thermal blanket
Total reactor volume	L	2548
Volume of active reactor solids	L	1900
<i>Aerobic Biodrying Reactor</i>		
Reactor type		Complete mix
Mixing mechanism		Mechanical
Heating mechanism		Thermal blanket
Total reactor volume	L	850
Volume of active reactor solids	L	765

equipped with thermal blankets and individual control panels so that they may be operated either manually or automatically. Further information on the UC Davis pilot-scale AD process design and performance can be obtained from Kayhanian and Tchobanoglous<sup>9</sup>, Kayhanian and Rich<sup>33</sup>, Kayhanian et al.<sup>35</sup>, Kayhanian<sup>36</sup>, Kayhanian and Hardy<sup>37</sup>, and Kayhanian et al.<sup>39</sup>

#### 48.7.7.3 Example of Codigestion Process for Energy Recovery Equivalent in Barrels of Oil

Compute the amount of energy (equivalent in barrels of oil) that can be produced from the digestion of a 1000 ton/day of MSW using primary sludge as cosubstrate.

##### Solution

Compute the BVS mass, biogas production, energy equivalent to barrels of oil as shown in the following steps:

1. Compute total organic mass.

Assume 75% of total mass is organic:

$$\text{Organic mass} = 0.75 \times 1000 = 750 \text{ ton/day}$$

2. Compute total dry organic mass.

Assume 20% of organic mass is moisture:

$$\text{Dry organic mass} = 750 \times 0.8 = 600 \text{ ton/day}$$

3. Compute the BVS mass in MSW.

Assume 90% of dry organic mass is VS and 70% of the VS mass is biodegradable:

$$\text{BVS mass} = 600 \times 0.9 \times 0.7 = 378 \text{ ton/day}$$

$$\text{BVS mass} = 378 \text{ ton/day} \times 1000 \text{ kg/ton} = 378 \times 10^3 \text{ kg/day}$$

4. Compute the amount of primary sludge required for codigestion of the BOFMSW. Assume the TS of the primary sludge is 7% and codigestion occurs at 28% TS. Compute the amount of sludge needed considering the water already present in the biodegradable matter:

$$\text{Sludge required} = 1170 \text{ ton} = 1.17 \times 10^6 \text{ kg/day}$$

5. Compute the BVS mass in the primary sludge. Assume the VS of the primary sludge is about 70% and the biodegradable fraction of VS is about 60% of VS:

$$\text{BVS mass of primary sludge} = 1.17 \times 10^6 \text{ lb/day} \times 0.07 \times 0.7 \times 0.6 = 34 \times 10^3 \text{ kg/day}$$

6. Compute the total BVS mass produced from the MSW and primary sludge.

$$\text{Total BVS mass} = 378 \times 10^3 + 34 \times 10^3 \text{ kg/day} = 412 \times 10^3 \text{ kg/day}$$

7. Compute the biogas production rate.

Assume biogas production of about 0.86 m<sup>3</sup>/kg BVS/day:

$$\begin{aligned} \text{Total gas production rate} &= (412 \times 10^3 \text{ kg BVS/day}) \times (0.86 \text{ m}^3/\text{kg BVS}) \\ &= 354.32 \times 10^3 \text{ m}^3/\text{day} \end{aligned}$$

8. Compute the energy value of the biogas volume produced.

Assume the thermal energy value of biogas is about 16.23 MJ/m<sup>3</sup>:

$$\text{Thermal energy} = (354.32 \times 10^3 \text{ m}^3/\text{day}) \times (16.23 \text{ MJ/m}^3) = 5.75 \times 10^6 \text{ MJ/day}$$

$$\text{Thermal energy} = (5.75 \times 10^6 \text{ MJ/day}) \times 365 \text{ day/year} = 2.098 \times 10^9 \text{ MJ/year}$$

9. Compute the energy value relative to petroleum.

Assuming thermal energy value of one barrel of oil is about 6.218 × 10<sup>6</sup> MJ:

$$\text{Energy equivalent in barrels of oil} = \frac{(2.098 \times 10^9 \text{ MJ/year})}{(6.218 \times 10^6 \text{ MJ/barrel})} = 337 \text{ barrels of oil/year}$$

#### **48.7.7.4 Example of Volume Reduction of BOFMSW Processed through Codigestion Compared to a Well-Compacted Landfill**

Compute volume reduction of 1000 ton MSW codigested with WWTPS compared to a well-compacted landfill under mixed and unmixed conditions:

*Case 1:* Sludge cake fills the interstices of the compacted MSW in the landfill:

- Input feedstock ratio (wet): 60% sludge to 40% BOFMSW by weight
- Density of compacted MSW = 540 kg/m<sup>3</sup>
- Sludge TS = 5%

*Case 2:* Sludge cake remains unmixed from compacted MSW in landfill:

- Input feedstock ratio (wet): 60% sludge to 40% BOFMSW
- Density of compacted MSW = 540 kg/m<sup>3</sup>

- c. Sludge TS = 5%
- d. Density of sludge cake at 51% solids = 1240 kg/m<sup>3</sup>

**Solution: Case 1 (Mixed)**

1. Compute the amount of sludge required for the anaerobic composting process.  
For every unit volume of BOFMSW (540 kg of MSW) added,  
 $540 \times (60/40) = 810$  kg of sludge at 5% solids is required.
2. Compute the corresponding mass of sludge dewatered to 51% solids.  
Dewatering the sludge to 51% solids would reduce the sludge weight to  
 $810 \text{ kg} \times (51/5) \times 0.01 = 82.6$  kg dewatered cake at 51% solids
3. Compute the combined weight of the MSW and sludge solids.  
Combined weight of MSW and sludge cake =  $540 + 82.6 \text{ kg} = 622.6 \text{ kg}$ .
4. Compute the density of the combined MSW and sludge.  
Assuming no change in MSW volume (1 m<sup>3</sup>), combined density =  $622.6 \text{ kg/m}^3$ .

**Solution: Case 2 (Unmixed)**

1. Compute the amount of sludge required for the anaerobic composting process.  
For every unit volume of BOFMSW (540 kg of MSW) added,  
 $540 \times (60/40) = 810$  kg of sludge at 5% solids is required.
2. Compute the corresponding mass of sludge dewatered to 51% solids.  
Dewatering the sludge to 51% solids would reduce the sludge weight to  
 $810 \text{ kg} \times (51/5) \times 0.01 = 82.6$  kg dewatered cake at 51% solids
3. Compute the combined weight of the MSW and sludge solids.  
Combined weight of MSW and sludge cake =  $540 + 82.6 \text{ kg} = 622.6 \text{ kg}$ .
4. Compute the combined volume of the MSW and sludge:
  - a. Volume of sludge =  $82.62 \text{ kg} / 1240 \text{ kg/m}^3 = 0.07 \text{ m}^3$
  - b. Volume of MSW =  $1 \text{ m}^3$
  - c. Combined volume =  $0.07 + 1.0 \text{ m}^3 = 1.07 \text{ m}^3$
5. Compute the combined density of the MSW and sludge (unmixed).  
Combined density =  $622.6 \text{ kg} / 1.07 \text{ m}^3 = 583 \text{ kg/m}^3$ .

---

## 48.8 Utilization of By-Products of Anaerobic Digestion Process

The principal by-product of an anaerobic composting process is biogas and a stable digestate material with a low biodegradability and high LC. The digestate material can be processed further to produce a high-quality humus material for marketing. The characteristics of biogas and the humus material are presented in this section.

### 48.8.1 Characteristics of Biogas

The gas produced during AD of biodegradable organic material in a healthy fermentation system, called biogas, consists mainly of a mixture of methane ( $\text{CH}_4$ ) and carbon dioxide ( $\text{CO}_2$ ) with small amounts of other gases, including hydrogen sulfide ( $\text{H}_2\text{S}$ ), hydrogen ( $\text{H}_2$ ), nitrogen ( $\text{N}_2$ ), and low-molecular-weight hydrocarbons. Typically, digester gas has 50%–75% methane and 25%–50% carbon dioxide; the remaining gases are present in very small quantities. The composition of biogas, as obtained from various sources, is reported in [Table 48.14](#). As reported in [Table 48.14](#), a large variation exists in the composition of biogas, primarily due to differences in feedstocks and operating conditions.

Because biogas normally consists of a mixture of gases, biogas characteristics must be evaluated for each individual case. However, in many cases, the physical characteristics of the three main gas constituents, namely methane, carbon dioxide, and hydrogen sulfide, can be used to characterize biogas. Some physical and chemical characteristics of the principal gases found in biogas are presented in [Table 48.15](#).

As a comparison, the weight of methane is roughly half that of air at 20°C (weight ratio =  $1 \text{ m}^3$  of methane/ $1 \text{ m}^3$  of air =  $0.716 \text{ kg}/1.293 \text{ kg} = 0.554$ ).

Methane gas is not very soluble in water. Only three units of methane (by volume) can be dissolved in 100 units of water at 20°C and 1 atmosphere pressure. Methane is a very stable hydrocarbon compound, and upon complete combustion, it produces a blue flame and a large amount of heat. The complete combustion of  $1 \text{ m}^3$  of methane can release 38 MJ or about 9500 kcal (1 kcal of heat will raise the temperature of 1 kg of water by 1°C). In comparison, a complete combustion of biogas yields a caloric value of about 20–26 MJ/ $\text{m}^3$  (depending on the methane content), which represents a low fuel value compared with methane gas alone. In addition, biogas requires a pressure of about 34,450 kPa (5,000 lb/in.<sup>2</sup>) to liquefy it for storage. Therefore, biogas requires a larger storage volume for a given amount of energy than other fossil fuels.

### 48.8.2 Utilization of Biogas

To understand the potential use of biogas, it is important to gain a perspective on its energy potential by comparing it with more familiar uses of energy. The following are some examples of the use of  $1 \text{ m}^3$  of biogas, at 60%–70% methane content, for common energy-consuming purposes (see [Table 48.16](#)).<sup>39</sup>

**TABLE 48.14**

Range and Typical Composition of Biogas Produced from BOFMSW

Biogas Component	Percent by Volume	
	Range	Typical <sup>b</sup>
Methane, $\text{CH}_4$	50–75	53.0
Carbon dioxide, $\text{CO}_2$	50–25	45.0
Hydrogen sulfide, $\text{H}_2\text{S}$	0.01–1.5	0.02
Hydrogen, $\text{H}_2$	Trace–3.5 <sup>a</sup>	1.7
Nitrogen, $\text{N}_2$	Trace–8 <sup>a</sup>	Trace
Other hydrocarbon	Trace–0.05	Trace

<sup>a</sup> The hydrogen and nitrogen gas reported in this table are more commonly found in landfill gases.

<sup>b</sup> Typical biogas composition from the biodegradable organic fraction of MSW.

**TABLE 48.15**

Physical Characteristics of Biogas

Characteristics	Unit	Average Value		
		CO <sub>2</sub>	CH <sub>4</sub>	H <sub>2</sub> S
Molecular weight	g	44.1	16.04	34.08
Vapor pressure at 21°C	kP	5719.0		1736.3
Specific volume at 21°C, 101 kP	m <sup>3</sup> /kg	0.456	1.746	0.701
Boiling point at 101 kP	°C	−164.0	−161.61	−59.6
Freezing point at 101 kP	°C	−78.0	−182.5	−82.9
Specific gravity at 15°C (air = 1)		1.53	0.555	1.189
Density at 0°C	kg/m <sup>3</sup>	1.85	0.719	1.539
Critical temperature	°C	31.0	82.1	100.4
Critical pressure	kP	7386.0	4640.68	9007.0
Critical density	kg/m <sup>3</sup>	0.468	0.162	0.349

<sup>a</sup> Reaction is temperature dependent, and the final product will be sulfuric acid (SO<sub>3</sub> + H<sub>2</sub>O → H<sub>2</sub>SO<sub>4</sub>).

**TABLE 48.16**

Equivalent Uses of Biogas

Use	Equivalent Use
Cooking	Can cook 3 meals for a family of 5–6
Lighting	Illumination equaling that of 60–100 W bulb for 6 h
Petroleum	Equivalent to 0.76 kg of petroleum
Car fuel	Can drive a 3 ton truck for 2.8 km
Motor power	Can run a 1 hp motor for 2 h
Electricity	Can generate 1.25 kW of electricity

**TABLE 48.17**

Uses for Biogas Produced from the Biodegradation of the Organic Fraction of MSW

Applications	Comment
Fuel in an IC engines	The most common application of biogas, usually used to generate electricity. Modified engines available from Caterpillar, Cooper-Superior, and Waukesha. Modifications include corrosion resistance and proprietary designing. Specialized lubricating oils are necessary and must be changed more often. Power ratings are usually 5%–15% below natural gas ratings.
Fuel in a gas turbine	Common application of biogas, used to produce electricity. Modifications similar to those for IC engines are necessary. Biogas gas turbines are made by the solar turbine division of Caterpillar. Power rating is 10%–15% lower than for natural gas. Turbines must be checked often for corrosion or deposition. Water vapor should be removed from biogas before use.
Boiler fuel	In moderate use, currently, requires little modification to current equipment. A mixture of biogas and natural gas may be used. Boilers appear to be less sensitive to gas contaminants than IC engines or gas turbines.
Pipeline quality gas	Less common use. CO <sub>2</sub> and all contaminant gases, including water vapor, must be removed before gas will be accepted into a pipeline. Usually not economical unless a large amount of gas is produced and a long-term contract for the sale is available.
Fuel in a steam turbine	Currently in limited use. A large amount of gas is necessary before the system will be economical for the production of electricity. However, modifications are small.
Fuel for space heating	Currently in limited use. Only minor modifications even on a small scale. Hampered only by unavailability of gas. Pipelines are not currently economical so only used at production sites.
Fuel for industrial heating	Currently in limited use. Can be used for lumber drying, kiln operations, and cement manufacturing. May be used in place of or with natural gas, using natural gas equipment.
Fuel for fuel cell	Technology under development. These open fuel batteries can be designed to use biogas, or biogas can be converted to hydrogen in a catalytic pretreatment unit.
Compressed vehicle fuel	Technology under development. Gas must be purified to near pipeline quality.
Convert to methanol	Technology under development. Currently too costly.
Synfuel or chemical feedstock	Technology under development. Liquid fuels and acetic acid production is being investigated.

The potential commercial uses of biogas as a source of energy are summarized in Table 48.17. Some applications listed in Table 48.17 are presently practiced and others are in the process of research and development.

### 48.8.3 Characteristics of Digested Biosolids (Humus Material)

The physical, chemical, and biological characteristics of the humus produced from an anaerobic composting using the sorted biodegradable organic fraction of MSW are presented in this section. The data reported in this section were obtained from the UC Davis pilot demonstration project.<sup>35,36</sup>

The physical characteristics of the humus that are of interest are bulk density, color, moisture content, odor, and particle size distribution. The physical characteristics of the humus are summarized in Table 48.18. The chemical characteristics of the humus that are of interest can be determined by ultimate analysis, metal analysis, fiber analysis, nutrient analysis, energy content, and other tests. The chemical characteristics of the

humus are summarized in [Table 48.19](#). The biological characteristics of the humus that are of interest are the presence and the concentration of pathogenic bacteria, biodegradability, and phytotoxicity. The biological characteristics of the humus are summarized in [Table 48.20](#).

#### 48.8.4 Utilization of Humus Material

Representative applications for the humus produced from AD processes are summarized in [Table 48.21](#). The most effective use of the humus material is as a soil amendment. Alternatively, because the humus is combustible, it appears that it can be fired directly in a boiler, when mixed with other fuels, or palletized for use as a fuel source. The application of the humus as a fuel source has been further studied, and readers are referred to Jenkins et al.<sup>41</sup>

It is important to note that, depending on the final use, further aerobic composting of the digestate may be necessary to produce humus with no phytotoxic affect to be used as a soil amendment. For other applications specified in [Table 48.21](#), no further stabilization may be needed.

### 48.9 Full-Scale Application of Anaerobic Digestion Technologies

In the United States, initial efforts to commercialize AD technology for converting waste into energy and other products have been conducted primarily by livestock enterprises. The barrier to commercialization of anaerobic technology in the United States has been described by Lusk.<sup>21</sup> In addition, the commercial firms interested in the technology, the economics of the process, the statutes that apply, and the future prospects for application

<sup>a</sup> Detection limit is 0–6 organisms/10 mL at 95% confidence level.

<sup>b</sup> BF is computed based on the LC presented in Table 48.19, using Equation 48.1:  $BF = 0.83 - (0.028)LC$ .

<sup>c</sup> Percent seed germinated is computed based on the ratio of seed germinated at each dilution, compared to the control.

**TABLE 48.21**

Uses for Humus Material Produced from Anaerobic Digestate

Applications	Remarks
Use as soil amendment	The humus must be odorless, low in heavy metals, and free of pathogens. In addition, the amount of humus applied to the topsoil may be limited by the phytotoxic characteristics of the humus.
Use as turf for sod production	Similar restrictions apply as specified for use of humus as a soil amendment.
Use as topsoil for erosion control	If humus is to be used for the control of agricultural soil erosion, it must be of similar quality to that specified for soil amendments. For other erosion control applications, specifications may be less restrictive.
Use as topsoil for landfills cover	Moisture content should be greater than about 35% to avoid wind erosion.
Use as marsh restoration	Humus can be used to build up the organic material required for the growth of marsh plants in marsh restoration projects. A higher degree of humus stabilization may be required for this application.
Use as absorbent agent for control of liquid hazardous wastes	Humus may be used as an absorbent to limit movement of hazardous wastes.
Use as fuel or fuel blend in power plants	Major characteristics of concern include moisture content, foreign matter, heating value, and environmental impact on air quality.

in the United States are identified and discussed. In general, the biggest barriers up to now have been financial rather than technical in nature.

Most large-scale AD applications for methane recovery in the United States are related to animal waste and wastewater treatment.<sup>20,21</sup> For instance, two large-scale farm digesters have been in operation in California since 1980.<sup>21</sup> With rising energy costs and examples of successful anaerobic digester operation, more interest has been generated recently in these systems. In the past, a number of studies have been performed in the United States to utilize the AD process for methane gas recovery from solid waste materials.<sup>14,35,42–49</sup>

Unfortunately, none of these projects have commercialized or implemented at full scale. AD technology has been used in full scale in food processing industry and wastewater treatment biosolids stabilization. Wide ranges of anaerobic digester design and operational method employed in municipal, agricultural, food processing, and wastewater treatment plant. Some of the most common reactor design and operating system used for the aforementioned application are described in the following.

#### 48.9.1 MSW

Western Europe has been a leader in developing new solutions. Commercial application of AD for the treatment and energy recovery from the BOFMSW<sup>50</sup> has increased steadily since the 1990s. The summary information in Table 48.22 on the application of different types of technologies is based on available information as of 2008, and hence, the number of current operating digesters is expected to be higher.

As reported in Table 48.22, the overall design capacity of the various technologies can range from as low as 1000 to as high as 270,000 ton/year. It is also worth to note that majority of digesters in Europe are operated as single-phase (93%), mesophilic (67%), and dry or high-solids (62%) condition. Also, while Biotechnische Abfallverwertung (BTA), Dry ANaerobic COMposting (DRANCO), Kompogas, and Valorga are still the dominant treatment systems, numerous new technologies are now available and in operational as compared to 10 years ago. The detailed information about each of the new technology is beyond the scope of this chapter and could be obtained from the respective company's website.

At present in the United States, because of the concern over the disposal of MSW in landfills, interest in reduction of greenhouse gases into atmosphere, and desire on less reliance on foreign oil sparks special interest on the utilization of AD technology as

**TABLE 48.22**

Summary of Commercial Anaerobic Digester Technologies in Operation as of 2008

Technology	Operating Plants	Capacity Range, ton	AD Operating Condition					
			Stage		TS		Temperature	
			SS	MS	Low	High	MF	TF
AAT	8	3,000–55,000	x		x		x

Notes: SS, single stage; MS, multistage; MF, mesophilic; TF, thermophilic.

an alternative sources of energy production. As part of this effort, researchers at UC Davis developed a new three-stage AD technology known as anaerobic-phased solids (APS) digester and tested under pilot operation.<sup>49</sup> This technology along with four of the dominant European AD technologies (BTA, DRANCO, Kompogas, and Valorga) are briefly described as follows.

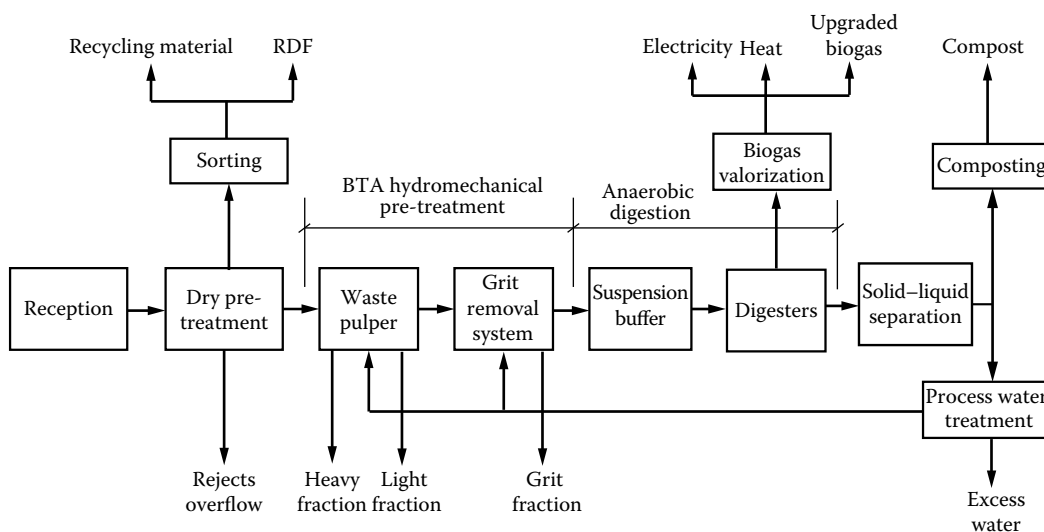

#### 48.9.1.1 BTA System

BTA system was developed in Germany and applied (via several licensing companies) throughout Western Europe and in select locations in Canada and Japan. The BTA system is one of the most successful in terms of the number of existing operational digesters.<sup>52</sup> The majority of the BTA digesters capacity are large (>100,000 MT/year) and usually operated as multistage, low-solids condition.

A schematic of the process flow diagram of the BTA International GmbH system is shown in Figure 48.10. As shown in Figure 48.10, the BTA system involves complete processing, pretreatment, AD, and final composting processes. The hydromechanical pre-treatment prior to AD is a trademark of this system. The pretreated organic fraction is digested within the fermenter, generally under mesophilic conditions between 35°C and 38°C. Digester content are mixed with compressed biogas using gas lances. Since 1991, more than 40 BTA® plants have been designed and constructed worldwide with a total capacity of approximately 1.2 million ton/year. More than 110 million N m<sup>3</sup> biogas are annually produced in BTA Plants, which corresponds to the energy equivalent of approximately 70 million N m<sup>3</sup> natural gas. Additional information on the BTA system can be obtained from the following web address: <http://www.bta-international.de/en/home>.

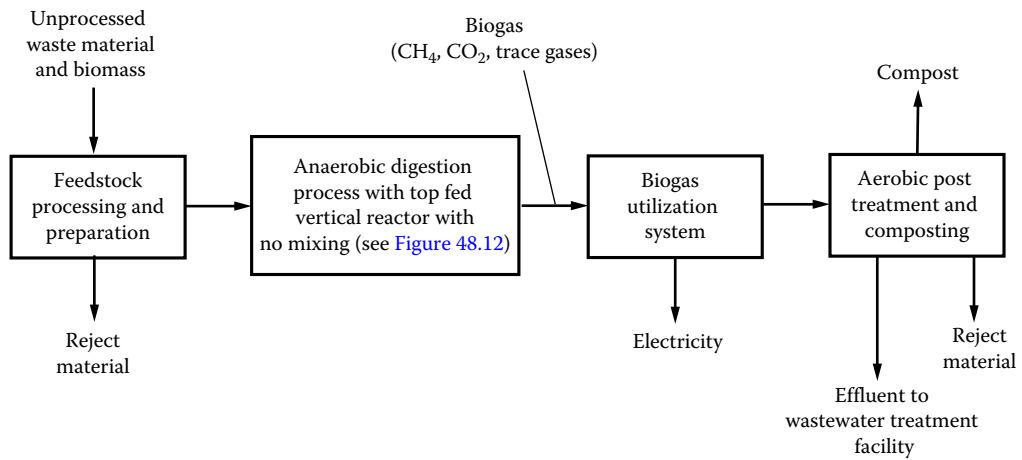

#### 48.9.1.2 DRANCO System

The DRANCO process (see Figure 48.11) was developed in Ghent, Belgium, for the high-solids AD of refuse-derived fuel (RDF). The RDF is prepared by completely sorting

**FIGURE 48.10**

Schematic flow diagram of the BTA process.

**FIGURE 48.11**

Schematic flow diagram of the DRANCO process.

incoming urban solid waste. The DRANCO system<sup>51–53</sup> is capable of removing most metals, glass, plastic, stone, recoverable paper, and other nonbiodegradable items.

The anaerobic treatment takes place in a vertical fermenter (see Figure 48.12) for a period of 12–18 days, followed by a postfermenter for a retention time of 2–3 days. The overall digestion time is, therefore, 14–21 days. The feed is mixed with recycled digester effluent and supernatant and then pumped into the top of the reactor at a solids concentration of 35%–40%.

**FIGURE 48.12**

Schematic of the DRANCO anaerobic reactor.

Solids move downward in the digester in a plug-flow manner, without mechanical mixing. The digester operates under mesophilic (35°C) conditions with a VS reduction of about 55%. The solids are dewatered from about 30% to around 70% solids using a filter press and are dried further and marketed as compost, while the supernatant is used to dilute incoming feed.

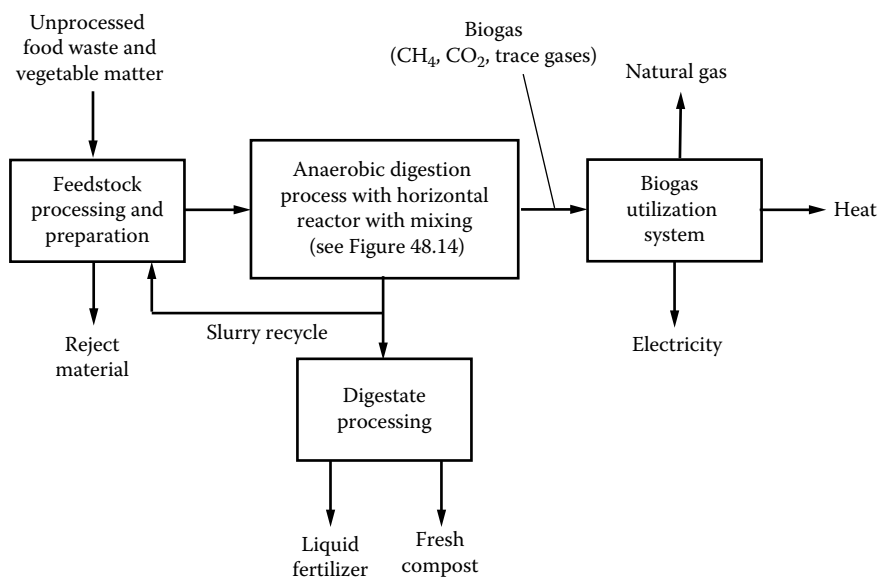

#### 48.9.1.3 Kompogas System

Kompogas technology was developed in Switzerland and is generally composed of four major components (see Figure 48.13): (1) feedstock preparation, (2) digestion process, (3) digestate processing and compost production, and (4) biogas processing and utilization. Most Kompogas plants operate by feedstock processing preparing mixture of easily biodegradable kitchen, food, and industrial wastes combined with wastes from gardens. To prepare the digester feed, a portion of the digestion slurry is mixed with the incoming biodegradable wastes.

The Kompogas digester consists of a horizontal, cylindrical plug-flow reactor that operates under thermophilic temperature and solid content of about 20%. The reactor content is gently mixed along the longitudinal axis. A simplified diagram of Kompogas digester is shown in Figure 48.14. The horizontal design, with an agitation only right angled to the flow direction, guarantees a good plug-flow behavior. The horizontal reactor design seems to be advantageous regarding clogging and sedimentation compared to vertical reactor designs.<sup>54</sup> With a few exceptions, nearly all Kompogas digesters are made out of steel.

#### 48.9.1.4 Valorga System

Valorga, a French company, was the first to use anaerobic technology for the treatment of MSW.<sup>55,56</sup> The complete schematic diagram of Valorga system is shown in Figure 48.15. The Valorga digester is distinguished by its unique design and is operated at a solids concentration of 35% under mesophilic (35°C) conditions with a retention time of 15 days.

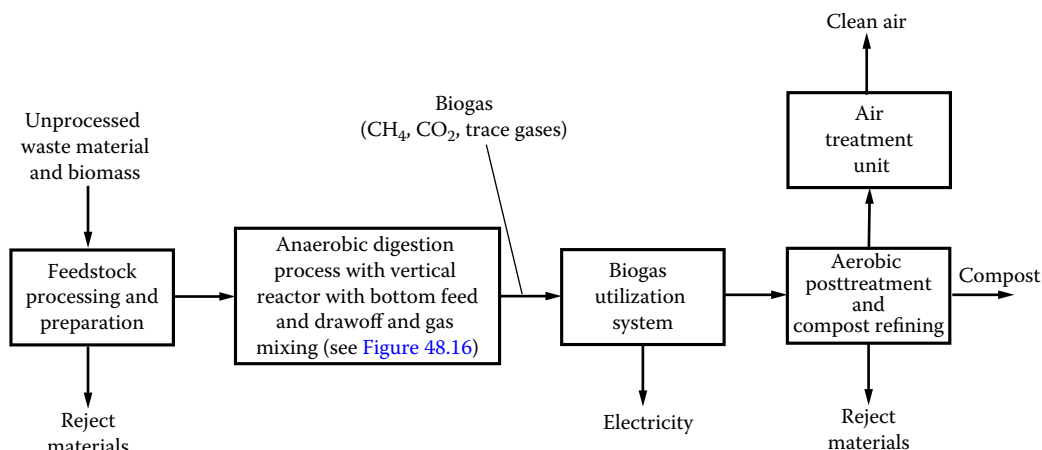

**FIGURE 48.13**

Schematic flow diagram of the Kompogas process.

**FIGURE 48.14**

Schematic of the Kompogas anaerobic reactor.

**FIGURE 48.15**

Schematic flow diagram of the Valorga process.

A typical Valorga reactor capacity is 500 m<sup>3</sup>, and it can treat from 20 to 28 ton of RDF per day. The VS removal rate is around 50%, and the average gas production is about 140 m<sup>3</sup> biogas per ton of feed.

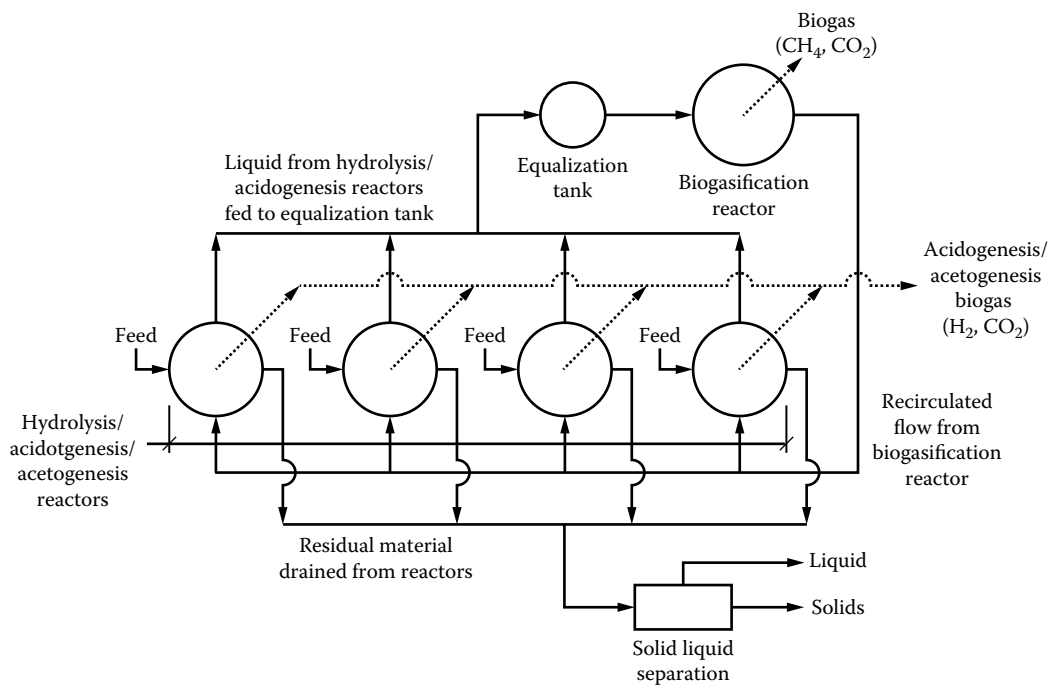

Two unique features of the Valorga process are (1) the loading and (2) mixing mechanisms (see Figure 48.16). A piston pump is used to load feedstock into the system, supplying the digestive system with feed on a continuous basis. A control isolation valve system injects sufficient pressure to transfer the feedstock into the digester; at the same time, a similar quantity of digestate is extracted from the outlet. Mixing takes place through the programmed injection of pressurized biogas into a different section of the system.

#### 48.9.1.5 Anaerobic-Phased Solids System

A schematic of APS digester is shown in Figure 48.17 and pictorially in Figure 48.18. As shown in Figure 48.17, the APS digester uses batch loading to stimulate rapid organic acid production in a two-stage digester system. However, the APS digester system

**FIGURE 48.16**  
Schematic of the Valorga anaerobic reactor.

**FIGURE 48.17**  
Schematic diagram of the APS digester system.

**FIGURE 48.18**

Views of the APS digester system: (a) view of four hydrolysis/acidogenesis reactors, shown in [Figure 48.17](#) (gas cleaning and utilization facilities are shown in the foreground), and (b) view of biogasification reactor.

avoids the problems caused by using leach bed reactors by combining high-solids reactors for the first stage with a low-solids mixed biofilm reactor in the second stage. The high-solids reactors are loaded in phased batches, and the leachate from the batch reactors is continuously circulated through a single low-solids digester. In theory, batch loading simplifies material handling, and because the hydrolysis reactors are high-solids digesters, they can handle relatively large inorganic materials for treatment. Leachate recirculation prevents solids from fouling the wet methanogenesis reactor. Because the batches are phased, the leachate contains a relatively constant concentration of organic acids.

### 48.9.2 Animal Wastes

Two types of AD are used for waste stabilization and energy recovery from animal wastes: (1) belowground systems (ANLs, see [Figure 48.7a](#)) and (2) aboveground systems with various reactor configurations. Typical examples of earthen lined and covered ANLs are shown in [Figure 48.19](#). As noted previously, ANLs are by far the most common anaerobic process in use today. Lined earthen lagoons are favored for animal wastes for small operations because of their simplicity. Aboveground installations are favored for larger installations where the recovered gas can be used for the generation of electricity.

### 48.9.3 High-Strength Industrial Wastes

Increasingly, industries with high-strength wastes have implemented the use of anaerobic treatment to (1) reduce the organic strength of the waste before disposal, (2) reduce the organic strength of the waste for treatment by an aerobic process before disposal, (3) recover products such as (PHA and alginate) that can be used as a raw material in manufacturing (typically biodegradable plastics), and (4) recover the energy contained in the waste stream along with reducing its strength. A representative listing of the industries in which anaerobic technologies are now used routinely is presented in [Table 48.23](#). Several examples of anaerobic treatment processes used for the treatment of high-strength wastes

**FIGURE 48.19**  
Views of covered ANL treatment process: (a) installation used for the treatment of cow manure with energy recovery and (b) installation for the treatment of piggery waste with energy recovery.

are shown in [Figures 48.20](#) and [48.7b](#) and c. Anaerobic processes are favored for the treatment of high-strength wastes because of their relatively small footprint.

**48.9.4 Wastewater Plant Biosolids Application**

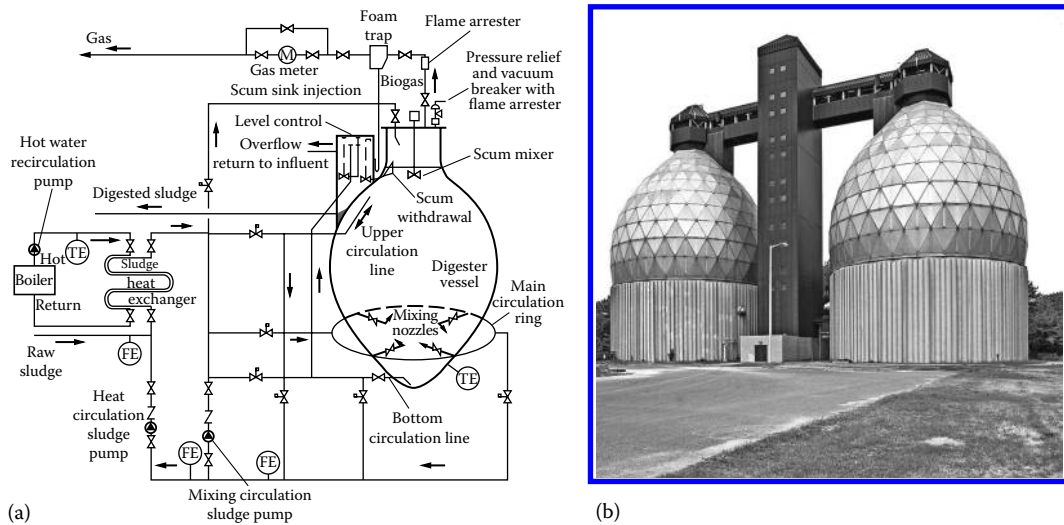

AD are typically used for biosolids stabilization on most large-scale wastewater treatment plant. These digesters are usually operated under mesophilic and low-solids condition. While biogas is produced from all digesters, the recovery of gas for energy or electric power production is not always practiced. In recent years, some of the larger wastewater treatment plant recovers the biogas to offset the energy used for treatment operation. The most common digester system for energy recovery is egg-shaped digester. A schematic and view of a typical egg-shaped digester is shown in [Figure 48.21](#). These digesters are known for their high performance, higher gas production, and lower operation maintenance.

Biomass can be converted into a combination of heat, power, and a variety of fuels via thermal conversion processes. Heat and power are the primary products from direct biomass combustion, but they are often coproducts in other thermal processes. Thermal processes can convert biomass into solid (charcoal, torrefied biomass), gas (biogas, synthetic gas), and liquid (ethanol, biodiesel, gasoline) products. Modern biorefineries convert biomass into a combination of these energy products and chemicals. The contents of this section can be grouped into two main topics: (1) an overview of the energy efficiency of biomass conversion systems and (2) descriptions of common industrial biomass conversion technologies.

### 49.1 Biomass Energy Systems

Biomass conversion processes involve a large number of complex thermodynamic phenomena occurring through multiple system units or steps. Each step may involve mass or heat transfer and chemical reactions. The overall system's efficiency will depend on its ability to recover heat and/or maximize the output of desired products.

The first law of thermodynamics provides a framework for evaluating changes in energy within a system in relation to heat and work transfer across the system's boundary.

**TABLE 49.1**

Facility Efficiency and Capacity Comparison of Biomass Conversion Systems

Technologies	Efficiency (%)	Typical Size
Combined heat and power (CHP) [1]	LHV	MWe Output
Co-firing	35–40	10–50
Dedicated steam cycles	30–35	5–25
IGCC	30–40	10–30
Gasific + engine CHP	25–30	0.2–1
Stirling engine CHP	11–20	<0.1
Solid fuels	LHV	MW <sub>th</sub> Input
Torrefaction [2]	96	<25
Slow pyrolysis [3]	72	<25
Carbonization [3]	65	<50
Liquid fuels		
Corn ethanol [4]	50	400
Cellulosic ethanol [5]	45	400
Fast pyrolysis gasoline [5]	54	<400
Gasification Fischer–Tropsch [5]	53	>400

It requires that the net heat transfer into a system be equal to the work done by the system plus the change in energy within the system. A thermodynamic system is a region in space delineated for analysis. The first law of thermodynamics requires that the energy change of macroscopically identifiable forms of energy be accounted for as heat and/or work transfer, and changes in internal, kinetic, or gravitational energy.

Biomass energy systems range from portions of a single equipment to multiple units or facilities in which biomass is transformed to heat, power, or other energy forms. A majority of biomass facilities focus on the production of one or two products (typically heat and power). However, some facilities produce a wide range of products, including heat, power, chemicals, and fuels. These systems can be compared based on their efficiency once an energy balance is established. The energy efficiency ( $\eta$ ) for a system is defined as

$$\eta = \frac{E_{out}}{E_{in}} = \frac{(\text{Fuel} + \text{Steam} + \text{Power})}{(\text{Biomass} + \text{Fuel})} \quad (49.1)$$

where

the energy inputs consist typically of biomass and heat or electricity from fossil fuels, nuclear, solar, wind, geothermal energy, and others

the energy output includes any combination of recovered heat, electricity, and fuels

Table 49.1 shows representative efficiency values for different biomass conversion systems.

## 49.2 Biomass to Heat and Power

There are numerous routes to convert the chemical energy in biomass into heat or electric power. Direct combustion releases heat that can be used in Stirling engines or Rankine steam power cycles. Alternatively, thermal treatment with low-oxygen concentrations

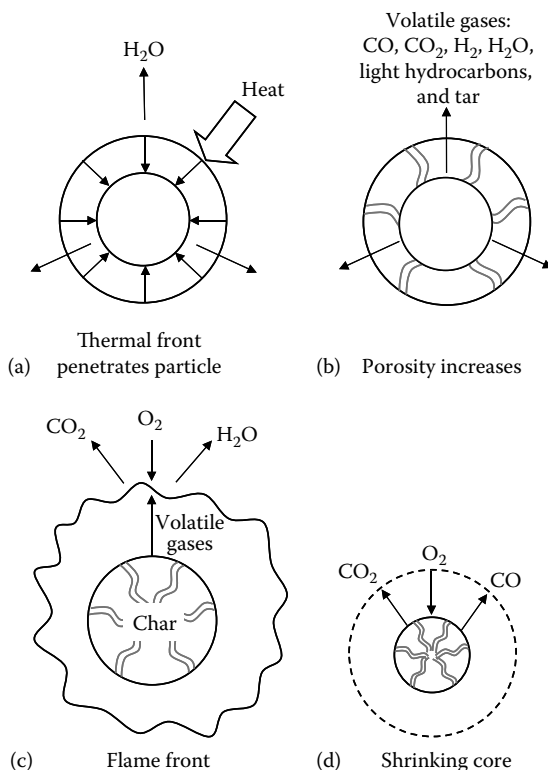

yields intermediate materials with varying energy properties. Carbonization and slow pyrolysis produce a charcoal material with high-carbon concentration. Biomass gasification results in a combustible gas. Fast pyrolysis generates mostly a liquid fuel. Each of these processes will be discussed in further detail later. This section will discuss direct combustion and co-firing for heat and power production.

#### 49.2.1 Direct Combustion

Combustion converts chemical energy directly into heat via rapid oxidation of the fuel. Primary products from combustion of carbonaceous products include carbon dioxide ( $\text{CO}_2$ ) and water. Secondary products result from incomplete combustion or reactions with fuel-bound nitrogen ( $\text{N}_2$ ), sulfur, and other impurities. Combustion conditions vary depending on the heating value and moisture content of the fuel, the amount of air used to burn the fuel, and heat losses from the furnace. Flame temperatures can exceed  $1600^\circ\text{C}$ .

Solid fuel combustion takes place in four steps (see Figure 49.1): heating and drying, pyrolysis, flaming combustion, and char combustion [6]. Chemical reactions do not occur during heating and drying. During heating and drying, a thermal front drives advances into the interior of the particle while driving water away. The particle temperature will not rise high enough for pyrolysis until most of the water has been released.

Pyrolysis, the second step during combustion, is a complex series of thermally driven chemical reactions. Pyrolysis decomposes organic compounds in the fuel [7]. It proceeds

**FIGURE 49.1**

Processes of solid fuel combustion: (a) heating and drying, (b) pyrolysis, (c) flaming combustion, and (d) char combustion.

at low temperatures depending on the plant material. Hemicellulose pyrolyzes at temperatures between 150°C and 300°C, cellulose at 275°C–350°C, and lignin pyrolysis initiates at 250°C–500°C.

Pyrolysis produces a wide range of volatile compounds with types and quantities dependent on the fuel and heating rate. The products include carbon monoxide (CO), CO<sub>2</sub>, methane (CH<sub>4</sub>), and high-molecular-weight compounds that condense to a tarry liquid if cooled before they are able to burn. These condensable compounds may form fine droplets, which constitute much of the smoke associated with smoldering fires. The pyrolysis thermal front leaves behind pores that penetrate from the surface to the core of the particle.

Both volatile gases and the resulting pyrolysis char can be oxidized if sufficient oxygen is available. Volatile gas oxidation above the solid fuel results in flaming combustion. The ultimate products of volatile combustion are CO<sub>2</sub> and H<sub>2</sub>O, although a variety of intermediate chemical compounds can exist in the flame including CO, condensable organic materials, and long chains of carbon known as soot. In fact, hot, glowing soot is responsible for the familiar orange color of wood fires.

The combustion flame will consume all intermediate compounds given sufficient temperature, turbulence, and time. High combustion temperatures assure that chemical reactions proceed at high rates. Turbulent or vigorous mixing of air with fuel allows all fuel molecules to come into contact with oxygen molecules. Long residence times are needed for the fuel to be completely consumed. Lack of good combustion conditions results in a variety of noxious organic compounds, including CO, soot, polycyclic aromatic hydrocarbons (PAH), and the particularly toxic families of chlorinated hydrocarbons known as furans and dioxins. Both CO and CO<sub>2</sub> may form on or near the surface of burning char (see Equation 49.2 [6]):

CO will completely oxidize if there is sufficient oxygen and residence in the immediate vicinity of the char particle; otherwise, it will appear in the flue gas as a pollutant.

The third step in solid fuel combustion involves char solid–gas reactions also known as glowing combustion, and they are responsible for the familiar red-hot embers in a fire. Char consists mostly of carbon with small quantities of mineral matter. Char oxidation occurs when there is mass transfer of oxygen to the char surface rather than by chemical kinetics. Oxygen mass transfer is very fast at the elevated combustion temperatures. Oxygen may react with char at the surface or penetrate through pores depending on the particle porosity, reactivity, and combustion temperature. Surface oxidation results in a shrinking core, whereas pore oxidation yields a constant diameter particle with increasing porosity.

#### 49.2.1.1 Combustion Equipment

Combustors convert fuel chemical energy into heat embedded in high-temperature exhaust gases. This heat can be utilized in a variety of applications, including space heating, drying, and power generation. However, with the exception of kilns used by the cement industry, most solid–fuel combustors today are designed to produce either low-pressure steam for process heat or high-pressure steam for power generation. Combustors designed to raise steam are known as boilers. Some boiler designs include distinct sections for combustion,

**FIGURE 49.2**

Common types of combustors: (a) grate-fired, (b) suspension, and (c) fluidized.

and high- and low-temperature heat transfer; these sections are called furnace, radiative, and convective segments, respectively. Other designs may not include clear, distinct separations between the processes of combustion and heat transfer.

Solid-fuel combustors can be categorized as grate-fired systems, suspension burners, or fluidized beds [8], as shown in Figure 49.2. The first burner systems developed were grate-fired, which evolved during the late nineteenth and early twentieth century into a variety of automated systems. The spreader-stoker is the most common system, and it consists of a fuel feeder that mechanically or pneumatically flings fuel onto a moving grate where the fuel burns. Most of the ash falls off the end of the moving grate, but some fly ash can appear in the flue gas. Combustion efficiencies for grate systems rarely exceed 90%.

Suspension burners employ a stream of rising air to suspend the fuel as fine powder. The fuel burns in a fireball and radiates heat to tubes that contain water to be converted into steam. Suspension burners are also known as pulverized coal (PC) boilers, and they have dominated the U.S. power industry since World War II. They achieve high volumetric heat release rates and combustion efficiencies of more than 99%. However, they are not designed to burn coarse particles and are notorious generators of nitrogen oxides. Feeding employs pulverizers designed to reduce the particle size enough to burn in suspension. The fuel particles remain suspended in the primary airflow prior to feeding to the burner section through ports where it burns as a rising fireball. A secondary air stream helps complete the combustion process. Steam tubes arrayed in banks of heat exchangers (waterwall, superheaters, and economizer) absorb the combustion gas heat before the gas exits through a bag house. Bag houses are designed to capture suspended ash.

Fluidized bed combustors are a relatively recent innovation in boiler design. They operate by injecting air into the bottom of the boiler to suspend a bed of sand or other granular, refractory material. The suspension produces a turbulent mixture of air and sand. This environment achieves high heat and mass transfer rates and is suitable for burning a wide

range of fuel types. The unit can be operated as low as 850°C due to the large thermal mass of the sand bed. The low temperature helps reduce the formation of N<sub>2</sub> compounds. A commercial market for fluidized bed boilers developed during the 1980s.

### **49.2.2 Co-Firing**

Biomass co-firing is the notion of supplementing a primary fuel, often coal, with biomass [9]. Coal burners are often designed to operate with specifications that can only tolerate small quantities (less than 20%) of biomass because of its combustion behavior. Co-firing is commonly employed to take advantage of economic or environmental benefits. For example, lumber mills or pulp and paper companies can use co-firing as an alternative to landfilling waste. Governmental environmental constraints can also drive the use of co-firing in existing boilers.

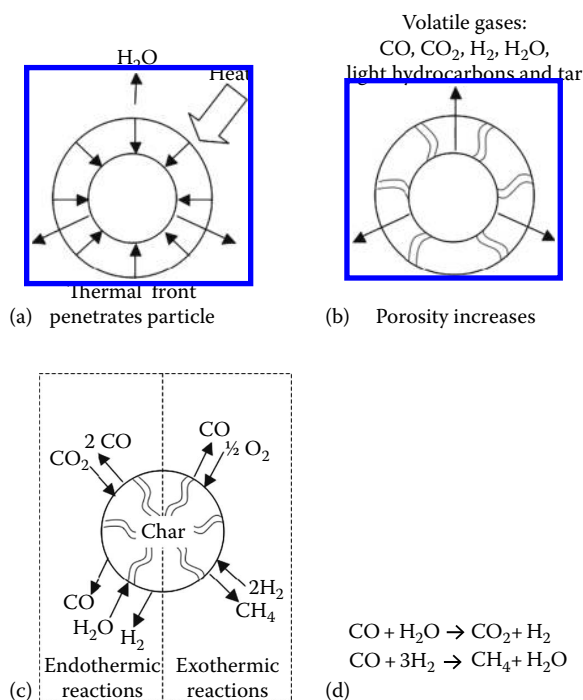

Wood-fired power plants have capacities of 20–100 MW and heat rates of about 12,500 Btu/kW h. Coal-fired power plants by comparison are much larger and have improved heating rates of 10,250 Btu/kW h or lower. The lower heating rate and limited capacity of wood-fired power plants could ultimately limit the use of direct combustion to convert biomass into power.

### **49.2.3 Gasification**

Gasification is a thermal process characterized by an oxygen-deficient environment and temperatures above 750°C. In this environment, most carbonaceous material converts into a flammable gas consisting of CO, hydrogen (H<sub>2</sub>), CH<sub>4</sub>, CO<sub>2</sub>, and smaller quantities of heavier hydrocarbons. Gasification may take place with either air or pure oxygen input. Air gasification yields gas with high N<sub>2</sub> content commonly known as producer gas; gas from oxygen gasification is known as synthetic gas or syngas. Steam may also be introduced into the gasification environment as an oxygen carrier. Gasification requires heat input that is delivered either internally from partial combustion of the feed input or via external heaters. Gasification performance depends on the ability to introduce oxygen and heat into its environment. Residual material from biomass gasification includes unconverted carbon (char) and ash.

The gasification process involves four primary steps [10]: heating and drying, pyrolysis, gas–solid reactions, and gas–phase reactions. These steps are illustrated in [Figure 49.3](#). As in combustion, heating and drying evaporates all feed moisture before the particle temperature increases to gasification temperatures. Pyrolysis occurs once the thermal front penetrates the particle, resulting in the release of volatile gases via pores of increasing number and size. The volatile gases include all gasification final products as well as tar. Tar consists of heavy and extremely viscous hydrocarbon compounds. After the pyrolysis step, these gases react with the particle surface, which is now primarily char, in a series of gas–solid endothermic and exothermic reactions that increase the yield of light gases. Finally, released gases continue to react in the gas–phase until they reach equilibrium conditions.

The heating and drying, and pyrolysis steps during gasification are similar to those of combustion. However, in the case of gasification, pyrolysis yields a larger quantity of tarry material because of insufficient oxygen and/or temperature to decompose the heavier compounds. Much of this tar elutriates from the particle and accumulates upon condensation. Where gasification differs from combustion is in the gas–solid and gas–phase reactions.

**FIGURE 49.3**

Thermal gasification process steps: (a) heating and drying, (b) pyrolysis, (c) gas–solid reactions, and (d) gas–phase reactions.

Gas–solid reactions include carbon–oxygen, Boudouard, carbon–water, and hydrogenation reactions shown in Equations 49.3. The carbon–oxygen reaction is highly exothermic and key to driving the Boudouard and carbon–water reactions, which are endothermic. The carbon–oxygen and Boudouard reactions yield CO, whereas the carbon–water reaction yields  $\text{H}_2$  and CO. This  $\text{H}_2$  goes on to react exothermically with C to yield  $\text{CH}_4$ . The amount of  $\text{H}_2$  involved in gas–solid reactions is relatively small:

Chemical equilibrium calculations predict that almost all carbon should react and form gas compounds. Practical systems typically achieve greater than 90% carbon conversion. Industrial engineers devote significant efforts to increase the carbon conversion by optimizing material treatment, equipment design, and operation parameters. In general, smaller particle sizes, longer residence times, and higher temperatures will increase carbon conversion. However, there are practical limitations that prevent the attainment of near-equilibrium conversions.

Gas-phase reactions consist of the exothermic water gas shift (WGS) and methanation reactions (see Equations 49.4). These reactions are significant because they determine the ultimate  $\text{H}_2$ :CO ratio in the gas. The  $\text{H}_2$ :CO ratio is an important parameter in synthetic fuel applications. WGS tends to increase the  $\text{H}_2$  gas concentration, which is desirable for fuel synthesis, and the methanation reaction increases  $\text{CH}_4$ , which is important for combustion applications. Both reactions are favored by low temperatures despite slower reaction rates at lower temperatures. Thus, the common strategy to shift yields toward the products is to introduce steam or increase the partial pressure of  $\text{H}_2$  depending on whether more  $\text{H}_2$  or  $\text{CH}_4$  is desired, respectively.

#### 49.2.3.1 Gasification Equipment

Gasification equipment can be classified based on the choice of oxygen input and heat delivery method. Gasifiers can be air-blown, or oxygen-blown with and without steam. They can be heated directly or indirectly. Direct heating air-blown gasifiers dilute syngas with  $\text{N}_2$ , resulting in a low calorific value of 5–6 MJ per standard cubic meter. Avoiding  $\text{N}_2$ -dilution with pure oxygen feed increases the calorific value to between 13 and 14 MJ/m<sup>3</sup>. Direct heating increases  $\text{CO}_2$  concentration, which has a similar energy dilution effect as  $\text{N}_2$ . Indirect heating gasifiers achieve the highest syngas calorific energy value with as much as 20 MJ/m<sup>3</sup> [11].

Direct heating air-blown gasifiers present the simplest and lowest cost option. These characteristics have made them attractive for commercial applications. However, the excess  $\text{N}_2$  concentration increases the size of downstream equipment and results in energy penalties for heating applications. Despite these challenges, producer gas from air-blown gasifiers have been employed in furnaces, boilers, and engines.  $\text{N}_2$  can also be problematic for synthetic fuel applications because in the best of cases it simply increases vessel sizes, and in some applications participates negatively in chemical reactions.

Oxygen-blown gasifiers have a smaller footprint but at the significant cost of requiring an oxygen separation unit. They generate a high-quality syngas for heat or fuel synthesis applications. Downstream equipment are also much smaller due to the  $\text{N}_2$  avoided. Another advantage is that oxygen-blown gasifiers can be very efficient with carbon conversion rates of 95% and higher. They can achieve temperatures of up to 1800°C. At these temperatures, syngas composition approaches equilibrium and contains limited quantities of tar, char, and light hydrocarbons [12]. These temperatures are above the ash melting temperature, resulting in a layer of hot, liquid ash called slag that collects on the reactor surface. Slag properties are critical for proper operation of high-temperature gasifiers. They can substitute for refractory material by regulating heat transfer between the reaction chamber and external walls. For this reason, the slag layer has to be maintained within a tight thickness tolerance. Excess slag flows to the bottom of the reactor where it is collected.

Indirect heating gasifiers provide reaction heat from external sources and can avoid the use of air or oxygen. Without oxygen addition, gasification products include higher concentrations of primary volatile compounds, char, and tar. These products can continue to react in the gas phase depending on the residence time and operating conditions. In principle, indirect heating gasifiers can operate at temperatures of up to 1500°C. However, most of these systems operate between 600°C and 850°C due to heat transfer limitations. These

**FIGURE 49.4**

Common types of biomass gasifiers: (a) updraft, (b) downdraft, (c) fluidized bed, and (d) entrained flow.

gasifiers produce syngas with low  $N_2$  and  $CO_2$  concentrations than air- or oxygen-blown gasifiers but yield moderate quantities of tar and dust.

An alternative classification for gasifier designs is based on the contact method between the oxidizing agent and the feedstock input. By this classification, there are four main types of gasifiers: updraft (countercurrent), downdraft (concurrent), fluidized bed, and entrained flow [13]. Figure 49.4 illustrates these different designs.

The simplest and earliest design is the updraft gasifier, which evolved from charcoal kilns and blast furnaces. Updraft gasifiers resemble grate furnaces with chipped fuel admitted from above and below stoichiometric air input from below. Reaction temperatures close to the grate are very high and combustion processes dominate. At this location, oxygen gets depleted rapidly but hot  $H_2O$  and  $CO_2$  reduce char to  $H_2$  and  $CO$ . The fuel cools down as it moves toward the grate, but temperatures remain high enough to heat, dry, and pyrolyze the fuel. Updraft gasifiers yield high quantities of tar ( $50 \text{ g/m}^3$ ), making them unsuitable for many biomass energy applications.

Downdraft gasifiers were introduced in the nineteenth century following the introduction of induced draft fans capable of drawing air downward along with fuel. Contemporary designs introduced an arrangement of tuyeres to admit air or oxygen directly into a region known as the throat where combustion forms a bed of hot char. With this design, pyrolysis volatiles are forced through the bed of hot char, thereby increasing gas–solid reactions. These reactions increase tar cracking making a producer gas have with low tar concentrations less than  $1 \text{ g/m}^3$ . These low tar concentrations make producer gas suitable for engine fuel. Strict requirements of particle size, ash, and moisture content make operation difficult. Slagging and ash sintering in the concentrated oxidation zone present another disadvantage. Mechanical and design measures can alleviate these problems such as the use of rotating ash grates. Downdraft gasifier capacities are limited to a maximum size of about  $400 \text{ kg/h}$ .

Fluidized bed gasifiers operate by introducing a gas stream flowing upward through a bed of inert particulate material to form a turbulent mixture of gas and solid. The bed material constitutes a well-mixed environment that approaches a theoretical continuously stirred tank reactor (CSTR). Thus, the temperature is uniformly kept at 700°C–850°C throughout the bed, although hot spots may form if improper mixing occurs. This design does not provide distinct regions for the various gasification steps. Feedstock is introduced into this environment at rates that maintain a low fuel to inert weight ratio. Since fuel is injected in the base of the bed, much of the tar can be cracked within the fluidized bed. However, a key portion of fluidized bed gasifiers is the free-board. The freeboard is a large insulated space above the bed where further tar cracking, gas-phase, and some gas-solid reactions can take place. Fluidized bed gasifiers achieve intermediate tar levels of about 10 g/m<sup>3</sup>. Fluidized bed gasifiers can convert a wide range of feedstock with few material property requirements. They can scale to large size, making them suitable for both fuel synthesis and electric power applications. Disadvantages include high power consumption to move gas through the bed; high exit gas temperatures; and relatively high particulate burdens in the gas due to the abrasive forces acting within the bed.

The entrained flow reactor is the fourth gasifier design. This reactor was developed for steam-oxygen gasification of PC at temperatures above 1200°C. They can achieve carbon conversion rates that approach 100%, produce trace tar quantities, and convert ash to molten slag. These properties make it attractive for both fuel synthesis and power generation applications. They can operate over a wide range of pressures, which allows them to be built at relatively smaller sizes. The key challenges for entrained flow gasifiers, particularly related to biomass applications, are requirements for small particle sizes, high operating temperatures, and low alkali levels. It is expensive to pulverize biomass, and biomass moisture and alkali content are comparably high for most feedstock. Pretreatment methods including torrefaction and pyrolysis can overcome many of these challenges [2].

There are many potential permutations of gasifier design and operation parameters. Furthermore, each gasifier design can be operated with various combinations of air/oxygen and steam input, resulting in different product compositions. Keeping this in mind, Table 49.2 shows typical composition, energy content, and quality of gas from the various gasifiers discussed previously.

**TABLE 49.2**

Producer Gas Composition from Various Kinds of Gasifiers

Gasifier Type	Gaseous Constituents (vol.% Dry)						Gas Quality	
	H <sub>2</sub>	CO	CO <sub>2</sub>	CH <sub>4</sub>	N <sub>2</sub>	HHV (MJ/m <sup>3</sup> )	Tars	Dust
Air-blown updraft	11	24	9	3	53	5.5	High (≈10 g/m <sup>3</sup> )	Low
Air-blown downdraft	17	21	13	1	48	5.7	Low (≈1 g/m <sup>3</sup> )	Medium
Air-blown fluidized bed	9	14	20	7	50	5.4	Medium (≈10 g/m <sup>3</sup> )	High
Oxygen-blown downdraft	32	48	15	2	3	10.4	Low (≈1 g/m <sup>3</sup> )	Low
Indirectly-heated fluidized bed	31	48	0	21	0	17.4	Medium (≈10 g/m <sup>3</sup> )	High

#### 49.2.4 Heat and Power Cycles

Biomass combustion processes can be combined with a variety of steam and power cycles to generate electricity. These include the classical Stirling, Rankine, and Brayton cycles, as well as fuel cells and combined cycles. A majority of U.S. power generation comes from conventional steam turbines with growing contributions from gas turbines (see Figure 49.5). Many of these systems could utilize biomass by simply co-firing or combining with the cycles described in this section.

##### 49.2.4.1 Stirling Cycle

The Stirling cycle employs heat from an external combustion engine to raise the temperature of an internal fluid undergoing a thermodynamic cycle [14]. The internal fluid never comes in contact with the combustion fuel, which lowers maintenance costs and pollution emissions. This arrangement also increases the tolerance to contaminants, which makes this cycle attractive for use with “dirty” fuels.

The Stirling cycle is similar to the Rankine cycle in its use of an external combustion process. In theory, Stirling cycles offer a higher thermodynamic efficiency than Rankine cycles. In practice, Stirling engines achieve relatively modest efficiencies and net power output of a few kilowatts. Their major obstacle might be high costs, which have so far prevented significant market entry.

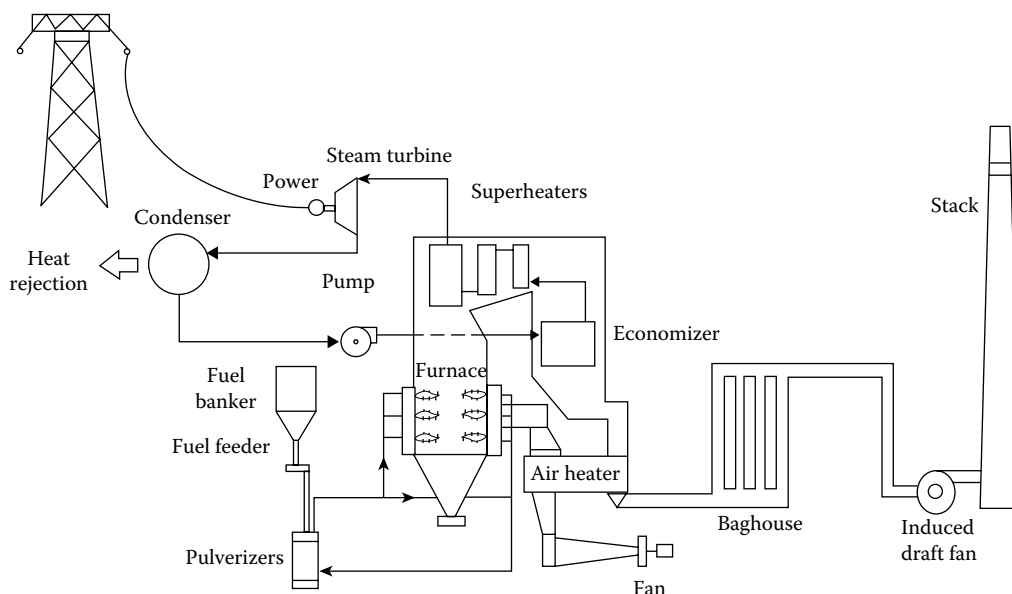

##### 49.2.4.2 Rankine Cycle

The Rankine cycle resembles the Stirling cycle in its use of an external combustion engine [15]. Figure 49.6 illustrates the major units found in a Rankine cycle. Fuel is fed from a bunker and pulverized before combustion in the furnace. Superheaters raise steam from

**FIGURE 49.5**

U.S. electric power generation capacity by generator/cycle type. (From Anon., Biomass for power generation and CHP, 2007.)

**FIGURE 49.6**  
Rankine steam power plant.

the hot gas exiting the furnace. Low-temperature heat is recovered in the economizer before gas cleaning through baghouses and rejection through the stack. The Rankine cycle depicted uses steam to operate a steam turbine, which drives a generator to produce electric power.

The Rankine steam power cycle has been the foundation of stationary power generation for over a century. Although Brayton cycles employing gas turbines and electrochemical cycles based on fuel cells will constitute much of the growth in power generation in the future, steam power plants will continue to supply the majority of electric power for decades to come. Steam power plants will find new applications in combination with advanced generation technologies. The reason for the Rankine cycle's preeminence has been its ability to directly fire coal and other inexpensive solid fuels. Constructed at scales of several hundred megawatts, the modern steam power plant can convert as much as 45% of chemical energy in fuel to electricity at a cost of \$0.02–\$0.05/kilowatt.

Utility-scale steam power plants are not expected to dominate future growth in electric power infrastructure in the United States. These giant plants take several years to plan and construct, which decreases their financial attractiveness in increasingly deregulated power markets. Coal and other fossil fuels burned in these plants are the major sources of air pollution, including sulfur and nitrogen oxides, both of which are precursors to acid rain and the latter an important factor in smog formation; fine particulate matter, which is implicated in respiratory disease in urban areas; and heavy metals, the most prominent being mercury, which accumulates in the biosphere to toxic levels. Substitution of bio-renewable resources such as wood and agricultural residues for coal in existing power plants could substantially reduce pollution emissions, although these plants are so large that the locally available biomass resources could supplant only a small fraction of the total energy requirement. Small-scale steam power plants sized for use of local biomass resources have low thermodynamic efficiencies, on the order of 25%, making them wasteful of energy resources.

#### 49.2.4.3 Brayton Cycle

The Brayton cycle produces electric power by expanding hot gas through a turbine [16]. These gas turbines operate at temperatures approaching 1300°C compared to inlet temperatures of less than 650°C for steam turbines used in Rankine cycles. Although this difference in inlet temperature would suggest that Brayton cycles have much higher thermodynamic efficiencies than Rankine cycles, the Brayton cycle also has a much higher exhaust temperature than does the Rankine cycle. Gas turbine exhaust temperatures are in the range of 400°C–600°C, whereas steam turbine exhaust temperatures are on the order of 20°C. Furthermore, Brayton cycles, which contain both gas compressor and gas turbine, have more sources of mechanical irreversibilities, further degrading thermodynamic efficiencies, which may only be marginally higher than the best Rankine steam cycles. However, improvements in gas turbine technology that allow operation at higher temperatures and pressures are expected to increase Rankine cycle efficiency for large power plants to greater than 50%, although 30% is more realistic for gas turbines sized appropriately for biomass power plants.

The two general classes of gas turbines for power generation are heavy-duty industrial turbines and lightweight aeroderivative gas turbines. The aeroderivatives are gas turbines originally developed for commercial aviation but adapted for stationary electric power generation. They are attractive for bioenergy applications because of their high efficiency and low unit capital costs at the modest scales required for biomass fuels.

Gas turbines are well suited to gaseous and liquid fuels that are relatively free of contaminants that rapidly erode or corrode turbine blades. In this respect, gas turbine engines are not suitable for directly firing most biomass fuels. Solid biomass releases significant quantities of alkali metals, chlorine, mineral matter, and lesser amounts of sulfur upon burning. These would be entrained in the gas flow entering the expansion turbine where they would quickly contribute to blade failure. Cleaning large quantities of hot flue gas is not generally considered an economical proposition. Even the gas released from anaerobic digestion contains too much hydrogen sulfide ( $H_2S$ ) to be directly burned in a gas turbine without first chemically scrubbing the gas to remove this corrosive agent.

Nevertheless, gas turbine engines are considered one of the most promising technologies for bioenergy because of the relative ease of plant construction, cost-effectiveness in a wide range of sizes (from tens of kilowatts to hundreds of megawatts), and the potential for very high thermodynamic efficiencies when employed in advanced cycles. The key to their success in bioenergy applications is converting the biomass to clean-burning gas or liquid before burning it in the gas turbine combustor.

#### 49.2.4.4 Fuel Cells

Among the most exciting new energy technologies are fuel cells, which directly convert chemical energy into work, thus bypassing the restriction on efficiency imposed by the Carnot relationship [17]. This does not imply that fuel cells can convert 100% of chemical enthalpy of a fuel into work, as the process still must conform to the laws of thermodynamics. In practice, irreversibilities limit their conversion efficiencies to 35%–60%, depending upon the fuel cell design. Thus, fuel cells can produce significantly more work from a given amount of fuel than can heat engines. However, carbonaceous fuels must first be reformed to  $H_2$  before they are suitable for use in fuel cells. The energy losses associated with fuel reforming must be included when determining the overall fuel-to-electricity conversion efficiency of a fuel cell.

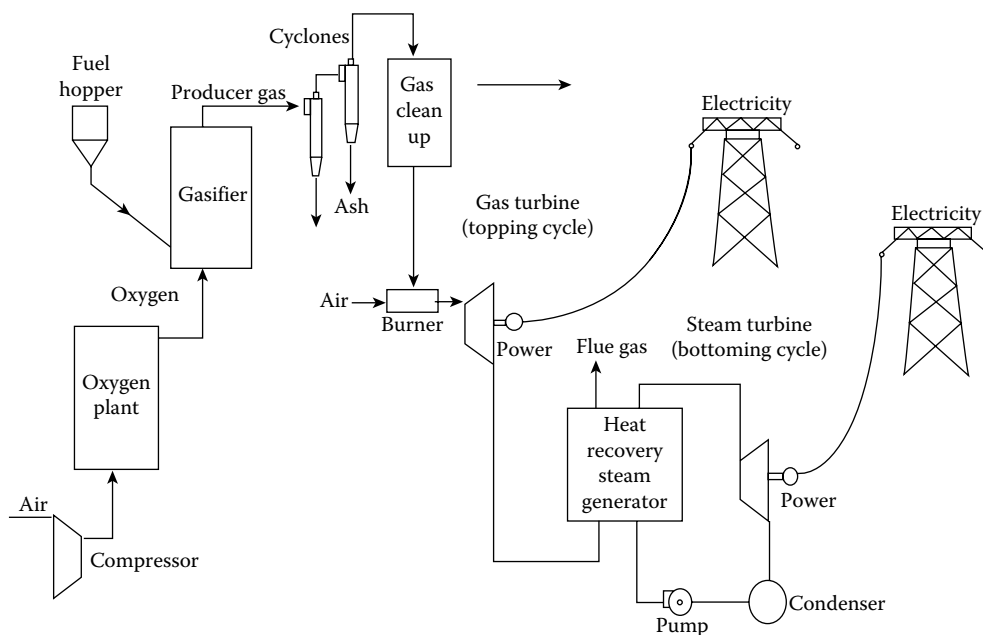

The gas mixture produced by a biomass gasifier contains dust and tar that must be removed or greatly reduced for most applications, including power generation in fuel cells. Removal of tar would ideally be performed at elevated temperatures. If the gas is to be

used in fuel cells, further cleaning is required to remove ammonia ( $\text{NH}_3$ ), hydrogen chloride ( $\text{HCl}$ ), and  $\text{H}_2\text{S}$  [18]. To obtain high-energy efficiency, trace contaminant removal must be performed at elevated temperatures for fuel cells that operate at relatively high temperatures. Low-temperature fuel cells cannot tolerate  $\text{CO}$ , which can be removed by the WGS reaction. The catalysts that facilitate the shift reaction, however, are poisoned by trace contaminants, which must be removed prior to the shift reactors. One method for removing  $\text{H}_2\text{S}$  and  $\text{HCl}$  is the use of a fixed bed of calcined dolomite or limestone and zinc titanate at temperatures around  $630^\circ\text{C}$ . This is followed by steam reforming at high temperature ( $750^\circ\text{C}$ – $850^\circ\text{C}$ ) to destroy tar and  $\text{NH}_3$  [19].

#### 49.2.4.5 Combined Cycles

In an effort to enhance energy conversion efficiency, combined cycle power systems have been developed, which recognize that waste heat from one power cycle can be used to drive a second power cycle [20]. Combined cycles would be unnecessary if a single heat engine could be built to operate between the temperature extremes of burning fuel and the ambient environment. However, temperature and pressure limitations on materials of construction have prevented this realization. Combined cycles employ a topping cycle operating at high temperatures and a bottoming cycle operating on the rejected heat from the topping cycle. Most commonly, combined cycle power plants employ a gas turbine engine for the topping cycle and a steam turbine plant for the bottoming cycle, achieving overall efficiencies of 60% or higher.

Clean-burning fuel from biomass for use in a combined cycle can be obtained by thermal gasification. Integrated gasification/combined cycle (IGCC) power is illustrated in Figure 49.7. Compressed air enters an oxygen plant, which separates oxygen from the air. The oxygen is used to gasify biomass in a pressurized gasifier to produce medium heating-value producer gas. The producer gas passes through cyclones and a gas clean-up system to remove particulate

**FIGURE 49.7**

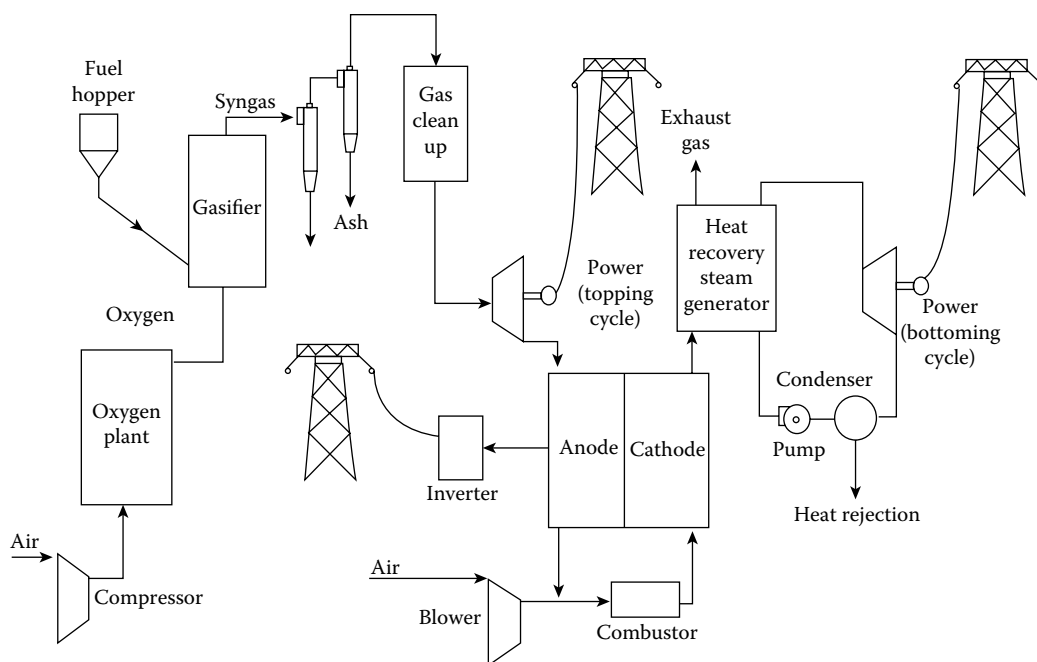

Integrated gasification/combined cycle power plant (IGCC) based on a gas turbine topping cycle.

matter, tar, and other contaminants that may adversely affect gas turbine performance (alkali and chloride being the most prominent among these). These clean-up operations are best performed at high temperature and pressure to achieve high cycle efficiency. The clean gas is then burned in air and expanded through a gas turbine operating as a “topping” cycle. The gas exits the turbine at temperatures ranging between 400°C and 600°C. A heat recovery steam generator produces steam for a “bottoming” cycle that employs a steam turbine. Electric power is produced at two locations in this plant, yielding thermodynamic efficiencies exceeding 47%.

Integrated gasifier/combined cycle systems based on gas turbines are attractive for several reasons. These reasons include their relative commercial readiness and the expectation that they can generate electricity at the lowest cost of all possible biomass power options.

An alternative to IGCC is to generate steam for injection into the gas turbine combustor, which increases mass flow and power output from the turbine. This variation, called a steam-injected gas-turbine (STIG) cycle [20,21] is less capital intensive than IGCC since it does not employ a steam turbine. The STIG cycle is commercially developed for natural gas; lower flammability limits for producer gas make steam injection more problematic for biomass-derived producer gas. The intercooled steam-injected gas turbine (ISTIG) is an advanced version of the STIG. This cycle further improves thermodynamic efficiency by cooling gas flow between several stages of compression (intercooling).

Figure 49.8 illustrates an IGCC power plant based on a molten carbonate fuel cell [18]. Biomass is gasified in oxygen to yield producer gas. Gasification occurs at elevated pressure to improve the yield of  $\text{CH}_4$ , which is important for proper thermal balance of this fuel cell. Hot-gas clean up to remove particulate matter, tar, and other contaminants is followed by expansion through a gas turbine as part of a topping power cycle. The pressure and temperature of the producer gas is sufficiently reduced after this to admit it into the fuel cell. High-temperature exhaust gas exiting the cathode of the fuel cell enters a

**FIGURE 49.8**  
Combined cycle power plant based on high-temperature fuel cells.

heat recovery steam generator, which is part of a bottoming cycle in the integrated plant. Thus, electricity is generated at three locations in the plant for an overall thermodynamic efficiency reaching 60% or more.

### 50.1 Biomass to Solid Fuels

Low energy density and high moisture content are two key disadvantages of using biomass as a solid fuel. Both can be overcome with thermal pretreatment methods. Torrefaction and (slow) pyrolysis are two main approaches to converting a significant portion of biomass into a high-energy-density solid fuel.

Biomass torrefaction is similar to the coffee roasting process. Both take place at moderate temperatures of about 250°C without oxygen addition and residence times of 30 min or more. The process is mostly endothermic, but torrefaction gases can be consumed to provide necessary heat. Torrefaction evolves over three main steps. Initially, the feedstock will simply absorb heat until the feed moisture evaporates. The next step involves the release of some volatile gases. Finally, the biomass undergoes minor chemical restructuring becoming dark, brittle, and hydrophobic. Material yields can be as low as 70 wt.% with corresponding energy yields of more than 90 wt.% [1].

Torrefied biomass resembles charcoal in appearance and physical properties. It is easier to pulverize, has a higher energy content (>20 MJ/kg), and can be stored for longer periods

without absorbing moisture and with minimal microbial degradation [2]. These properties make it attractive for direct combustion, co-firing, and entrained flow gasification applications.

Slow pyrolysis is a higher-intensity form of torrefaction [3]. Slow pyrolysis conditions consist of an inert environment with temperatures above 400°C and residence times of more than 30 min. This process releases a greater amount of pyrolysis volatiles resulting in solid yields of <30 wt.%. The solid product shares many similarities with torrefied biomass including a higher heating value (HHV) of about 30 MJ/kg. However, its products are not well suited to synthetic fuel applications.

Finally, carbonization, which takes place at temperatures of 450°C–600°C, yields about 35 wt.% solids with a similar HHV as slow pyrolysis charcoal. Carbonization can convert large feed sizes without prior grinding. It is also the simplest of technologies to operate in part because the product requirements are less strict than other thermal processes.

## 50.2 Biomass to Gaseous Fuels

Anaerobic digestion and gasification are two of the main ways to convert biomass into gaseous fuels. Both pathways generate a combustible gas: biogas and synthetic gas (syngas), respectively. Biogas is relatively inexpensive to produce, but has a smaller range of applications than syngas. This section will discuss the technologies that enable biomass fuel gas production.

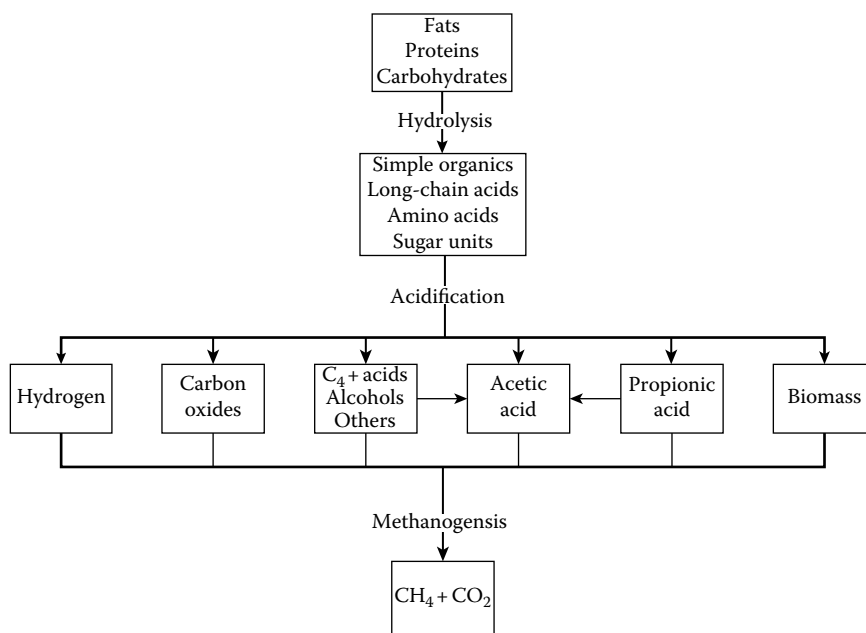

### 50.2.1 Biogas

In the absence of oxygen, bacteria decompose organic wastes into a mixture of CH<sub>4</sub>, CO<sub>2</sub>, and trace gases. The decomposition productivity is sensitive to feedstock properties including moisture and ash content. Anaerobic digestion yields vary from 23 to over 250 m<sup>3</sup>/Mg (wet basis) with a methane content of 55%–75% by volume with an energy efficiency of about 60%.

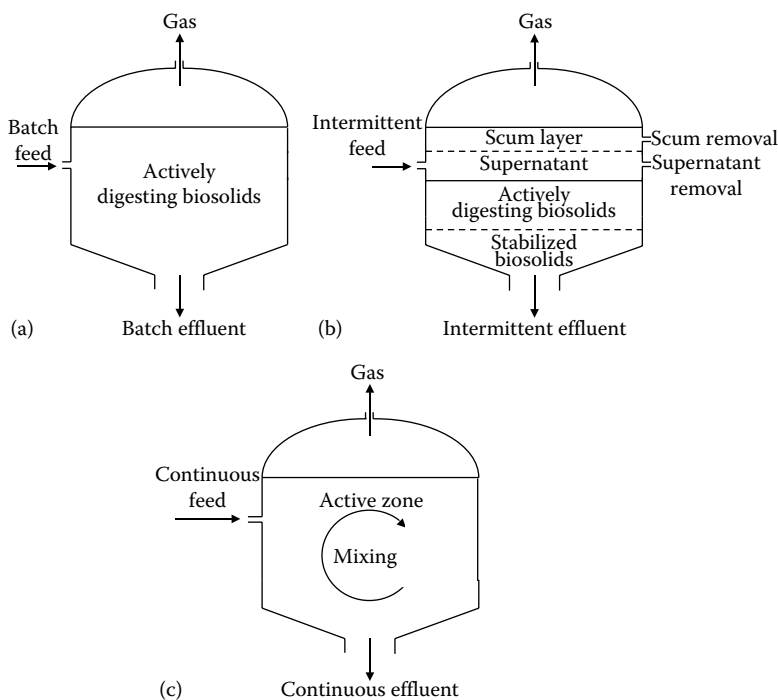

Methane is the primary component in biogas, which makes it a candidate for substituting natural gas in many applications. Clean biogas is suitable for engine generator sets, small gas turbines, and some kinds of fuel cells. However, biogas often contains contaminants like sulfur that must be removed before use in some equipment.

Anaerobic digestion involves several complicated steps illustrated in [Figure 50.1](#) [4]. During this process, several bacteria species break down proteins, carbohydrates, and fats into simple acids, alcohols, and gaseous compounds via hydrolysis and acidification. The final step is methanogenesis, where most of the intermediate organics decompose to CH<sub>4</sub> and CO<sub>2</sub>.

On the other hand, the anaerobic digester systems where these processes take place are simple (see [Figure 50.1](#)). Anaerobic digesters operate as batch, semi-batch, or continuous units ([Figure 50.2](#)). Reactor designs include batch, plug-flow, continuously stirred tank, upflow, and two-tank reactors. The most common reactor design is the batch system in which most of the digestion steps take place within a single vessel. Improvements to this design aim to increase contact time between bacteria and the organic wastes and/or to separate and control the environments for acid-forming and methane-forming bacteria. There are numerous parameters to optimize the performance of anaerobic digestion: pretreatments, heating, mixing, nutrient addition, bacteria selection, and pH to name a few.

**FIGURE 50.1**

Microbial phases in anaerobic digestion. (Adapted from Klass, D., *Biomass for Renewable Energy, Fuels, and Chemicals*, Academic Press, San Diego, CA, 1998c, p. 462.)

**FIGURE 50.2**

Types of anaerobic digesters: (a) batch fed, (b) intermittently fed, and (c) continuously stirred and fed.

The effluent from these systems is a mixture of biogas and sludge. Biogas often requires scrubbing to remove hydrogen sulfide in order to minimize emissions of sulfur dioxide (SO<sub>2</sub>). Digested sludge contains materials that bacteria are unable to digest within the timescales of most systems: lignin, mineral matter, and water. Digested sludge is amenable to use as a fertilizer.

### 50.2.2 Light Gases

The ideal transportation fuel is a stable liquid at ambient temperature and pressure that can be readily vaporized and burned within an engine. However, some gaseous compounds are potential transportation fuels by increasing their density through compression. Among these gaseous transportation fuels are hydrogen, methane, ammonia, and dimethyl ether (DME).

Hydrogen can be manufactured from syngas via the water–gas shift reaction. This moderately exothermic reaction is best performed at relatively low temperatures in one or more stages with the aid of catalysts. Biomass to hydrogen processes face the same fuel delivery challenges as hydrogen from fossil sources in addition to the increased costs associated with using biomass.

Methane can be the main product of gasification under conditions known as hydrogasification (see Equation 50.1) [5]:

Although methane is more easily pressurized or liquefied than hydrogen, its density is still too low to be an attractive transportation fuel except in some urban mass transit applications [6].

Ammonia is produced by the Haber process (see Equation 50.1) at 200 bar and 500°C [7]:

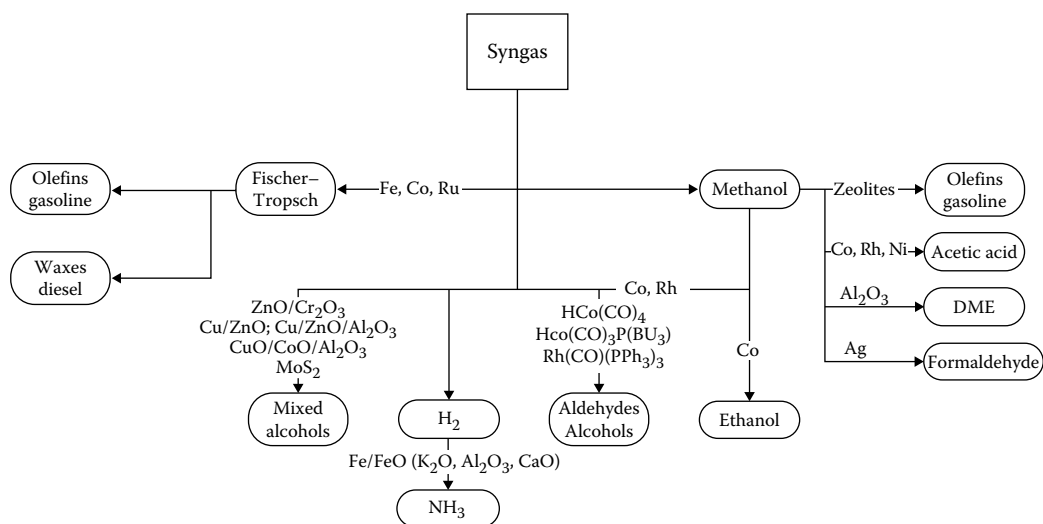

As a widely employed agricultural fertilizer, the United States already has in place production, storage, and distribution infrastructure for its use.

DME, like liquefied petroleum gas, is a nontoxic, flammable gas at ambient conditions, which is easily stored as a liquid under modest pressures [8]. It can be produced from syngas and can substitute for diesel after minor engine modifications.

### 50.2.3 Synthetic Gas

Biomass gasification generates syngas, which is attractive for energy applications because of its H<sub>2</sub>, CO, and CH<sub>4</sub> contents. As discussed previously, syngas composition varies by reactor operating conditions and can be tailored to specific applications. The two main syngas applications are power generation and fuel synthesis.

Clean syngas can replace natural gas use in gas turbines without major equipment modifications. It is often employed in coal-based integrated gasification/combined cycle, but efforts to reduce greenhouse gas emissions could encourage co-firing of biomass in these systems. However, the low cost of natural gas coupled with the lower construction costs of gas-based systems makes it unlikely that new facilities will be built to convert solid fuels to syngas for power applications.

**FIGURE 50.3**

Catalytic pathways for converting synthetic gas to fuels. (Adapted from Spath, P.L. and Dayton, D.C., Preliminary screening-technical and economic assessment of synthesis gas to fuels and chemicals with emphasis on the potential for biomass-derived syngas, Technical Report, DTIC Document, National Renewable Energy Laboratory NREL/TP-510-34929, pp. 1–160, 2003.)

Fuel synthesis converts solid carbonaceous materials into higher-value liquid fuels. While solid fuels such as coal and biomass are valued below \$100 per Mg, liquid fuels including gasoline and diesel often have prices of over \$1000 per Mg. These higher prices reflect the value of high energy density, portability, and fuel consistency. Solid fuels can be pretreated to improve these characteristics, and they have been historically used in portable applications including onboard passenger vehicle fuels. However, the mass production of liquid fuel engines has led to the development of numerous pathways to produce synthetic fuels [9].

Figure 50.3 shows several catalytic pathways for converting syngas into liquid fuels [10]. A large number of catalysts can convert syngas into Fischer-Tropsch liquids (FTLs), alcohols, short-chained hydrocarbons, and ammonia via  $H_2$  synthesis. DME, ethanol, methanol, formaldehyde, acetic acid, olefins, and gasoline can be synthesized following syngas conversion to methanol. Details for these pathways will be discussed in the following section.

This wide range of fuels highlights the versatility of syngas. Thus, syngas from inexpensive, renewable, environmentally friendly sources could replace fossil fuels in a variety of applications. However, the development of any of these pathways depends heavily on a variety of technical, economic, and policy constraints.

### 50.3 Biomass to Liquid Fuels

Almost 25% of energy consumption in the United States goes to transportation. Approximately half of this amount comes from imported petroleum. Thus, the development of transportation fuels from biorenewable resources is a priority if decreased dependence on foreign sources of energy is to be achieved. Table 50.1 lists properties of both traditional and bio-based transportation fuels.

**TABLE 50.1**

<sup>d</sup> Kajitani et al. [13].

Traditional transportation fuels are classified as gasoline, diesel fuel, or jet fuel. Gasoline is intended for spark-ignition (Otto cycle) engines; thus, it is relatively volatile but resistant to autoignition during compression. Diesel fuel is intended for use in compression-ignition (Diesel cycle) engines; thus, it is less volatile compared to gasoline and more susceptible to autoignition during compression. Jet fuel is designed for use in gas turbine (Brayton cycle) engines, which are not limited by autoignition characteristics but otherwise have very strict fuel specifications for reasons of safety and engine durability.

Gasoline is a mixture of hundreds of different hydrocarbons obtained from a large number of refinery process streams that contain between 4 and 12 carbon atoms with boiling points in the range of 25°C–225°C. Most of the mixture consists of alkanes with butanes and pentanes added to meet vapor pressure specifications. A few percent of aromatic compounds are added to increase octane number, the figure of merit used to indicate the tendency of a fuel to undergo premature detonation within the combustion cylinder of an internal combustion engine. The higher the octane number, the less likely a fuel will detonate until exposed to an ignition source (electrical spark). Premature denotation is responsible for the phenomenon known as engine knock, which reduces fuel economy and can damage an engine. Various systems of octane rating have been developed, including research octane and motor octane numbers. Federal regulation in the United States requires gasoline sold commercially to be rated using an average of the research and motor octane numbers. Gasoline rated as “regular” has a commercial octane number of about 87 while premium grade is 93.

Diesel fuel, like gasoline, is also a mixture of light distillate hydrocarbons but with lower volatility and higher viscosity. Because diesel fuel is intended to be ignited by compression rather than by a spark, its autoignition temperature is lower than for gasoline. The combustion behavior of diesel fuels are conveniently rated according to cetane number, an indication of how long it takes a fuel to ignite (ignition delay) after it has been injected under pressure into a diesel engine. A high cetane number indicates short ignition delay, for example, no. 2 diesel fuel has a cetane number of 37–56, while gasoline has a cetane number <15.

Jet fuel is designated as either Jet A fuel or Jet B fuel. Jet A fuel is a kerosene type of fuel with relatively high flash point, whereas Jet B fuel is a wide-boiling-range fuel, which more readily evaporates.

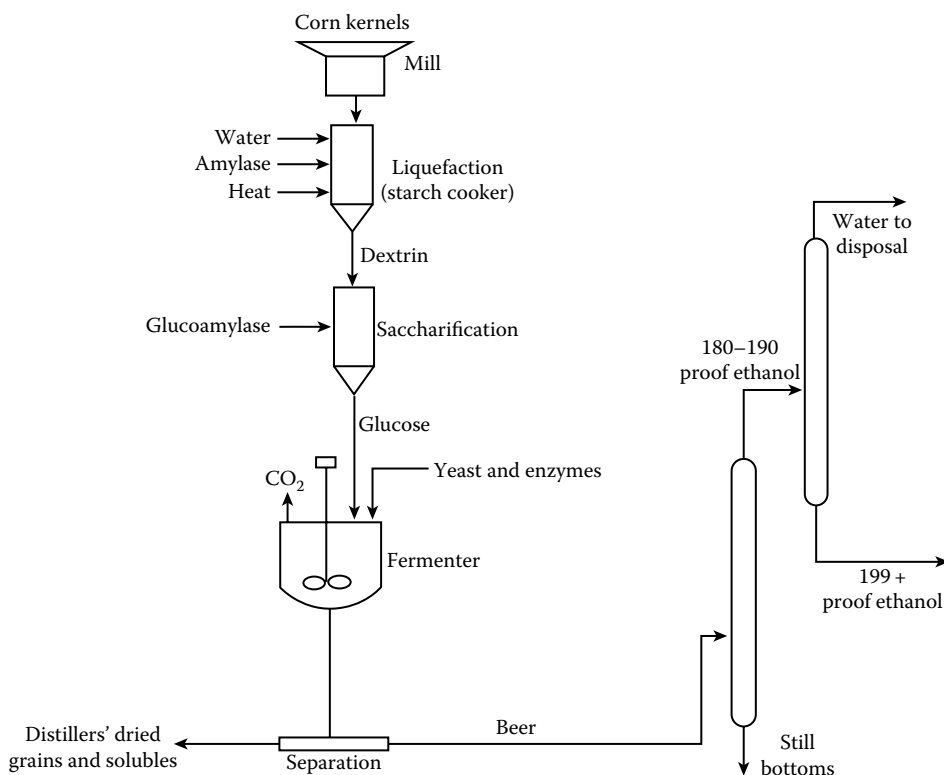

Bio-based transportation fuels, also known as biofuels, are currently dominated by ethanol and biodiesel. Ethanol, by virtue of its high octane number, is suitable for use in spark-ignition engines, while the high cetane numbers of biodiesel, which are methyl or ethyl esters formulated from vegetable or animal fats, make them suitable for use in compression-ignition engines. However, there are other candidate liquid biofuels including methanol, mixed alcohols, and FTLs, as well as gaseous biofuels including hydrogen, methane, ammonia, and DME, which will also be discussed.

### 50.3.1 Alcohols

#### 50.3.1.1 Corn Ethanol

Ethanol is the dominant biofuel with global production exceeding 50 billion L. The majority of this ethanol comes from Brazilian sugarcane and the U.S. corn grain. Microbes convert these sugar-rich crops into alcohols with relative ease and at low cost. Two major corn-to-ethanol facilities have been operated in the United States: dry grind and wet-milling.

Dry grind ethanol plants, shown in [Figure 50.4](#), grind the whole kernel while wet-milling plants soak the grain with water and acid to separate the corn germ, fiber, gluten, and starch components before mechanical grinding [14]. The capital investment for dry grind

**FIGURE 50.4**  
Dry grind corn to ethanol.

is less than that for a comparably sized wet-milling plant. However, the higher value of its by-products, greater product flexibility, and simpler ethanol production can make a wet-milling plant a more profitable investment.

Dry grind ethanol takes place in four major steps: pretreatment, cooking, fermentation, and distillation. Pretreatment consists of grinding the corn kernel into flour “meal,” which is mixed with water, enzymes, and ammonia. This mixture (“mash”) is then “cooked” to reduce bacteria levels. After cooling, the mash is sent to the fermenter where it remains for 40 h or more. The beer resulting from fermentation consists of a mixture of ethanol and stillage. Energy-intensive distillation of the beer is necessary to separate the stillage and water content from the ethanol and achieve maximum concentrations of 95%. This is followed by further purification to 100% ethanol using molecular sieves.

A modern dry grind plant will produce over 2.7 gal of ethanol per bushel of corn processed. Yields of coproducts per bushel of corn are 7.7–8.2 kg (17–18 lb) of dry distiller’s grain with solubles and 7.3–7.7 kg (16–17 lb) of carbon dioxide evolved from fermentation, the latter of which can be sold to the carbonated beverage industry. As a rule of thumb, the three products are produced in approximately equal weight per bushel. Table 50.2 shows ethanol yields for various feedstock.

Costs for ethanol from corn grain have been developed by the USDA [15] for the dry mill process. Capital costs for a 40 million gal/year ethanol plant were estimated at \$46.7 million with fuel production costs of \$1.03 per gal (2006).

**TABLE 50.2**

Ethanol Yields from Various Biorenewable Resources

Feedstock	Yield (L/Mg)
Apples	64
Barley	330
Cellulose	259
Corn	355–370
Grapes	63
Jerusalem artichoke	83
Molasses	280–288
Oats	265
Potatoes	96
Rice (rough)	332
Rye	329
Sorghum (sweet)	44–86
Sugar beets	88
Sugarcane	160–187
Sweet potatoes	125–143
Wheat	355

### 50.3.1.2 Cellulosic Ethanol

Much of the carbohydrate in plant materials is structural polysaccharides, providing shape and strength to the plant. This structural material, known as lignocellulose, is a composite of cellulose fibers embedded in a cross-linked lignin–hemicellulose matrix [16]. Depolymerization to basic plant components is difficult because lignocellulose is resistant to both chemical and biological attack [17]. However, depolymerization is necessary for microbes to efficiently convert cellulosic biomass into alcohols.

Cellulose to ethanol consists of four steps: pretreatment, enzymatic hydrolysis, fermentation, and distillation [14]. Of these, pretreatment is the most costly step, accounting for about 33% of the total processing costs [18]. An important goal of all pretreatments is to increase the surface area of lignocellulosic material, making the polysaccharides more susceptible to hydrolysis. Thus, comminution, or size reduction, is an integral part of all pretreatments.

Enzymatic hydrolysis was developed to better utilize both cellulose and hemicellulose from lignocellulosic materials. Three basic methods for hydrolyzing structural polysaccharides in plant cell walls to fermentable sugars are available: concentrated acid hydrolysis, dilute acid hydrolysis, and enzymatic hydrolysis [17,19]. The two acid processes hydrolyze both hemicellulose and cellulose with very little pretreatment beyond comminution of the lignocellulosic material to particles of about 1 mm size. The enzymatic process must be preceded by extensive pretreatment to separate the cellulose, hemicellulose, and lignin fractions.

Although thermodynamic efficiencies for the conversion of carbohydrates to ethanol can be calculated, it is more typical to report the volumetric yield of ethanol per unit

mass of feedstock. The yield of ethanol from energy crops varies considerably. Among sugar crops, sweet sorghum yields 80 L/ton, sugar beets yield 90–100 L/ton, and sugarcane yields 75 L/ton. Among starch and inulin crops, the ethanol yield is 350–400 L/ton of corn, 400 L/ton of wheat, and 90 L/ton of Jerusalem artichoke. Among lignocellulosic crops, the potential ethanol yield is 400 L/ton of hybrid poplar, 450 L/ton for corn stover, 510 L/ton for corn cobs, and 490 L/ton for wheat straw.

Researchers at the National Renewable Energy Laboratory [20] developed a design report showing capital costs of \$114 million and operating costs of \$1.07 per gal (2000) of ethanol for a 69 million gal/year ethanol plant.

### 50.3.1.3 Butanol

Ethanol has several limitations as a transportation fuel, including its affinity for water, which prevents it from being fully compatible with the existing fuel infrastructure, and its low volumetric heating value, which is only two-thirds that of gasoline. For this reason, fermentations that produce metabolites other than ethanol have been proposed. Alternative fermentations could produce hydrophobic molecules that are less oxidized than ethanol including higher alcohols (most prominently butanol), fatty acids, fatty alcohols, esters, alkanes, alkenes, and isoprenes.

Butanol is of particular industrial interest because of its high compatibility with the existing vehicle technologies. In addition to a higher heating value than ethanol, butanol can power existing gasoline engines without major modifications. In fact, gasoline engines can operate on up to 100% butanol blends. This would overcome the 10% volumetric blend limit of ethanol to gasoline in modern vehicles. The challenges for butanol are mostly associated with its production. Butanol production proceeds through either the intermediate hydrocarbon propylene or acetaldehyde. The propylene route employs a rhodium catalyst. The acetaldehyde pathway is a fermentation process commonly known as the acetone–butanol–ethanol (ABE) process. The ABE process shares many similarities with corn fermentation. However, it suffers from low product specificity and yield due in part to high butanol toxicity to the fermenting microorganisms [21]. Low product yields and butanol concentrations in the bioreactors are key reasons for higher butanol production capital and fuel costs relative to ethanol fermentation [22]. There are recent industry indications that some of these challenges have been overcome to allow rapid conversion of existing corn ethanol facilities to butanol.

### 50.3.2 Biodiesel

There is growing global interest to produce biodiesel from lipid-rich biomass. There are abundant sources of inexpensive lipid-rich biomass including dedicated, fast-growing crops like jatropha, oils from food waste, and algae-based oils. Lipids are a large group of hydrophobic, fat-soluble compounds produced by plants and animals for high-density energy storage. Triglycerides of fatty acids, commonly known as fats and oils depending upon their melting points, are among the most familiar form of lipids and have been widely used in recent years for the production of diesel fuel substitutes. The solution to this problem is to convert the triglycerides into methyl esters or ethyl esters of the fatty acids, known as biodiesel, and the by-product 1,2,3-propanetriol (glycerol).

A wide variety of plant species produce triglycerides in commercially significant quantities, most of it occurring in seeds [15]. Average oil yields range from 15,000 L/km<sup>2</sup> for cottonseed to 81,400 L/km<sup>2</sup> for peanut oil although intensive cultivation might double these numbers. Soybeans are responsible for more than 50% of world production of oilseed, representing

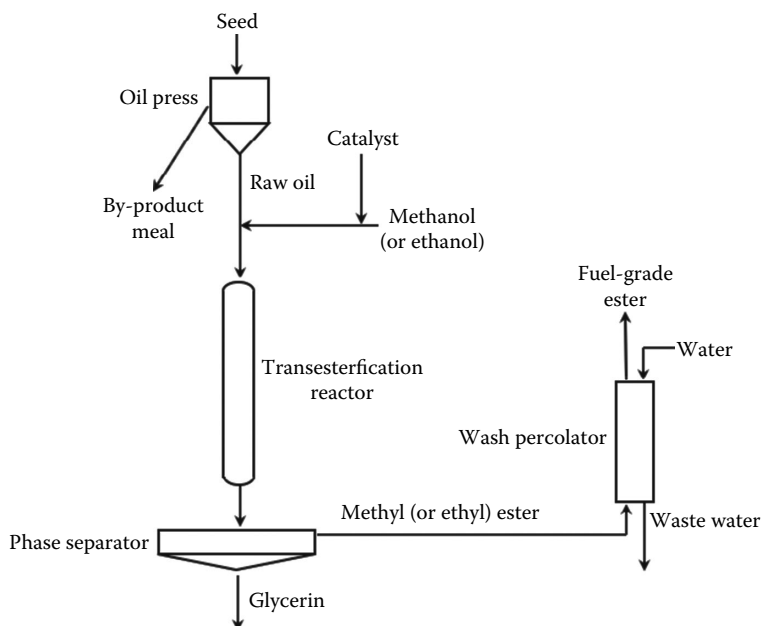

4882 million bbl/year. The average oil yield for soybeans is 38,300 L/km<sup>2</sup> [15]. A higher-yielding crop is oil palm, already grown in plantations for vegetable oil production [23].

Although oil palm yields are 10 times higher than soybeans, some environmentalists are concerned that its cultivation for fuel production will encourage rainforest destruction. However, several oil seed crops have been identified that could be grown on wasteland or even saline soils, which reduces concerns about competition for food crops and rainforest destruction. These alternative oil seed crops include jatropha, Chinese tallow tree, and salicornia [24,25].

Triglycerides can be converted into transportation fuels via transesterification [26]. The process, described in Figure 50.5, has been commercialized for the production of biodiesel. Although biodiesel can substitute for diesel fuel, it has some shortcomings. Fatty acid methyl esters found in biodiesel are subject to microbial or oxidative attack, making them unsuitable in applications requiring long-term fuel storage. Low-temperature performance of biodiesel is sometimes problematic.

For these reasons, hydrogenation is being evaluated as a replacement for transesterification in the production of lipid-based biofuels [26]. Hydrogenation includes a number of reactions: large molecules are broken into smaller molecules; carbon-carbon double bonds are converted into more stable single bonds; molecular structures are rearranged; and undesirable atoms such as sulfur, nitrogen, and oxygen are removed from the hydrogenated compounds. In the case of lipids, hydrogenation yields alkanes, which are highly desirable fuel molecules.

Finally, lipid-rich microalgae might be grown in brackish water or even in seawater [27]. Algae can produce as much as 60% of their body weight as lipids when deprived of key nutrients such as silicon for diatoms or nitrogen for green algae. They employ relatively low substrate concentrations, on the order of 10–40 g/L. However, algae require the proper combination of brackish water, CO<sub>2</sub>, and sunlight, which could limit the number of sites where this process would be profitable. Berkeley researchers have estimated that biofuels from algae would require break-even oil prices of \$332 per bbl [28].

**FIGURE 50.5**

Conversion of triglycerides to methyl (or ethyl) esters and glycerol (biodiesel synthesis).

### 50.3.3 Mixed Alcohols

Thermochemical technologies can also produce alcohols as an alternative to biochemical conversion. Mixed alcohol synthesis dates back to before the development of Fischer–Tropsch synthesis. Both processes employ similar catalytic materials and operating conditions. Mixed alcohol synthesis involves the conversion of syngas over copper, zinc, and/or cobalt catalysts at temperatures of 300°C and 6.8 MPa pressure. The syngas  $H_2:CO$  ratio should be between 1.0 and 1.2. One of the main challenges for mixed alcohol biorefineries is the need to market their coproducts. Mixed alcohols contain mostly ethanol (>70 wt.%), but the longer-chained alcohols (propanol, butanol, and pentanol) need to be marketed separately. Market availability for these coproducts would help improve the economics of mixed alcohol synthesis (see work by NREL [29]).

### 50.3.4 Gasoline and Diesel

#### 50.3.4.1 Fischer–Tropsch Synthesis

FTLs from biomass have antecedents in the coal-to-liquids industry. Germany extensively developed the Fischer–Tropsch process during World War II when it was denied access to petroleum-rich regions of the world. Likewise, when South Africa faced a world oil embargo during their era of apartheid, they employed Fischer–Tropsch technology to sustain its national economy. A comprehensive bibliography of Fischer–Tropsch literature can be found on the web [30].

Fischer–Tropsch catalysis produces a large variety of hydrocarbons including light hydrocarbon gases, paraffinic waxes, and alcohols according to the generalized reaction (50.2):

FTL composition depends on the process selectivity. Process selectivity is affected by various factors including catalyst and feed gas properties. The Anderson–Schulz–Flory distribution describes the probability of hydrocarbon chain growth where the molar yield for a carbon chain can be calculated using the following equation [31]:

$$C_n = \alpha^{n-1}(1 - \alpha) \quad (50.3)$$

where  $\alpha$  is the chain growth probability of a hydrocarbon of length  $n$ . Light hydrocarbons (mostly methane) can be fed into a gas turbine to provide power. FTLs can be separated into various products in a process similar to petroleum distillation.

Product distribution is a function of temperature, pressure, feed gas composition ( $H_2/CO$ ), catalyst type, and composition [32]. Depending on the types and quantities of Fischer–Tropsch products desired, either low- (200°C–240°C) or high-temperature (300°C–350°C) synthesis at pressures ranging between 10 and 40 bar is used. For example, high gasoline yield can be achieved using high process temperatures and an iron catalyst. Fischer–Tropsch synthesis requires careful control of the  $H_2/CO$  ratio to satisfy the stoichiometry of the synthesis reactions as well as avoid deposition of carbon on the catalysts (coking). The optimal  $H_2/CO$  ratio for the production of naphtha and diesel range fuels sold in Western markets is 2:1.

Swanson et al. developed an analysis of FTL fuels from biomass [33]. Their estimates of a 2000 Mg/day corn stover facility found capital costs of \$498–\$606 million with minimum fuel selling prices of \$4.27 and \$4.83 per gal of gasoline equivalent depending on whether the process was based on a fluid bed or entrained flow gasifier.

#### 50.3.4.2 Bio-Oil Upgrading

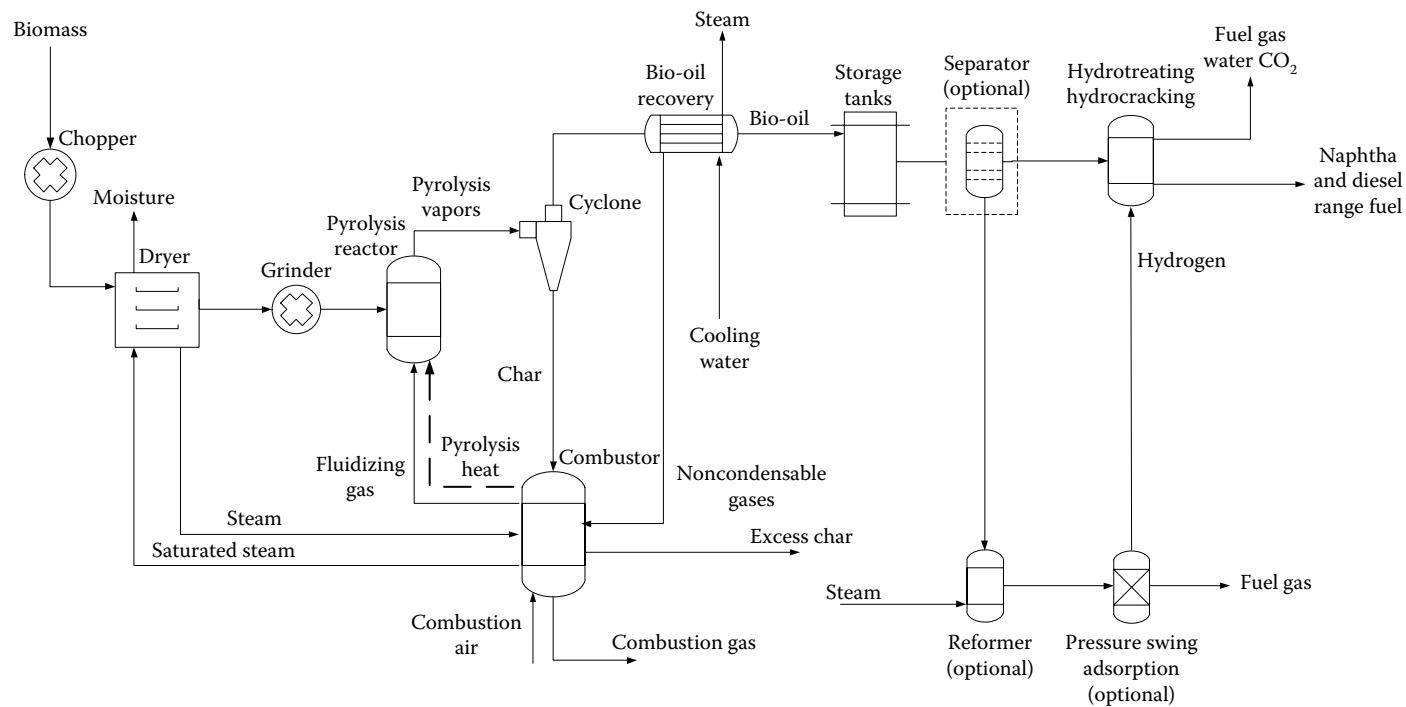

Pyrolysis is the thermal decomposition of organic compounds in the absence of oxygen. The resulting product streams depend on the rate and the duration of heating. Liquid yields exceeding 70% are possible under conditions of fast pyrolysis, which is characterized by rapid heating rates (up to 1000°C/s), moderate reactor temperatures (450°C–600°C), short vapor residence times (<0.5 s), and rapid cooling at the end of the process. Rapid cooling is essential if high-molecular-weight liquids are to be condensed rather than further decomposed to low-molecular-weight gases.

Pyrolysis liquid, also known as bio-oil, is a low-viscosity, dark-brown fluid with up to 15%–20% water, which contrasts with the black, tarry liquid resulting from slow pyrolysis [34]. Fast pyrolysis liquid is a complicated mixture of organic compounds arising from thermal degradation of carbohydrate and lignin polymers in biomass [35]. The liquid is highly oxygenated, approximating the elemental composition of the feedstock, which makes it highly unstable. The HHV of pyrolysis liquids ranges between 17 and 20 MJ/kg with liquid densities of about 1280 kg/m<sup>3</sup>. Assuming conversion of 72% of the biomass feedstock to liquid on a weight basis, yields of pyrolysis oil are about 135 gal/ton.

Production of pyrolysis oils and its coproducts involves several steps [36], which are illustrated in [Figure 50.6](#). Lignocellulosic feedstock, such as wood or agricultural residues, is milled to a fine powder to promote rapid reaction. The particles are augured into the pyrolysis reactor where they are rapidly heated and converted into condensable vapors, liquid aerosols, noncondensable gases, and charcoal. These products are transported out of the reactor into a cyclone operating above the condensation point of pyrolysis vapors where the charcoal is removed. Vapors and gases are transported to a quench vessel where a spray of pyrolysis liquid cools vapors sufficiently for them to condense. The noncondensable gases, which include flammable carbon monoxide, hydrogen, and methane, are burned in air to provide heat for the pyrolysis reactor. The condensable liquids consist of a mixture of hundreds of organic compounds commonly known as bio-oil.

Bio-oil can be upgraded using conventional oil refinery processes. The most common of these processes are hydrotreating and hydrocracking. Hydrotreating can remove most of the bio-oil impurities such as nitrogen, alkali metals, and oxygen carried over from the original biomass. The purpose of hydrocracking is to break down heavy hydrocarbons with long carbon chain lengths into compounds within the naphtha and diesel range (7–20 carbon atoms). Bio-oil contains organic compounds with molecular weights of several hundred grams per mole. These compounds can be cracked into lighter hydrocarbons increasing the yield of naphtha and diesel range fuels. Hydrocracking consumes significant quantities of hydrogen, which can be obtained by reforming bio-oil or natural gas within the facility [37].

Gasoline and diesel from corn stover fast pyrolysis followed by bio-oil upgrading could cost between \$2.00 and 3.10 per gal for a 2000 Mg/day biorefinery [36,38]. This facility would generate 35.4 million gal/year.

**FIGURE 50.6**

Biomass fast pyrolysis and bio-oil hydrotreating/hydrocracking to gasoline and diesel.

### 50.3.5 Hydrothermal Processing

Hydrothermal processing (HTP) is the use of water at near-critical-state conditions (374°C, 22.1 MPa) for thermochemical conversion. At temperatures below (subcritical) and above (supercritical) the critical point, water exhibits unique properties attractive for biomass depolymerization and product extraction [39]. HTP encompasses a wide range of operating temperatures (200°C–600°C) and pressures (5–40 MPa). At lower temperatures, the process is often called liquefaction, and its primary products are a mixture of organic liquids commonly known as bio-crude. At higher temperatures, the primary products are methane and hydrogen [40].

HTP presents several benefits compared to other thermochemical processes: feedstock flexibility, heat integration, and tunable chemical reactions. HTP reactors can convert a wide range of materials including high-moisture-content feedstock. However, alkali metals can affect the equipment lifetime. High water temperatures allow for heat integration opportunities. As long as the water retains its latent heat, it can be reheated with small energy input. Excess heat can be recovered upon cooling spent reaction media. Finally, fine-tuning of process temperature, pressure, and catalytic media can significantly improve product selectivity and yield.

Researchers at the Pacific Northwest National Laboratory have developed preliminary techno-economic analyses for HTP of various types of biomass [41]. However, there are limited industrial data to support detailed cost estimates of this technology.

---

## 50.4 Biofuel Properties

Biomass can be converted to a wide range of biofuels with significantly different combustion properties as shown in [Table 50.1](#). Combustion properties determine the suitability of the biofuel to different engines and combustion equipment. In general, a combination of these properties determines the ultimate fuel performance, but a single factor may make the fuel unsuitable for a specific equipment.

Most of the global biofuel production has focused on ethanol and biodiesel. These fuels can be blended in small quantities with traditional fossil fuels. Conventional engines can operate with low levels of ethanol and biodiesel blends. In the United States, both E10 and E85 (ethanol:gasoline blends of 10% and 85% ethanol, respectively) have been marketed to consumers. The most common biodiesel blend in the United States is B20 with other blends ranging from 5% to 100% biodiesel. Both E85 and B20 typically require modern engines with modifications to adjust for the biofuel properties.

There is growing interest in the production of drop-in biofuels. Drop-in fuels refer to gasoline and diesel-type biofuels that can operate in existing gasoline engines without modifications. Companies have been able to produce drop-in biofuels that meet most of the specifications required by modern vehicles via several of the pathways discussed previously. The use of existing engines and infrastructure is one of the advantages of producing drop-in biofuels. On the other hand, hydrocarbons in first-generation drop-in biofuels have some minor differences compared to fossil fuels that are still being addressed. Researchers continue to study innovative ways of synthesizing fuels with improved combustion properties that could not only replace but also improve upon conventional gasoline and diesel.

## 51.1 Introduction

Roman mythology holds that humans obtained fire from the gods on Mount Olympus to meet their needs for light and heat. In much of today's industrialized world, the use of electricity has edged out fire for these age-old needs. However, the convenient use of electricity is now faced with increasing cost and concerns about the availability and environmental consequences of the fuels that are needed to produce it. Can those Roman gods again come to mankind's aid?

Deep below Mount Olympus, Vulcan toils over his forge. The forge glows red as Vulcan hammers out weapons for the gods, including Jupiter's own thunderbolts. Vulcan's forge is stoked by geothermal energy that humans, too, have used for the production of electricity since 1904, starting in the very homeland of the Romans.

Geothermal power production in the United States approached 18,000 GW h in 2005,<sup>1</sup> or an average of more than 2000 MW over the year. It does so on an around-the-clock basis, providing baseload power to several western utilities in California, Nevada, Hawaii,

Utah and starting in 2006, Alaska. The power generated has very low emissions and is immune to price fluctuations in the fossil fuel markets. Similar benefits are derived around the world from plants operating in 24 countries worldwide, including Italy, the Philippines, Indonesia, Kenya, New Zealand, and Iceland. In Iceland, geothermal power not only provides 16.6% of the electric power generated every year, but 54% of the total primary energy use in the country, including the 87% of households that are heated by geothermal water.<sup>2</sup> Worldwide direct use of geothermal energy is documented in 76 countries.<sup>3</sup>

This chapter examines geothermal power technologies and the issues involved in further utilization of geothermal energy for the production of electric power.

---

## 51.2 Definition and Use of Geothermal Energy

Geothermal energy is present on Earth from two sources:

1. As heat that flows upward and outward across the entire surface of the world from the very deep (mantle and core) radioactive decay of uranium, thorium, and potassium. In most regions of the world, this energy flux is too small to be commercially useful for any purpose.
2. As localized heat resulting from the movement of magma into the earth's crust. In some areas of the world, most frequently along the so-called "Ring of Fire," this localized heat, with high heat flux and high temperatures, can be found between the surface and 10,000 ft below ground. Where such heat flux meets the requisite conditions, geothermal energy can be developed for multiple and varied purposes. Where temperatures are sufficiently high, geothermal energy may be used for electric power generation. This form of geothermal energy is the subject of this chapter.

Geothermal energy was first used for experimental power generation in Larderello, Italy, on July 4, 1904, by Prince Piero Ginori Conti. However, commercial development followed slowly thereafter. The Larderello site also saw the first commercial geothermal power plant (250 kW) in 1913, as well as the first large-power installation in 1938 (69 MW). It would be 20 years before the next large geothermal power installation would be built: halfway around the world in Wairakei, New Zealand, with the first unit—commissioned in 1958—that, under a steady development program, grew to 193 MW of installed capacity by 1963. In the United States, the installation of the first unit (11 MW) of what was to become the largest geothermal power complex in the world, The Geysers, in Sonoma County, California, occurred in 1960. Over the next quarter-century, a total of 31 turbine generator sets were installed at The Geysers, with a nameplate capacity of 1890 MW. Plant retirements and declining steam supply have since reduced generation at The Geysers to an annual average generation of 1020 MW from 1421 MW of installed capacity—still the largest geothermal field in the world.<sup>1</sup>

Since those early efforts, Lund et al. report that a total of 2564 MW of geothermal power generation capacity is currently installed in the United States, generating approximately 2000 MW of annual average generation. In 2005, worldwide annual geothermal power

was estimated at 56,875 GW h from 8,932 MW of installed capacity.<sup>3</sup> These values put the United States and worldwide geothermal power plant capacity factors\* at 78% and 73%, respectively.

Geothermal energy is also utilized in direct-heat uses for space heating, recreation and bathing, and industrial and agricultural uses. Geothermal energy in direct-use application is estimated to have an installed capacity of 12,100 MW thermal, with an annual average energy use of 48,511 GW h/year energy equivalent.<sup>3</sup> This excludes ground-coupled heat pumps (GCHPs, see below). In the United States, the first geothermal heating district was installed in Boise, Idaho, in 1892, and is still in operation today.

GCHPs are also often referred to as *geothermal*. GCHP units are reported by Lund to have 15,721 MW of installed capacity and 24,111 GW h of annual energy, representing 56.5% and 33.2% of worldwide direct use, respectively.<sup>3</sup> It should be noted that although these numbers are reported as “geothermal,” in many instances the ground temperature is primarily controlled not by the flow of heat from below the surface, but by the annual average ambient temperature of the location, which is a solar phenomenon. From the numbers above, it can be seen that GCHPs provide an additional worldwide energy production of almost 50% more than that provided by geothermal electric power generation. For more information on GCHP usage, see Chapter 27.

This chapter will cover the technologies and issues in the utilization of geothermal energy for electric power generation, with a particular focus on the issues facing the development of new capacity, both technical and economic. Although the technologies of geothermal energy for power and for direct use are quite different, the issues covered in this chapter related to reservoir issues, and the economic factors affecting or controlling the development and maintenance of the reservoirs are often the same or similar.

---

## 51.3 Requirements for Commercial Geothermal Power Production

For new geothermal power to be installed, or an existing geothermal power plant to continue operating, commercial geothermal power production requires two major elements: a geothermal resource and economic access.

### 51.3.1 Definition of a Geothermal Resource (Heat, Permeability, Water)

A geothermal resource for power production comprises three major elements: heat, sufficient reservoir permeability, and water.

1. Heat is clearly the first element for commercial power generation. Most commercial geothermal resources produce fluids from reservoirs with a resource temperature of at least 320°F. However, there are examples of geothermal fields with lower temperature fluids. Nonetheless, resource temperature is a good first indicator of economic viability, see [Table 51.1](#). As can be calculated from the table, the flow requirements for a 60 MW plant are 18 million lb/h of 300°F geothermal liquid, but only 4 million lb/h of geothermal liquid if the reservoir temperature is 450°F.

---

\* Capacity factor is defined as the actual generation produced compared to the theoretical generation that would be produced in 1 year with the power plant running at full rated capacity.

**TABLE 51.1**

Power Generation Potential from a Range of Resource Temperatures

1000 lbm Geothermal Fluid of	Electrical Generation (kW h)	Power Plant Type <sup>a</sup> (see Later Sections)
Liquid at 300°F	3.3	Binary
Liquid at 350°F	5.6	Single-flash steam
Liquid at 400°F	10.4	Double-flash steam
Liquid at 450°F	14.5	Double-flash steam
Steam at 350°F	53.5	Dry steam

Source: From DiPippo, R., *Geothermal Power Plants: Principles, Applications and Case Studies*, Elsevier Advanced Technology, Oxford, U.K., 2005, p. 424.

<sup>a</sup> The column labeled “power plant type” is the technology used as a basis for the power generation calculation. All plant types are used over a larger range of temperatures than that indicated in the table.

2. *Permeability* describes the ability of the reservoir fluid (water or steam) to flow through the rock formation. Permeability allows deep-seated geothermal heat sources to create a geothermal resource through the convection (flow under the influence of heating and cooling) of hot water or steam. The convection of the geothermal fluids through the reservoir heats a large volume of rock, thereby storing a large quantity of energy over a period of tens of thousands of years. Geothermal reservoir permeability is dynamic, with the hotter fluids dissolving minerals and increasing permeability, and the cooling fluids depositing minerals and restricting permeability. Reservoir permeability is what allows the extraction of that stored heat through a relatively few number of wells in commercial geothermal developments.

*Matrix permeability* is the ability of the fluid to flow through the bulk rock itself. Fresh water wells, natural gas wells, and oil wells are frequently observed to obtain a significant portion of their total flow from matrix permeability. In other words, the fluids enter the wellbore as uniform flow along an area of unfractured rock. Sufficient matrix permeability is rare in geothermal wells that will support commercially significant flow rates.

*Fracture permeability* is low most geothermal wells which obtain the majority of total wellbore inflow through naturally occurring fractures in the rock. Pervasive fracturing allows a single well to obtain flow contributions from a large area at high flow rates, even where the matrix permeability is low. In most cases, the fractures extend over large areas and volumes as a result of tectonically active areas, but some fields have been discovered and developed that essentially comprise a single fault system (which may be comprised of multiple fractures in the rock). In such fields, only wellbores that cross the fault produce geothermal fluid at commercial rates.

3. Water is the motive fluid for geothermal power production. It may be brought to the surface as steam from one of the few (but typically large) geothermal steam fields, such as Larderello (Italy), The Geysers (California), and Kamojang (Indonesia). A water–steam combination may also be produced to the surface from high-temperature liquid-dominated or liquid-and-steam reservoirs. In low- or moderate-temperature resources, pressurized water may be pumped to the surface using downhole pumps.

The development of new geothermal power plants and the expansion and maintenance of existing geothermal fields depends on the three elements of heat, permeability, and water.

The three occur simultaneously in relatively few places around the world, but there remain many thousands of megawatts of undeveloped worldwide and U.S. resources. Over the long term, the natural resource base for geothermal power could be supplemented with human intervention to create new systems or enhance existing systems.

### 51.3.2 Improving a Geothermal Resource through Human Intervention

The terms *hot dry rock* (HDR) or *hot fractured rock* (HFR) refer to a family of experimental technologies that are not yet commercially proven. The objective is to establish one or more of the missing elements of a commercial geothermal resource (specifically, permeability or water) where a heat source already exists. HDR experiments have been undertaken as research projects by the U.S. Department of Energy and similar agencies in Europe and Japan. The problems are daunting and the costs are high; U.S. DOE funding, for example, has diminished substantially from its maximum in the 1980s.

The concept behind HDR and HFR is to drill a well into the hot rock and then pump water into the well at very high pressure, causing the rock to fracture. The fractures provide a heat transfer surface and flow path allowing water to be pumped from the surface into an injection well, circulated through the man-made fractures, and ultimately recovered in a production well some distance away from the injection well. The theory is straightforward; unfortunately, the implementation to date has not been.

As of 2005, the first privately-funded HFR development had commenced at the Cooper Basin in southern Australia, and it will be watched closely for its success. The developer's plans call for an initial installation of a 3 MW power plant if the fracturing process is successful.<sup>5</sup>

If HDR and HFR technology is developed and implemented in significant quantities over the next 20 years, the geothermal reservoir management strategies and the energy-to-power conversion technologies will be much the same as that described in the rest of this chapter.

Between the naturally-occurring resource base and the potential man-made resource base of HDR/HFR is the enhanced geothermal system (EGS). EGS technologies seek to supplement a naturally occurring geothermal resource primarily by the addition of more liquid, or by stimulation of wells to tie into a larger, naturally occurring fracture network. The goal of EGS is to extend the life or capacity of existing fields, rather than the creation of an entirely new resource, as is being attempted at the Cooper Basin described above. There have been many studies, evaluations, and proposals to date, and the use of EGS at The Geysers project—including those plants owned and operated by Calpine\* and NCPA†—has been a proven success.

At The Geysers, two pipelines bring 77,000 m<sup>3</sup>/day (20 million gal/day) of treated wastewater from adjoining cities to the mountains where The Geysers facilities are located. The water serves to replace that which has been depleted from The Geysers over its approximately 50 year operating history. Stark et al. report that tracer tests show that 40% of the injected water is recovered as steam within a year. The injection of the water from just one of the two pipelines (delivering about 55% of the total wastewater) is forecast to result in an annual average generation increase of 84 MW. With a parasitic pump load of 9 MW, the annual average benefit is roughly 75 MW.<sup>6</sup>

### 51.3.3 Geothermal Energy as a “Renewable” Resource

Throughout this chapter, declines in flow rates from geothermal wells and output from geothermal power plants are discussed. What does this mean in terms of whether geothermal energy is renewable?

In recent years many thoughtful papers have been published on the renewability and sustainability of geothermal energy... However, no universally accepted definitions of the words “renewability” and “sustainability” seem to exist and definitions used often have ambiguities...<sup>7</sup>

From a thermodynamic point of view, it may seem that the only true renewable geothermal development would be one in which the extraction rate is the same as the natural heat influx rate into the system. However, reservoir simulations and field observations frequently reveal that the natural heat influx rate increases as production occurs, due to pressure changes that allow more hot liquid to flow into the system. Therefore, operating at a “nonrenewable” level increases the ultimate energy extraction from the resource. More importantly, a true “renewable” level of energy extraction would very often be sub-economic, and is therefore of little interest in the development of geothermal resources for society’s benefit.

Another definition argues that, as long as the power or heat usage from the resource continues at a constant level for hundreds of years, it approximates a true renewable resource, although it may be termed a “sustainable resource.” Again, this is an interesting theoretical discussion, but not one that actually is put into practice in the development of most geothermal resources, for both the reasons of economics and an inability to know what this actual level would be.

Sanyal (2004) argues that sustainable geothermal development occurs if the project maintains its output, including make-up well drilling, over the amortization period of the power plant.<sup>7</sup> This definition recognized the critical role that economics plays in actual natural resource development decisions. In short, projects are developed to meet economic requirements. This is true of any new power project, whether geothermal, another renewable source, or a fossil-fired resource. Section 51.3.4, will illustrate why the question of sustainable development for a 50-year period, let alone a 300-year period, will not play a role in the development decisions for a particular geothermal resource. The reason, in summary, is that even at a mere 50 years in the future, there are no meaningful economic consequences to development decisions made today when using a discounted cash flow analysis.

More valuable than the theoretical discussion of whether geothermal energy is renewable, sustainable, both, or neither, is to look at the history of geothermal development. Geothermal use at Larderello, Italy, is over 200 years old, starting with mineral extraction in the early 1800s and including almost 100 years of commercial power generation. During the last 100 years of power generation, turbines have been renewed or replaced, power output has grown and shrunk and grown again, and new methods of extracting more energy have been developed. In fact, geothermal power generation in 2003 was higher than any other year, with 5.3 billion kW h produced.<sup>8</sup>

Many further decades of geothermal power generation are expected from the Larderello region, as well as Wairakei, The Geysers, and other fields that are approaching 50 years of power generation. Geothermal power-generating facilities only very rarely cease operation, although few will reach their 50th anniversary at their maximum generation level.

### 51.3.4 Economic Access

Given that a geothermal resource exists—whether naturally occurring or developed with EGS or HDR technologies—the resource will be economically viable for power generation only if the four elements of economic access are met: wellhead energy cost, electricity transmission, a market for the electric power, and the power plant cost.

#### 51.3.4.1 Economic Access: Wellhead Energy Cost

Wellhead energy cost is the total cost to bring useable geothermal energy to the surface and to return the cooled geothermal fluids to the reservoir. The thermodynamic condition (pressure, temperature, and flow rate) of the geothermal energy at the surface will influence the capital cost of the power plant. The wellhead energy cost is the result of the combined effects of the productivity of the well, the cost to drill the well, and the enthalpy (or available energy) of the fluid that is produced from the well, among other aspects. These factors vary widely from field to field, and even within a single field.

- Well productivity is the ability of the well to bring fluid to the surface at a temperature and pressure useful for power generation. Clearly, the more fluid that is produced by each well, the fewer wells are needed for a given power plant size, and therefore the lower the total cost of the geothermal well-field development. Less obvious is the fact that highly-productive wells can also have a major impact on the cost and design of the power plant itself.
- Highly-productive wells allow the power plant inlet pressure to be increased (and thereby increase the available energy) on plants that directly use the geothermal steam in a turbine. An increase in the power plant inlet pressure can allow the size of the plant to be increased, because last-stage turbine blades can only be built to a limited maximum size in geothermal service and in binary power plant turbines as well (see Sections 51.5 and 51.6). Alternatively, for plants contractually limited to a particular megawatt capacity, e.g., 60 MW, higher inlet pressures reduce the amount of fluid that must be extracted from the reservoir and delivered to the power plant, thereby reducing the size of the heat rejection system and the injection capacity (two major components of geothermal power costs, as will be discussed in later sections).
- In binary power plants (see Section 51.6) with pumped wells, highly productive wells not only reduce the direct drilling costs, but also reduce the number of pumps that must be installed (at an installed 2005 cost of roughly \$500,000 each). Even more importantly, the pumps can be set at a shallower depth, thereby reducing the pump parasitic loads. The energy for the production pump parasitic loads (400–1000 hp per pump) is supplied by the power plant itself. Again, the productivity of the wells will either reduce the size of the plant that must be built to meet contractual and pump parasitic obligations, or can increase the amount of power available for sale from a particular power plant. The combined effect of fewer wells and more power sales dramatically increase the economic viability of a new or expansion geothermal binary power plant development. Well injectivity is a similar issue for the disposal of the residual geothermal liquids for both binary and steam power plants.
- The energy production rate (a combination of mass flow, temperature, and steam content) of production wells vary from field to field, often varying substantially

within a given field itself, and almost always changes over time for a particular well. In steam power plants, high-enthalpy wells can result either from a high-temperature portion of the field, or as a result of what is termed “excess steam” production. Excess steam occurs when the enthalpy of the produced fluid is higher than the enthalpy of the reservoir fluid as a whole due to the greater mobility of the steam through the reservoir rock than liquid water. In pumped brine binary power plants, high-enthalpy wells are simply wells with higher flowing temperatures. For both steam and binary power plants, higher enthalpy wells result in lower power plant cost, as the benefits of the higher enthalpy are found in lower drilling costs (fewer wells), lower heat-rejection system costs (higher available energy per unit mass into the plant), and lower brine-injection costs (less produced fluid).

- The depth of geothermal resources is highly variable, with most geothermal resources produced between depths of 1500–7000 ft below surface, although resources commonly exist outside of this range. One example of a shallow resource is the Salt Wells field in Nevada, in which the production and injection wells are between 450 and 750 ft deep. One particular well at that field is reported to be only 470 ft deep and to be capable of between 4 and 5 MW of power from 140°C (284°F) fluid. The drilling time for this well was only 12 days.<sup>9</sup> The cost of the well is on the order of hundreds of thousands of dollars. By contrast, make-up wells drilled at one field in the Philippines almost 25 years after the start of production had a true vertical depth of over 10,000 ft, and an even greater measured depth due to the lateral reach of the well. The cost of these wells between 2001 and 2003 was on the order of \$3 million to \$5 million each. At the Puna geothermal project in Hawaii, drilling is difficult and the location remote, so the daily drilling cost is high. Wells drilled in 2005 cost approximately \$6 million, and were drilled to a depth of about 6000 ft.

There is no threshold value for the wellhead energy cost below which geothermal development is viable and above which it is not. Rather, there is a continuum in which the effects of transmission, market, and the power plant cost affect to varying degrees the ability to construct a new geothermal plant.

For existing power plants, the wellhead energy cost determines whether or not a make-up well will be economical, and ultimately the end of make-up well drilling. After make-up well drilling ends, geothermal power plants enter a period of slow decline in the output of the power plant over the coming years and decades. Although the plant is no longer able to achieve its initial rated capacity, it will continue to operate economically, literally for decades. There are very few examples of geothermal resources that, once in operation, shut down completely.

#### **51.3.4.2 Economic Access: Electricity Transmission**

With a suitable geothermal resource and a viable market for geothermal power, the link between the two is transmission. As with other renewable and nonrenewable energy sources, transmission can be a significant issue in the viability of development of a new geothermal resource, or in the expansion of an existing geothermal power facility.

Occasionally, geothermal resources are found in close proximity to existing transmission access. Examples include Steamboat Springs, Nevada and Raft River, Idaho. For these developments, the cost of transmission access is low, and transmission line construction and interconnection does not play a major role in the development of the resource.

However, geothermal resources often occur at substantial distances from existing transmission, and entail the need for considerable capital expenditures on the transmission system to deliver the power to the customer. If the field is large enough, the long transmission lines and expenses can be justified. Two separate subsea cables were built in the Philippines to transport hundreds of megawatts of electricity generated from geothermal resources from islands with small native loads to the main load center on the island of Luzon.

The cost of the transmission line has most often been the responsibility of the utility that was receiving the power (e.g., Pacific Gas and Electric for the power generated at The Geysers), whereas in more recent years, the development of the power line has been the responsibility of the geothermal developer in the United States. The power price offered to geothermal and other renewable developers may fail to recognize this cost (e.g., the Idaho PURPA posted rate), yet the cost must still be borne by the developer, and as such, the cost of transmission construction can become a substantial burden to the project economics. A 107-mile-long dedicated transmission line was built and paid for by a consortium of geothermal power developers in the Imperial Valley, California, to deliver some 500 MW of power to a common customer, Southern California Edison. After the line was built, it was turned over to the local utility, the Imperial Irrigation District, for ongoing operation and maintenance.

When a transmission system is used to deliver power and the transmission lines are owned by an entity other than the ultimate purchaser of the power, the use of that transmission system incurs wheeling costs. Wheeling costs comprise a monthly reservation/use fee and a power loss that can be paid either with funds or with power delivered to the transmission entity. Typically, wheeling charges are not charged by the utility that actually is receiving the power under contract. "Pancaked charges" refers to the circumstances in which power crosses multiple transmission segments owned by different entities, incurring separate transmission charges through each segment. The losses assessed by each utility usually are not based on actual losses for the power being transmitted, but represent a system-wide average apportioned out to the users of the system on a pro-rata basis. In the United States, wheeling protocols are established by the FERC (Federal Energy Regulatory Commission).

Common wheeling charges are 1%–5% for losses, plus \$1000–\$3000 per MW-month for the reservation costs for firm capacity. Therefore, wheeling through more than one, and often even only one, utility becomes prohibitive. As a result, the viability of development is strongly influenced by the willingness of the utility in whose control area the power plant is located to accept the power. Delivery to the closest utility generally eliminates wheeling fees and losses and improves the economic viability of the plant. On the other hand, having only a single party with whom to negotiate a contract puts the developer in a difficult position.

In deregulated markets, such as the United States, transmission reservations are the mechanism by which a power plant ensures access to the market for the life of the contract. The ability to obtain that reservation is critical to development, or else the geothermal development may face greatly increased transmission costs for transmission upgrades or longer transmission lines. One of the advantages of geothermal power as opposed to wind power is the efficiency of transmission usage. Both resources must reserve transmission capacity for their peak delivery, e.g., 100 MW. Wind will typically deliver between 25 and 40 MW on an annual average basis, while geothermal will typically deliver about 90–95 MW. On the transmission system peak hours, the difference in utilization will be even greater, due to the intermittency of the wind resource and the typical incentives in

a geothermal contract to be on-line during peak hours. A geothermal power plant can be expected to be on-line and at near-full capacity for over 95% of the peak hours.

Where transmission system capacity is limited, geothermal and other baseload resources will make much greater use of that capacity. Comparisons of new generation costs seldom account for the efficiency and hidden costs of transmission usage, which is unfortunate in the evaluation of the economics of geothermal power generation, because it is so efficient in its use of transmission capacity.

#### **51.3.4.3 Economic Access: Viable Market**

Power generation, regardless of the technology, is a highly specialized form of manufacturing. As with all manufactured products, there must be a place to sell the manufactured product. Therefore, for new geothermal power to come online, regardless of how low the wellhead energy cost and even if transmission is readily available and affordable, without a market, there is no development. Market consists of three elements: willing buyer, price vs. characteristics, and contract provisions. The first two are much the same for all power developments, whether renewable or otherwise. For geothermal power, there are unique contract provisions that must be present for realistic expansion of the role of geothermal power in the electrical demand of the United States.

##### *51.3.4.3.1 Willing Buyer*

The willing buyer must be just that: “willing” and a “buyer.” In the United States, this rare beast has been found in a number of geothermal development habitats over the last 40 years. More recently, the captive breeding program seems to be showing success. A much larger number of willing buyers have been observed, as many U.S. electric utilities have been stung first by wild swings in natural gas prices, second by 2004–2005 gas prices climbing from \$4 or less to over \$10 per million Btu, with long-term price forecasts for gas remaining high, and lastly by state-mandated renewable energy targets.

From 1960 through roughly the mid-1980s, geothermal development in the United States (and in many places around the world) was most commonly undertaken by two parties: the resource developer and the local utility. The resource developer drilled wells and built cross-country pipelines to deliver a flow of steam or mixed brine and steam to the power plant boundary. The resource developer also was responsible for injection of the residual liquids, both brine and condensed steam. The local electric utility—i.e., the willing buyer—used the steam to generate power. Under this U.S. development model, the utility met the mandate of its monopoly franchise to supply power. The utility also met its investor’s objective of investing in new facilities, the power plant and transmission lines, for which it was able, under its monopoly, to earn a regulated rate of return on the invested capital dollars. However, an inherent inefficiency was created in this development model by having two owners who each had different economic drivers, separate operating groups that worked side by side, double administration costs, and other factors. One common and unfortunate outcome of the two-owner model occurred because the steam was sold on a \$/MWh basis instead of on the energy content of the steam. The consequence was that the power plant owner built inefficient power plants because inefficiency is cheaper than efficiency, if one only looks at the power plant cost. Of course, the consequence was that the steam developer had to drill additional risky and expensive wells to supply additional steam for the inefficient power plant. Those few contracts that had steam sales based on energy content saw exactly the opposite effect in power plant design. The power plants tended to be very efficient to minimize steam use

(fuel cost). The net result of two-owner operation was that the price of geothermal power was comparatively high and resource utilization was inefficient.

With the widespread occurrence of independent power producers (IPP) in the United States in the mid-1980s, a regulated utility could theoretically obtain a lower price through the integrated operation of geothermal field and power plant and could meet its mandate for power supply, but by buying power from the IPP, the utility could not meet the objectives of its shareholders for new investment. The IPP developer's objective of building a power plant put it in direct competition with the utility for the return on investment in new power plant capacity. Under the IPP model, each megawatt of capacity installed by an IPP directly equates to less investment by the utility in baseload power (potentially \$700,000–\$1,700,000 per MW). Consequently, because the utility faces a reduced rate base (the capital on which the utility is allowed to earn a return), the IPP faces an intrinsic unwillingness in the utility to procure the output of a new geothermal (or any other type of fuel) plant. Although geothermal development should, in theory, thrive under the IPP model, the reality is that utilities in the United States have shown little interest in bringing on new geothermal development unless forced to do so in the interest of the ratepayer by governmental authority.

From the mid-1980s through the mid-2000s, many geothermal power plants were built exclusively because of the Federal PURPA\* regulations and the consequent requirement of state public utility commissions for the utility to buy the power at a published avoided cost. For example, California's Standard Offer Number Four resulted in the construction of several of the Salton Sea and Heber Units, among others, in the late 1980s and early 1990s. Idaho's Posted Rate 10 MW PURPA contracts resulted in the development of the Raft River Geothermal Power Plants in southern Idaho, with anticipated operation dates of 2007 through 2009. In California and Nevada, the passage of Renewable Portfolio Standards has also spurred utilities to contract for geothermal power to comply with state law. Both PURPA and the RPS have created utility buyers, but they have not necessarily been "willing." The state RPSs and the prospect of a federal RPS is now emerging as a major factor in the decision of utilities to sign contracts for IPP-developed geothermal (and other renewable) power plants, in spite of the fact that it is against the interests of their shareholders, though not their ratepayers.

#### 51.3.4.3.2 *Price of Delivered Power*

The price vs. the characteristics for the electrical energy is the most obvious component of a viable market. The characteristics of geothermal power are very attractive and rare in the renewable power industry. It is price-stable, has low to negligible environmental impact, and has a steady, predictable, and reliable output.

The unit price paid for geothermal-generated electrical power must cover the expense of the power plant and the wellfield development, as well as the often long and expensive exploration phase. In addition, the price paid per MW h must satisfy annual cash flow requirements and the return on investment sought by the geothermal developer. As most contracts from the late 1990s onward are not in the public domain, it is hard to know what constitutes an adequate price for electricity generated from geothermal energy. A few that have emerged are described below.

In 2003, the power purchase prices awarded to three geothermal power plants after a round of renewables bidding in Nevada were inadvertently released. The contracts were for both the power output and environmental attributes ("green tags," carbon credits, etc.).

---

\* PURPA is the Public Utility Regulatory Policies Act.

Two were for expansions to existing power plants. One price was less than \$45 per MW h, and the other was more than \$52 per MW h. The third contract was for a greenfield power plant at under \$50 per MW h. All were for resources with temperatures greater than 320°F. Only the power plant that bid the highest price was ever built. The other plants proposed power purchase prices too low to actually accomplish development drilling, build the power plant, and close financing. The prices bid for these plants were offered before the 2004–2005 worldwide run-up in steel prices that had a tremendous negative impact on the cost of building a geothermal power plant with its miles of steel well casing, miles of steel surface piping, and enormous steel heat exchangers.

In January 2005, the Idaho Public Utility Commission approved a 20-year PURPA contract to supply power from the U.S. Geothermal, Inc.\* Raft River Geothermal Power Plant for an initial price of \$52.70, escalating at 2.3% per year.<sup>10</sup> This gives an equivalent levelized price of \$60.99. Although Raft River is a greenfield development, the production and injection wells were drilled in the late 1970s, with those costs written off by previous owners.

In May 2005, two 10 MW contracts were announced at a fixed price of \$57.50 per MW h with an annual escalation of 1.5%. These contracts were for expansions to existing power plants at two different fields in southern California (Heber and East Mesa). The price includes the value for the energy, as well as the environmental attributes. The contract also allowed for the sharing of U.S. federal production tax credits (PTCs) with the power purchasers.<sup>11</sup> The levelized price, excluding the PTCs, would be about \$63. Speaking at the groundbreaking of an additional 8 MW expansion of the Heber facility, Robert Foster, the President of Southern California Edison, said, “I like... the geothermal plant... because we know that these plants produce reliable power 24 × 7. Unlike other forms of renewable energy, I know that this energy will always be there and we don’t need to have shadow generation to support geothermal power. Even though we like to have dispatchable<sup>†</sup> power, we can forego dispatchability for the reliability of geothermal power.”<sup>11</sup>

An international benchmark is the Sarulla, Indonesia, development, in which the state oil company drilled the wells for the power plant and the power plant developer was responsible for the power plant and pipeline system (excluding the cost of transmission and drilling.) The power price was bid at approximately \$45 per MW h in 2005 by two companies. Price escalations and adjustment factors are not available at the time of this writing.

An adequate selling price for the generated electrical power in a geothermal development is determined in part by resource temperature (higher temperature means lower power plant price), wellhead energy costs, power plant size (smaller requires higher price) and whether the new power plant is greenfield or an expansion (expansion can take advantage of existing infrastructure and personnel costs). Within the geothermal community, the general rule of thumb is that for geothermal resources above 300°F, a true grassroots geothermal power plant must sell power for \$60–\$65 per MW h for at least 20 years, for an all-in project (wells, pipelines, power plant, and transmission). Expansions to existing facilities can reduce the cost by 10%–15%,<sup>12</sup> or roughly a \$5–\$15 per MW h reduction, with most of the savings being in a lower drilling failure rate, use of the existing transmission line, and sharing of operating personnel and spare well capacity. [Figure 51.1](#) provides representative cost elements in a geothermal power development.

\* U.S. Geothermal, Inc., <http://www.usgeothermal.com>.

† A dispatchable plant can be ordered to vary its load from zero to full load to meet the needs of the electric power grid.

**FIGURE 51.1**

Typical cost breakdown of geothermal power projects. (From Hance, C.N., Factors affecting the costs of geothermal power development, Geothermal Energy Association and the U.S. Department of Energy, Washington, DC, 2005.)

#### 51.3.4.3.3 Contract Provisions for Operation

Contract provisions for a viable geothermal power market are twofold: those governing once the plant is up and operating, and those that govern prior to the operation date.

**Baseload:** The nature of geothermal power plants lead to the general requirement that geothermal plant contracts allow them to operate *baseloaded*\* at full available capacity. Three factors lead to this requirement: low variable costs (see Table 51.2), high plant availability, and high fuel/plant capacity factor.

Geothermal plants have low variable costs, which are those costs resulting from changes in plant output. Therefore, any dispatch order that reduces the output of the geothermal plant simply raises the cost of power during noncurtailed periods to recover the fixed costs. The geothermal power plant operates most effectively and at greatest economic efficiency at full baseload.

Geothermal power generation typically operates at a 95%–99% plant availability (hours capable of operation per year divided by hours per year). What this means is that as long as the plant has permission to operate, it will generate power, because it also has a high fuel availability. By contrast, wind generation also has high mechanical availability, but because the wind is not blowing all the time (no or low “fuel” availability), the plants do not generate, even though they are “available.” Although there is little difference in wind and geothermal generation plant mechanical availability, the capacity factors are very different because of the nature of the fuel supply.

Geothermal power plants typically operate at high capacity factor (MW h generated per year divided by the product of hours per year and plant capacity).† The high mechanical availability and the steady flow of energy from the production wells means that geother-

\* The term baseload refers to the minimum amount of power continuously required by a utility's customers over a 24 h or annual basis. A baseloaded plant is one that remains on-line at all hours of the day at maximum or near maximum output to serve that demand.

† The fuel-capacity factor is useful in addition to the plant-capacity factor, because after make-up drilling is completed, the power plant mechanical capacity remains essentially constant, but the resource capacity declines. Consequently, the power plant capacity factor drops each year, even though the power plant maybe converting essentially 90%–99% of the available fuel supply. The output and performance of the plant remains highly predictable, however, on both an hourly and annual basis.

TABLE 51.2

Comparison of Fixed and Variable Costs for Geothermal and Fossil-Fired Plants

Cost Category	Geothermal Power Plant with Wells and Piping		Fossil-Fuel Power Plant	
	Variable Cost	Fixed Cost	Variable Cost	Fixed Cost
Fuel costs to increase plant output from 50% to 100%	Geothermal royalties (1%–5% of gross power sales)	Drill wells and build pipelines, mostly before start-up of plant	Essentially entire additional fuel cost	Not applicable
Cost/savings to stop plant and restart later	Low cost savings other than royalties. Low additional costs other than ongoing fixed costs	May have to vent steam to air rather than shut-in wells, and expose wells to thermal cycling damage	Fuel savings when stopped. Fuel costs to keep warm or cold start plus start/stop related maintenance costs	Not applicable
Fixed operating personnel costs (number of MW that carry cost of each staff person)	Not applicable	10–13 people for 0–15 MW = 1–1.5 MW/person 13–18 people for 40–120 MW = 2–8 MW/person	Not applicable	15–20 people for 250–550 MW = 13–36 MW/person
Fixed capital costs	Not applicable	\$1400–\$3000 per kW of capacity	Not applicable	\$700–\$1300 per kW of capacity

mal power plants as a class are unsurpassed by any other generation technology, whether renewable, fossil-fueled, nuclear, or hydro.

*Seasonal Pricing:* Another contractual provision in many geothermal power supply contracts is for the utility to have seasonal pricing. For example many California and Nevada geothermal contracts have prices that are higher in the summer and lower in the spring and fall. This provides the geothermal plant operator incentive for the power plant to be online in the peak summer hours, when replacement power is the most expensive for the utility. The reliable and predictable summer peak output is one of the advantages for a utility (and its ratepayers) to have available energy sources using biomass, geothermal power, and solar generation. Because summer peak power spot market costs and the cost for simple-cycle gas turbine generation can commonly rise to over \$150 per MW h in the summer, the reliable fixed-cost prices of nonintermittent resources reduce the cost of meeting summer peak loads.

#### 51.3.4.3.4 Contract Provisions for New Geothermal Development

Unique contract provisions are advantageous for *development* of new grassroots geothermal power plants as opposed to the expansion of an existing geothermal power plant. The expansion of an existing geothermal power plant is based on the historical performance of the geothermal resource. Therefore, operators of existing plants can commit to definitive start-up schedules and subsequent liquidated damages (LD) for missing those schedules. This is not so with new geothermal plants. Unique contract provisions can assist in the development of a grassroots geothermal power plant by recognizing and mitigating the risks, uncertainties, and costs of such development.

One unique challenge to the development of a grassroots geothermal power plant can be a contractual “chicken and egg” situation in which two events must occur, neither of which can occur before the other has been satisfied. The first of these is that it is very difficult and expensive, if not almost impossible, to secure funding for exploration drilling without a power sales contract. Geothermal energy, in comparison to natural gas or oil, is neither transportable nor does it have an automatic market after its discovery. Therefore, before risking the large capital for an exploration program, investors (whether as shareholders or venture capital) want a utility commitment to buy the geothermal power if a commercial resource is discovered. On the other hand, it is often not possible to sign a power sales contract without a proven resource, because the power sales contract may contain a large LD clause for failure to deliver the contracted power by a contracted date, and may include the requirement to post a large bond.

One solution for those utilities that would like to add geothermal power to their mix of resources to consider contracts with geothermal developers that recognize the risk, uncertainty, and cost in the discovery of a new geothermal field. Such contracts would not contain penalties for failure to discover a resource, but will assure the developer a market should their exploration efforts be fruitful. Provisions of the contract to protect the utility can include the following:

1. A price acceptable to the utility.
2. An expiration date 2–5 years beyond the date on which the contract is signed, by which time the developer must produce a resource discovery report or forfeit the contract.
3. A requirement for a notice of intent from the developer to deliver first power to the utility after 2–3 years.
4. The requirement for bonds or LDs for failure to deliver after the submission of the notice of intent.

The delay between the notice of intent and first power is of minor consequence for the developer, as the cycle time from resource confirmation to commercial operation will generally be 2 years or more, and the delay gives the utility the necessary time to time to plan for the delivery of the power. There are no statistics on success rates for grassroots exploration to power plant commercial operation under such a contract scenario, but it is likely that a utility that wants 50 MW of geothermal power should plan on signing resource discovery and power purchase contracts for between 75 and 100 MW from two or more exploration prospects.

### 51.3.5 Economic Access: Power Plant Cost

Power plant costs comprise two elements: the capital cost and the operating cost.

#### 51.3.5.1 Capital Costs

Capital costs vary according to four major variables:

1. *Resource temperature*: Higher temperature resources have lower \$/MW capital cost. [Table 51.1](#) indicates the first benefit of higher temperature, namely lower flows, and hence, fewer wells and smaller components are needed. However,

the reduction of the size of the heat rejection system (condenser and cooling system) required per megawatt of capacity is also of great value. Higher-temperature fuel sources require much less cooling than lower-temperature sources. This is illustrated by a comparison of fossil-fuel power plants and geothermal plants in which geothermal power plants may have a heat rejection system eight times as large per megawatt as that in a combustion-turbine combined cycle plant.

2. *Power technology*: Power plants using a binary process generally have a cost several hundred dollars per kilowatt higher than power plants using only steam turbine technology. However, this is not universally true, and binary power technology plants have won numerous open bids around the world over suppliers of steam turbine technology.
3. *Wet or dry cooling*: Steam flash power plants generally use wet cooling with the water supplied by the condensed geothermal steam. Binary power plants can use wet or dry cooling. In most climates, wet cooling gives an advantage in net plant output over dry cooling, and also causes less capacity degradation than dry cooling in the peak summer hours. Because these peak hours are generally the utility's most expensive hours, wet cooling offers utilities a benefit. However, there is often not water available (neither condensed geothermal steam nor meteoric waters) for a binary power plant cooling system, and therefore, dry cooling is used.
4. *Plant size*: Larger plants and larger machines are less expensive per kilowatt of installed capacity than smaller plants and smaller machines. This occurs both because of the general economy of scale of machine size, as well as a distribution of fixed costs (e.g., civil engineering, roads, site preparation, instrumentation, insulation, and paint) over a greater plant size.

### 51.3.5.2 Operating Costs

Geothermal plants have low variable costs, which are direct costs resulting from changes in plant output. Fixed operating costs are those costs that exist even if the power plant is not operating, e.g., personnel and interest on loans. If output is reduced, the staff costs are the same, the fuel costs are the same (i.e., the amortization of the well costs), and chemical use changes negligibly. Thus, there are no cost savings with a reduction in geothermal plant output other than the royalty paid to the holder of the geothermal rights. For all intents and purposes, a geothermal power plant has only fixed operating costs. [Table 51.2](#) illustrates the difference in variable costs between a geothermal plant and a combined cycle plant using a combustion turbine. The table illustrates why baseloaded operation is optimal for geothermal power plant cost structure whereas a dispatchable operation fits the cost structure of fossil-fired power plants.

Not only does reducing the output from a geothermal plant not reduce operating costs, but throttling a geothermal turbine to reduce its power output actually has a negative effect on long-term operations, because it increases scale formation at the turbine inlet. Reducing the flow from geothermal wells on a regular basis, as would be required if the plant is not operated at baseload, can also induce damage in both the wellbore and the steel well casing in certain geothermal fields due to thermal or pressure cycling.

## **51.4 Exploration and Assessment of Geothermal Resources**

Geothermal resources capable of sustaining commercial electrical production require specialized methods of exploration and assessment. To finance the high initial capital cost of a geothermal power plant and wellfield, the equity and debt providers must be assured that a geothermal reservoir is capable of sustaining the expected amount of energy production for a period of 20–30 years. Likewise, the purchaser of power, typically a local electrical utility, must have adequate assurances to justify entering into a long-term power purchase agreement (PPA). The geothermal industry has developed a suite of exploration and reservoir assessment techniques which provide the assurances required by all parties involved in a particular project.

Even when an active geothermal system is found, many geothermal discoveries do not lead to commercial development for a host of reasons, as discussed previously. This does not necessarily mean that a particular geothermal resource is forever noncommercial. Raft River (Idaho), Salt Wells (Nevada), and other resources under development in 2005 were discovered, drilled, and assessed in the 1970s and 1980s and were deemed noncommercial. Today, these resources are under commercial development, through a combination of improvements in exploration techniques, changing electrical power and natural gas markets, and advances in geothermal power technology.

Although this section is written from the perspective of geothermal development for power production, the same considerations and approaches are used for geothermal resources developed for direct-use applications.

### **51.4.1 Overview**

The discovery of a geothermal resource and the assessment that it will be capable of sustaining 20–30 years of commercial production is a complex and costly undertaking, and has been the subject of entire books and many journal articles. This section is meant to provide a brief overview of the subject, much like learning geography while looking out the window of the space shuttle at the earth passing by below. In that brief glance, the shape of some of the continents would be largely visible, and one might be able to discern some forest, desert, and cities.

The process of geothermal exploration generally begins with the observation of surface manifestation of geothermal heat; for example, hot springs, fumaroles, or surface deposits of silica (sinters). However, some geothermal resources have no surface manifestations, and are discovered by accident when drilling takes place for purposes unrelated to geothermal development. Several commercial geothermal fields in the western United States have been discovered through the drilling of irrigation wells or mineral exploration holes.

From this initial surface exploration, detailed geoscientific work is undertaken to characterize and assess the size of the geothermal resource underlying the visible manifestations. After a promising resource is identified by the geoscientific study, wells must be drilled to prove the existence of the essential elements of a commercially viable geothermal resource, as described in Section 51.3.1, i.e., heat, permeability, and fluid. The critical first step in the drilling campaign is to drill a discovery well that is capable of producing commercial quantities of hot fluid. With the successful completion and testing of one or more additional wells, the process of exploration ends and the resource is considered “proven.”

Finally, the remaining wells for the development must be drilled. Once the geothermal resource is under production, pressure, temperature and chemistry of the

reservoir are monitored to evaluate and optimize resource production, and to make plans for further development (Section 51.5).

#### 51.4.2 Exploration and Discovery

Surface geoscientific investigations are the first step in the process of discovery. These investigations include geochemical analysis of hydrothermal manifestations (hot springs, fumaroles, mudpots, etc.) and surface geologic mapping, including the type and extent of rock units, hydrothermal mineralization and surface expression of faulting, fracturing, and other structural features. Surface mapping techniques have been greatly enhanced by the use of remote sensing (satellite imagery). Together, these methods may indicate the ultimate resource temperature, provide clues as to the resource structure, and provide evidence of the vigor and extent of the resource. If a water sample can be obtained from a hot spring, the geochemistry, via various chemical “geothermometers,” can provide an indication of the maximum temperature to which the water was heated on its journey to the surface. However, the surface geoscience does not provide a good definition of the depth to the commercial geothermal reservoir, nor can it define its lateral extent or ultimate productivity. Not all hot springs are indications of commercial geothermal power resources, even if the geothermometers indicate a high-temperature origin of the fluid; the geothermometers can be erroneous, or, even if high-temperature water is available, it may not be producible at commercially viable flow rates.

The second step is geophysical investigation to map the lateral extent, depth, and distribution of permeability of the active geothermal system. These investigations and their objective may include those listed in Table 51.3.

The cost of conducting and interpreting a typical suite of geophysical surveys can vary greatly, depending on the individual characteristics of a particular exploration project. The total cost is dependent on the methods chosen, overall size of the area to be explored, the maximum depth to be explored, surface topography and the remoteness of the site. For example, an effective geophysical program to explore and define a small geothermal reservoir in Nevada may cost as little as \$150,000, whereas a program in the remote jungles of Indonesia may cost in excess of \$1,500,000.

**TABLE 51.3**

Geophysical Investigations for Geothermal Exploration

Exploration Tool	Objective	Indicative of
Resistivity	Detection of a clay cap, transition depth to high temperature mineralization	Convecting geothermal system that has deposited minerals to seal-off the top of the system
Seismic reflection	Faulting, structure	Flow paths (good drilling targets), structural block volume
Microearthquake monitoring	Identify active faulting and fracturing	Fracture permeability, fracture density, injection and production drilling targets
Magnetics	Loss of iron minerals	Convecting geothermal system
Geodesy	Active surface deformation	Rapid natural subsidence overlying active rift zones
Self potential	Map natural ground voltage	Shallow active hydrothermal systems
Microgravity	Faulting, mineral deposits	Flow paths, convecting geothermal system
Shallow wells	Temperature gradient	High heat flux, possible max T at depth, lateral reservoir extents

The third, and final, step is the riskiest and most expensive portion of the exploration program: the exploration drilling to determine if the resource is commercially viable. The exploration drilling program can involve both full-size development wells (commonly final casing size of 9–13 in. with reservoir hole diameter of 8–12 in.) and slim holes (final casing size of 6 in. or less and reservoir hole diameter of 5.5 in. or less). Slim hole wells have the advantage of costing only about two-thirds to three-fourths that of a full-size well, but have little commercial value, even if drilled into the heart of the resource. Depending on terrain, remoteness, road requirements, possible maximum resource temperature, depth, and other factors, the cost of the first exploration well will often exceed \$2,000,000, and may reach \$5,000,000 for deep or remote locations. Unexpected drilling problems can result in enormous cost overruns or the total loss of a wellbore and all the investment in it. Rare shallow resources may see exploration wells at less than \$1 million. Follow-up wells, if drilled at the same time, will save on the order of several hundred thousand dollars as a result of shared mobilization and construction costs.

Typically, three to eight wells will be required to prove and delineate an undeveloped geothermal resource, depending on the efficacy of the exploration program used to target the wells, the size of the first power plant, and other factors that cannot be predicted prior to drilling. Sometimes a nonproductive well will eventually be used for injection, so the investment may not be altogether wasted if a particular well fails to encounter commercial production. There are instances when, even after a multiwell exploration program, the resource that is discovered cannot be economically developed at all.

After the first (or, preferably, two or more) well(s) have been drilled and found to flow with commercial temperatures and flow rates, a long-term flow test and an interference test will be conducted. The budget for the flow test, with cross-country pipelines, staff, instrumentation, chemical sampling, interpretation, logistics, travel, and so on, can cost \$200,000–\$500,000, although long multiwell tests can incur greater costs.

The final stage of the geothermal reservoir assessment process is the analysis of the well and reservoir flow testing data. This analysis is done using established reservoir engineering techniques in which the behavior of the geothermal reservoir is numerically simulated at the proposed production rates for the expected duration of the power plant life, typically 20–30 years. The numerical model is used to investigate different production and injection strategies to optimize the resource development strategy. Positive results of this analysis are an essential factor for obtaining the debt and equity financing required for completing the wellfield and initiating power plant construction.

#### **51.4.3 Risk of Exploration**

A modest exploration budget of \$2–\$10 million, staged over the phases above, may suffice for many geothermal resources, but much greater budgets are well documented. Western GeoPower Corp. is a company seeking to commercialize the South Meager Creek Geothermal Project in British Columbia. Because they are a public company, various aspects of their development work are available in the public domain and can be used as a case study.<sup>13</sup>

The company raised over U.S. \$24 million for corporate expenses and a three-well exploration program in the remote area where the resource was located; the program was executed in 2004–2005. As of the time of this writing, the three wells had been drilled, but not flow-tested. These exploration wells were targeted on the basis of previously-drilled wells and surface exploration over the previous 20 years since the resource was first

identified. Temperatures in the three wells were announced to have ranged from 240°C to 260°C (460°F to 500°F), which demonstrates that the thermal basis for the targeting was sound. Western GeoPower has not yet announced whether the other elements of a commercial geothermal resource (permeability and water), per Section 51.3.1, have been discovered.

Regardless of whether or not a geothermal power plant is eventually developed at South Meager Creek, the exploration program demonstrates the potentially high risks and high costs of grassroots geothermal resource exploration. Not only was there substantial cost, but it has taken two decades for the exploration project to get to its current state.

Both geothermal and wind resources are renewable energy sources that must be converted at the location at which they are found, but it is much more difficult to demonstrate a viable commercial geothermal resource than a commercial wind resource. The cost of an array of wind exploration towers, the data collection, and analysis is miniscule by comparison with the cost of geothermal resource exploration. Additionally, the time to prove a commercial wind resource is much shorter. These cash and time costs not only affect the ease and extent of exploration, but the power price that must be obtained to pay for the exploration. The resource discovery process is by far the greatest disadvantage and barrier to expanding geothermal power generation. The costs and risks are why geothermal exploration is most often undertaken outside of the United States with strong government support or with government funding. In the United States, continued DOE support of exploration and discovery through cost-share programs will be necessary to bring significant quantities of new geothermal resources under development.

In spite of the barriers to exploration and discovery of commercial geothermal resources, they are discovered, developed, and electric power is delivered to the transmission grid. The remainder of this chapter is dedicated to these processes, from the resource (fuel) management issues to the power cycles.

---

## 51.5 Management of the Geothermal Resource for Power Production

Geothermal resource management initially seeks to ascertain the initial and long-term behavior of the geothermal reservoir so as to select the optimal power process for the particular geothermal resource, including the changing conditions that might be encountered over the first 20 years. Second, geothermal resource management seeks to design the geothermal resource development to meet short- and long-term economic goals that may include some or all of the following: minimizing invested capital cost in the wells and the power plant, maximizing the power plant installed capacity that the resource can support, and minimizing operating costs.

The complexities and issues of geothermal resource management have no equivalent in any other electric power generation technology, whether conventional or renewable.

- The fuel supply is located 2,000–10,000 ft below the surface, and may be more than 10 cubic miles in volume.
- The response of the resource to development plays a huge role in the overall economic and generation performance of the resource, but the details of the response are largely unknowable until after the resource is under full production for a number of years.

- The “fuel supply” almost invariably changes with time, and as a result, the power plant either must be operated off-design or modified to meet the new conditions.
- Through much of the resource life, make-up wells will need to be sited and drilled to maintain adequate geothermal energy supply to the power plant, which is a combination of flow rate and pressure or temperature.

Although the management of natural gas and oil fields face many of the same issues, fossil-fuel power plants are seldom tied to a single and solitary gas or oil resource.

In this section, the issues involved in managing the geothermal resource, and how the characteristics of the fuel supply interact with the design and operation of the power plant, will be examined. Case studies illustrate successes, changes, and occasional failures in geothermal resource management.

Section 51.5 begins with the large goals, examines some of the subgoals, and ends with the beginning—the characterization of the geothermal resource for the selection of the power process.

### 51.5.1 Goals of Resource Management

Geothermal energy production is the science and technology of heat recovery. At commercially-significant extraction and power generation rates, the heat extraction rate from the production wells is almost always far greater than the natural heat addition rate that created the geothermal resource. The energy balance is closed by extraction of the heat-in-place in the volume of the reservoir, i.e., cooling of the geothermal resource.

$$\text{Heat produced out of the geothermal system per year} - \text{Natural heat inflow to geothermal system per year} = \text{Cooling of geothermal system per year.}$$

The geothermal resource volume is large, however, so the cooling is a long, slow process that allows the geothermal resource to be productive for many decades. (Some of the issues of renewability and sustainability in geothermal power are addressed in Section 51.3.4.) Therefore, the overall strategic goal of resource management is efficient heat mining (cooling) of the geothermal resource. Four of the most important resource management subgoals include (1) minimizing the capital cost of the development, (2) residual brine management (if applicable), (3) injection placement to enhance production, and (4) geothermal fluid monitoring and control, including chemistry, rate, pressure, and temperature.

#### 51.5.1.1 Minimizing Development Capital Cost

To achieve heat recovery from the resource, geothermal fluids (steam or brine) must move through and be heated by the rock. Boiling is the most efficient mechanism, because of the high heat transfer rates of vaporization and the high heat capacity of steam. The native, in-place water is the primary mechanism for many years of the production. Geothermal reservoir rock porosities are most commonly in the range of 3%–10%, but may be as high as 20% in sedimentary systems.

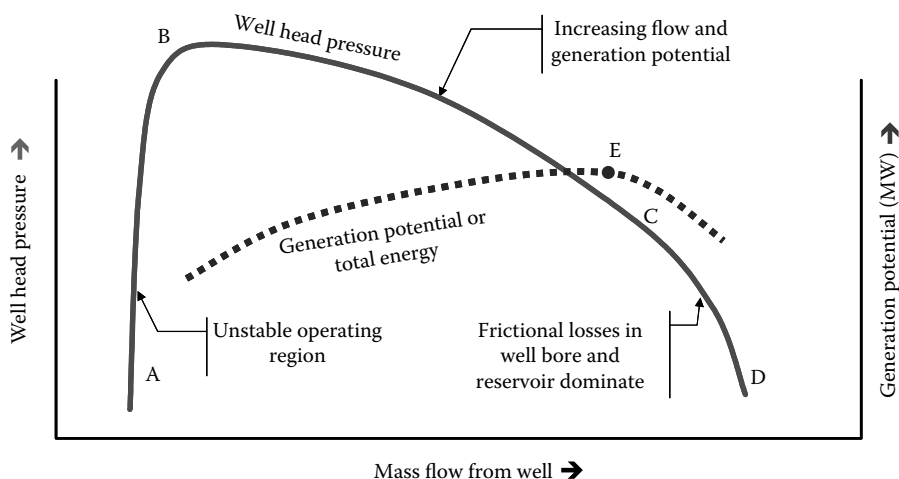

As discussed in Section 51.3, matrix flow of fluid through the bulk rock occurs at only very low rates, so much of the heat of the reservoir volume must transfer by the much slower process of conduction through the rock to the fracture surfaces, where liquid is mobile and heating or vaporization can more readily occur. (This also explains part of the difficulty of creating the HDR/HFR geothermal resources of Section 51.3.2.) The native-state fluid

mass is not sufficient to achieve the goal of heat mining the reservoir. This can only be achieved by flowing supplemental water through the resource. Therefore, the placement of the residual geothermal fluids through the injection wells can have a large effect on the overall capability of the field over the long term. From an ideal heat transfer perspective, the optimal development would be to have many production wells drilled into the hottest areas of the field, with many injection wells ringing the production area to sweep heat and provide pressure support to the production wells. Unfortunately, the need to manage and limit the capital cost of the development intrudes on this Utopian development, and forces geothermal resource developers to seek compromises to the ideal.

Figure 51.2 illustrates a deliverability curve for a hypothetical well producing a mixture of steam and brine. The curve segments are as follows:

- Segment A to B is an unstable flow regime (not all wells have this segment).
- Segment B to C is increasing flow due to greater differential pressure between wellbore and reservoir.
- Segment C to D is the same as B to C, except for an increasingly dominant frictional pressure loss in the wellbore or fractures feeding the wellbore that reduces flow rate at a faster rate than in the segment from B to C.

In the Utopian geothermal development, the well would be operated somewhere just to the right of point B, because point B has the highest available energy per unit mass, and will therefore allow the greatest cumulative power generation over time from the resource. However, there is not much flow at point B, and thus a large number of wells and long lengths of connecting pipelines would be required. This is an unacceptable barrier to economic commercial development, in part because of the high capital, and in part because the additional generation occurs so far in the future that its present worth value is minimal, as discussed in Section 51.5.3. Therefore, a much more common optimization of the wells is to maximize the energy production from the wells (shown as point E on the dashed line in Figure 51.2); doing so minimizes the amount of money invested in production wells because of the high energy production per well. The disadvantages to

**FIGURE 51.2**

A hypothetical free-flowing geothermal production well deliverability curve.

this strategy stem from larger flows per megawatt-hour of generation that result in higher injection well costs (more spent fluid because of lower available energy per pound), higher power plant heat rejection costs (lower useful energy per unit mass), lower ultimate field capacity, and more make-up drilling sooner. The choice of the exact operating point on this curve is much more complex than a single number, but these two extremes (point B and point C) illustrate two of the important issues. A third issue is the provisions of the power sales contract. Power sales contracts that do not limit the output capacity of the field, and in which the field capacity can be fully developed in a short period of time, will tend to push the optimal operating point closer to point B because point B maximizes the ultimate field capacity. Those in which the power sales limit is much smaller than the capacity limit of the field will tend to push the operating point toward point C.

The knowledge of how a resource will respond to development can often be used to minimize the capital cost of the development. For example, at the Salak geothermal field in Indonesia, the reservoir modeling prior to production indicated that there was a region of the reservoir that would quickly evolve from producing a mixture of steam and brine to almost entirely steam production. Wells and a power plant were located in this area to minimize piping costs and to capture the benefit of lower brine handling and injection costs that resulted from the production of nearly dry steam.

#### 51.5.1.2 Residual Brine Management

A large variety of operating practices has developed around the world over the use and disposal of brine, from primarily the two-phase (steam and brine) reservoirs. This is because in two-phase reservoirs, the reservoir pressure is primarily controlled by the steam pressure in the reservoir, whereas in primarily liquid reservoirs, the reservoir pressure is strongly influenced by the injection of the liquids back into the reservoir. A table of options and applications for use of the residual brine is presented in Table 51.4.

**TABLE 51.4**

Uses of Separated Brine in Worldwide Geothermal Power Operations

Option	Use of Separated Brine	Fields in Which it is Used <sup>a</sup>
1	Surface disposal	Wairakei, New Zealand (river disposal). Cerro Prieto, Mexico (evaporation ponds). Tiwi, Philippines (ocean disposal in early years of operation). Svartsengi, Iceland (The Blue Lagoon swimming, bathing, and health spa)
2	District or sensible heating	Nesjavellir, Iceland (indirect heat exchange with fresh water to supply district heating in Reykjavik)
3	Separated hot brine injected back in geothermal reservoir after a single flash due to silica saturation	Bacon-Manito, Philippines. Tiwi, Philippines (current operation). Salak, Indonesia
4	Separated hot brine used as source for binary power plant, and then reinjected	Mak-Ban, Philippines. Rotokawa, Kawerau, and Mokai, New Zealand. Brady Hot Spring, Nevada
5	Hot brine flashed multiple times for steam to power plant, and then brine reinjected	Salton Sea, California. Mt. Apo, Philippines. Hatchobaru, Japan
6	Minerals extraction, followed by reinjection	Salton Sea, California. (After a four-stage flash process, silica is precipitated to stabilize the brine for injection. The silica is disposed in landfill. A multiyear, multimillion dollar effort to recover zinc was abandoned in 2004.)

<sup>a</sup> Examples, not a complete list.

In geothermal reservoirs, both heat mining and pressure support are managed by injection well placement. When this is accomplished according to objective, the results can be seen and monitored in the production well characteristics. Injection well placement is best accomplished in a manner similar to Goldilocks and the three bears: not too close (rapid cooling of produced fluids), not too far (no benefit), but just right (reservoir management).

When separated brine is disposed of through injection, the brine is generally injected into either the bottom of the reservoir or outside the reservoir. The location of the brine disposal is a difficult task, and in the history of many geothermal fields, brine injection locations have had to be adjusted at least once during the life of the field, usually because the injection wells are too close and cold-water breakthrough is observed. If the injection is ideally placed, it provides both pressure support for the production wells, as well as “mining” of the stored heat of the reservoir rocks as the injectate flows from the high-pressure zone of the injection to the low-pressure zone of the production well. However, if the injection well is too close or if the injection well encounters a highly permeable crack linking the production and injection areas, cold injectate can enter a production area, and quickly reduce the enthalpy (temperature or steam content) of the fluid produced by that zone. Therefore, in many instances, the preferred option is to inject some portion of the total injectate volume in steam/brine systems effectively outside of the geothermal reservoir, sacrificing the benefits of in-field injection, but also avoiding the potentially severe consequences of enthalpy loss at the production wells. As a result of the need to move injection distant from production, it is common in geothermal fields to have injection pipelines several miles long that carry the brine to distant injection wells.

As with almost every situation in geothermal resource development not tied to conservation of energy or mass, there are exceptions to the long injection pipeline option. The particular characteristics of the deep vertical fracturing of the Steamboat Hills (Nevada) geothermal resource have allowed a large-capacity injection well to operate without negative consequences to nearby production wells. In most geothermal fields, such geographic proximity would have resulted in cold water breakthrough to the production well within a very short time, perhaps on the order of days or months.

#### ***51.5.1.3 Clean-Water Injection Placement to Enhance Steam Production***

The dryout of a region of a reservoir can occur when the water present in the region is no longer sufficient to remove the heat that is stored in the rock. At that point, the adoption of a new clean-water injection strategy can improve a number of the negative consequences of that dryout: specifically, loss of production, superheat, and acid gas production.

As dryout occurs, the temperature of the rock and the heat stored therein remain high, but there is no water to capture or transfer the heat. Production declines, and as it does, the pressure drops. Steam passing through rock that has a temperature higher than the saturation temperature of the steam's pressure becomes superheated. Superheated steam, upon mixing at the surface with wells that are not superheated, can evaporate the water from the brine flowing from other wells. If the brine rates are low enough and the evaporation is high enough, minerals will precipitate in the pipelines or separation vessels.

Superheated steam is also capable of carrying hydrochloric acid gases produced from certain rock formations out of the reservoir. Because the gases are extremely hydrophilic, they can only pass through the reservoir and into the steel-lined wellbore if no water is present. The hydrochloric gases are harmless to the steel as long as the steam is superheated. They can be removed at the surface by one of several methods: mixing with large quantities of water, mixing with smaller quantities of brine (which is naturally buffered

against changes in pH), or, in some instances, by caustic injection into the pipeline. However, if scrubbing of the hydrochloric acid is not accomplished before the onset of condensation, the rate of corrosion at the condensation point can be so high that the steel pipe wall can be thinned to failure in less than a year.

Injection into the reservoir can be used to solve all three problems. Adding water to the dried-out region through injection not only provides the means to increase production and heat-mining, it eliminates the superheat, and with the elimination of the superheat, also eliminates the acid gas production and pipeline scaling.

### 51.5.2 Resource Chemistry

The geothermal water and steam that are produced contain the chemical signatures of the rocks and processes (e.g., boiling) through which they have passed. Measuring the steam and brine chemistry is an important tool in the exploration process for new geothermal resources, in determining the brine processing requirements of the power cycle, and as an ongoing activity in developed geothermal resources for analyzing the response of the resource to production and for resource management planning. Examples include:

- In the exploration phase, geothermal water is collected from surface springs or fumaroles for clues as to the nature of the geothermal resource. For example, the relative concentrations of sodium, calcium, magnesium, and potassium in the water tell geochemists whether the fluid started out hot and then cooled (indicating a high-temperature resource elsewhere and indicating commercial geothermal resource potential) or whether the observed temperature of the fluid is close to the maximum temperature of the resource (not hot enough for power production).
- The extreme example of geothermal fluid chemistry is the Salton Sea (California) geothermal brine that contains more than 200,000 ppm total dissolved solids (TDS), or 20%, in its native state in the reservoir. The high TDS is a result of the high temperatures and the marine sediments that comprise the geothermal reservoir. The brine is produced and is flashed to steam at four pressures (~250, 125, 20, and 0 psig). In so doing, the brine becomes supersaturated with respect to silica and other minerals and salts, resulting in large chemical processing facilities necessary to prepare the brine for injection back into the geothermal reservoir. The silica treatment processes can either reduce the pH to prevent precipitation in the equipment or, alternatively, the silica can be removed from the brine by the controlled precipitation of the silica in tanks and vessels.
- Silica concentration is primarily a function of the reservoir temperature, but the concentration of silica determines how far the brine temperature can be lowered (how much energy can be extracted) before the onset of silica scaling. The power process is frequently designed to prevent silica from reaching saturation. In such cases, the operating point of the well is pushed to the left of point C in [Figure 51.2](#), regardless of other considerations. The injection of acid or chemicals to inhibit the precipitation of silica can be used to lower the minimum allowable brine temperature and extract more energy from the brine. Another strategy to extract more energy from the brine is to use a binary power plant after the first steam flash. This strategy is discussed in more detail in Section 51.7.
- Tritium (an artifact of atmospheric nuclear weapons testing) detected in the geothermal steam or water indicates that young groundwater is entering the

geothermal reservoir as a result of geothermal exploitation. Native-state geothermal water, which has typically been underground for tens of thousands of years, contains no detectable tritium. Tritium from groundwater may occur in the geothermal reservoir as a result of intentional injection programs to replenish water, such as at The Geysers, or the result of unwanted cold water influx from the surface. At Tiwi (Philippines), the cold water in question has quenched several square miles of productive resource. The advancing surface water could be detected in the tritium concentrations long before the temperature indicated a cooling process was occurring at the well.

- Increasing salt concentrations and other mineral concentrations indicate the return of injected brine from flash steam plants. Again, this can occur long before a change in production temperature is measured. If the rate of cooling is negligible or small, these chemical signatures indicate successful heat mining through the injection program.

### 51.5.3 Barriers to Resource Management

In most human endeavors, the best results come by starting with the end in mind. This is true of geothermal resource development and resource management as well. By understanding the particular resource the wells can be placed to ideally collect and convert the geothermal energy stored in the reservoir. Unfortunately, in practice, the ideal placement of the production and injection wells may be either impractical or even impossible for three reasons: incomplete information, capital limitations and sunk costs, and economic impetus.

#### 51.5.3.1 Incomplete Information

First, many aspects of the geothermal resource are simply not known in the early stages of development of a new resource. Such incomplete information includes whether cold water from injection will short-circuit to the production wells, how strong the natural influx to the system will be, or where that influx will actually occur. In fact, the exact area and volume of the resource is commonly not even known until 10 years or more after the onset of production.

The Geysers facility illustrates this point. The unit 1 power plant went into operation in 1960, and the final power plant—the J.W. Aidlin Plant that began operation in 1989—brought the total installed capacity to 1890 MW, although deratings and retirements commenced soon thereafter. However, reservoir information and analysis was not complete, even in the mid-1980s. Two additional power plants were ordered and never completed because there was insufficient steam for their operation. Therefore, the geothermal resource management strategy is dynamic and evolving from the beginning. As more information becomes available about the resource over time, the knowledge of the resource improves, and the decisions about its management more informed.

A surprising and interesting example of this evolving knowledge has occurred in recent years at Larderello, Italy. Almost 100 years after the start of power generation, it now appears that the historical development in the Larderello area is at the top of a much larger and deeper regional system, perhaps 400 km<sup>2</sup> in size and between 3,000 and 4,000 m deep (10,000–13,000 ft). Plans have been announced to begin drilling and developing this deep hot resource in 2007 with 11 deep-production wells.<sup>8</sup>

### 51.5.3.2 Capital Limitations and Sunk Costs

There may be capital limitations and sunk costs that must be taken into account in well placement decisions. For example, suppose that it would be ideal to inject the cooled brine to the north of the power plant, but an unsuccessful exploration well will serve as an injection well to the east, saving over a million dollars. In one development in Indonesia, a well that was targeted as an injection well was found, after being drilled, to have a very large production capacity. However, pipelines were already under construction, the well was distant from the power plant, and production well capacity had already been essentially completed. What was needed for plant operation was injection capacity, so the well was used for injection. Time and capital constraints forced the decision, even though it was against the ideal resource management strategy. This example also illustrates the first point about incomplete information at the onset of the project.

### 51.5.3.3 Economic Impetus

The third driver for well placement decisions is the economic impetus. The economic test criterion used for investment decisions is discounted cash flow, in which decisions are based largely on achieving the highest net present value or the lowest net present cost in which all costs and earnings are brought back to the present at an assumed discount or interest rate. For public (government) development, that discount rate may vary from 5% to 15%; for development by private corporations, the rate for normal equipment and operational investments is typically 9%–12%, but for resource development issues is not uncommonly as high as 20%, due to the greater risk and uncertainty. The lower the discount rate, the more important future performance is to the total value of the project, as viewed by “today’s” decision makers. The converse is also true, and in fact dominates spending decisions for resource management at the start of the development. Suppose that the publishers of this text elected to develop a new geothermal power plant named “CRC #1.” They are sharp businesspeople, and are told by their resource development experts that there are several resource development options that can be pursued. Both strategies produce the same income with the same expenses for the first 15–20 years. However, the second strategy will produce significantly more value in the outer years because of better resource management. They perform a discounted cash flow calculation and develop in Table 51.5. The conclusion that is reached

**TABLE 51.5**

Amount of Spending That Can Be Justified “Today” for a Savings or Earnings of \$10 Million in the Future

Discount Rate Scenario	Economically Justified Spending “Today” at a Discount Rate of				
	0%	4%	11%	15%	20%
\$10 Million value in 15 years	\$10,000,000	\$5,552,645	\$2,090,043	\$1,228,945	\$ 649,055
\$10 Million value in 20 years	\$10,000,000	\$4,563,869	\$1,240,339	\$611,003	\$ 260,841
\$10 Million value in 30 years	\$10,000,000	\$3,083,187	\$436,828	\$151,031	\$42,127
\$10 Million value in 50 years	\$10,000,000	\$1,407,126	\$54,182	\$9,228	\$1,099

is that, for an investment as risky as resource performance in 15–20 years, the corporation will use a discount rate of 15%–20%. The table shows that the resource managers have a budget to optimize the resource development of between \$0.25 and \$1.2 million (the highlighted area in [Table 51.5](#)) to create \$10 million of value. In most cases, this will not be sufficient to implement an enhanced resource management plan. At the extreme, in looking at resource development strategies that would create the \$10 million value in 50 years, the table shows that less than \$10,000 of additional spending today can be justified at a 15% discount rate and only \$1,000 at a 20% discount rate. In short, there is virtually no economic impetus for resource development decisions that yield a benefit after 50 years.

Even if not implemented at the onset of the resource development, some resource management strategies will be able to be implemented at a later date. However, other decisions are irreversible, such as inefficiency in the conversion of the resource to electrical power. Conversion inefficiency directly reduces the total generation from the resource (megawatt-hours), but may also ultimately lead to a reduction in the installed capacity of the field (megawatts). While this is clear from the beginning, if such additional generation does not occur for 30 years, [Table 51.5](#) demonstrates that the generation is of inconsequential value at the time of initial development. A scenario under which this occurs is where the generation contract for the geothermal field is limited to a given output.

Suppose that a PPA is for 100 MW average over the year. With the high-efficiency power plant, the resource is forecast to provide 100 MW for 40 years before beginning its decline. With the lower-efficiency (and less expensive) power plant, the plant is forecast to be able to maintain 100 MW for 25 years. In terms of today's decision making, the value of the additional 15 years of full-capacity generation are of marginal value, and the economic calculations will almost certainly show that the power plant and resource strategy with the lower capital cost is the preferred investment strategy "today."

The same calculations also apply to the efficiency of nonrenewable natural resources, such as natural gas and petroleum. Straight discounted cash flow calculations provide little incentive for the conservation of depletable natural resources for a time frame greater than 20 years. However, at the end of the 20 years, the impact of the inefficiency can be very large on the future value.

#### 51.5.4 Resource Characterization

An early task of the geothermal resource management team is to characterize the resource based on the exploration and initial development wells. The characteristic of the fluids that will be produced from the well must be determined: steam only, brine and steam, or brine only. Subsequent tasks must address the design issues within each resource type.

[Table 51.6](#) provides a list of some of the design issues and options that derive from this first basic resource characterization. The characteristics of the wells will determine the options for the power cycle, and from that the configuration of the surface facilities. As illustrated in [Table 51.6](#), there are three types of resources that are used in the two dominant power plant types: steam power plants and binary power plants, as discussed in detail in subsequent sections.

**TABLE 51.6**

Geothermal Facilities Design Parameters Resulting from the Geothermal Resource Type

<b>Wells Flow: Design Issue</b>	<b>Steam Only</b>	<b>Steam and Brine Two-Phase Flow</b>	<b>Brine Only</b>
<i>Representative fields</i>	Geysers, California Lardarello, Italy Kamojang, Indonesia	Cerro Prieto, Mexico Coso, California Wairakei, New Zealand Mak-Ban, Philippines Miravalles, Costa Rica	East Mesa, California Steamboat Springs, Nevada Raft River, Idaho
<i>Production well design</i>			
Production of fluid to surface by	Free flow	Free flow	Pumped
Well design—flow	Minimize pressure drop (velocity) to maximize flow	Maximize flow, but must maintain high velocity to lift liquid out of the well	12-in. inside diameter (min) to deepest expected pump installation depth
Well design—pressure	Maximum reservoir pressure (generally less than 600 psi, and falls with time)	Saturation pressure at maximum temperature. (generally less than 400 psi, but can be 2000 psi.)	Often less than 200 psi at surface and less than 600 psi for pumps at the zero flow condition
Production pump parasitic load	Not applicable	Not applicable	Usually between 5% and 8% of gross generator output, but can be as high as 15%
<i>Surface facility design</i>			
Production pipeline network	Steam only to power plant. Build with large cross-section for low pressure drop. Condensate knockout pots must be provided	Two-phase flow to separators requires high velocities and pressure drop to prevent slugging. After separator, two pipelines of single phase steam and separated brine	Single-phase liquid flow to binary power plant or separator. Size pipe for low pressure drop. Water hammer at start-up is an issue
Brine steam separator	Not applicable	Required. installed vessel cost greater than \$600,000 per 10–20 MW	Only required if steam turbine to be used
Steam washing system to remove impurities and condensate	Usually required on a continuous basis. Installed cost greater than \$500,000 per 10–90 MW	Same	Not required
<i>Power plant design</i>			
Power plant location	Center of initial and long-term production. Usually accomplished	Same goal. Not uncommonly, the center of production (make-up well drilling) moves away from the power plant site as new resource is discovered, resulting in large pipeline costs and available energy loss	Same goal. Usually accomplished, as these tend to be smaller and better-defined geothermal resources

(Continued)

**TABLE 51.6 (Continued)**

Geothermal Facilities Design Parameters Resulting from the Geothermal Resource Type

<b>Wells Flow: Design Issue</b>	<b>Steam Only</b>	<b>Steam and Brine Two-Phase Flow</b>	<b>Brine Only</b>
Steam turbine	Single pressure entry  Size from 5 to 125 MW. Most commonly 25–75 MW	Size as per other geothermal steam turbines  1. Single inlet pressure, as for steam only resource 2. Multiple inlet pressures on same or multiple turbines (needs multiflash design of brine system)	Not commonly used  Size is less than 40 MW
Binary power plant Size has historically been 1–8 MW per turbine/generator set. Since 2004, size has increased to 20 MW/T/G	Not applicable	1. Can be used for recovery of energy from brine instead of multiple flashes 2. Can be used instead of steam turbine on small plants	Most commonly used instead of steam turbine
Geothermal combined cycle power plant	Has not been used in practice, but could be	1. Steam turbine with binary plant used as steam turbine condenser 2. Brine energy recovered in separate binary plant	Not applicable
Effect of brine chemistry on total available energy	Not applicable	Determines lowest temperature to which brine can be flashed without scaling Temperature can be lowered by adding acid	Determines the lowest brine temperature at discharge of binary plant heat exchangers to avoid scaling. Acid addition lowers temperature
Condenser	Generally sub-atmospheric. Direct contact of cooling water and steam, unless H <sub>2</sub> S abatement is required, then shell and tube often used	Same, unless a geothermal combined cycle unit is used	Same for steam-only plants Generally supra-atmospheric for binary plants
Condenser gas removal equipment	Large to handle 0.5%–8% NCG in steam. Sized for NCGs and air infiltration  Creates large parasitic steam or power load	Same  Not applicable for geothermal-combined cycle units	Small. Sized only for minimal breakdown of hydrocarbon and air infiltration
Cooling System	Water-cooled, usually uses condensed steam as make-up water for cooling tower	Same for steam turbine plants Most often air-cooled for binary and geothermal combined cycle plants	Usually air-cooled condenser, unless surface water or steam condensate is available. Air cooling creates a large parasitic load and summer capacity loss

*(Continued)*

**TABLE 51.6 (Continued)**

Geothermal Facilities Design Parameters Resulting from the Geothermal Resource Type

<b>Wells Flow: Design Issue</b>	<b>Steam Only</b>	<b>Steam and Brine Two-Phase Flow</b>	<b>Brine Only</b>
Abatement of H <sub>2</sub> S gas contained in geothermal steam	If required by regulators	Same	Not required for an all-binary system, as H <sub>2</sub> S never leaves brine
<i>Surplus fluid design</i>			
Brine injection pipeline	Not applicable	Often long and expensive. Lengths of 0.5–1 mile from production area, or longer	Same as steam/brine system
Brine injection wells	Not applicable	Required, generally 1 well/10–40 MW (Often negative wellhead pressure)	Required, generally 1 well/3–10 MW (usually positive wellhead pressure)
Cooling water blowdown well	Usually required. One per power plant	Same. Should not mix with brine because of corrosion/precipitation if condensate is used in cooling tower  Not required for geothermal combined cycle, as steam condensate is not oxygenated and can be mixed into brine	Not required for binary-only power plant
Fluid injection or disposal strategy	Inject cooling tower blowdown to regenerate steam (80% is evaporated in cooling tower). Supplement with fresh water injection. Water injection can minimize the production of hydrochloric acid gas with the steam	1. Generally, all brine and condensate must be injected into or outside of the active reservoir for reservoir management (heat mining, steam flow and pressure support) and environmental compliance 2. Rarely, some may be surface disposed to evaporation pond, river, or ocean to reduce capital and operating costs, but may be against best reservoir management practice	Always reinjected to maintain a high reservoir liquid level because of the production well pumps
Parasitic load of injection	Cooling tower blowdown pump load is very small, approaching zero	Generally pump load is small because of two-phase reservoir	Pump loads can consume 3%–7% of total gross generator output

---

## 51.6 Geothermal Steam Supply (from Wellhead to Turbine)

The first two columns of [Table 51.6](#) discuss resources in which steam is produced from the wells, as opposed to the third column, in which only pressurized brine is produced. In almost every case, the steam that is produced from these wells is used in a steam turbine. In this section, the technology of handling geothermal steam from the wellhead to the geothermal steam turbine is discussed.

### 51.6.1 Overview of Steam/Brine Separation for Steam Turbine Supply

In the vast majority of geothermal fields in the world, a two-phase mixture of steam and brine is brought to the surface through the production wells. The brine must be separated from the steam before delivering the steam to the turbine. Separators of many different configurations are in use throughout the world, but the most common is a vertical vessel with a tangential entry to centrifugally separate the steam and brine. The level of purity of the steam varies between that which meets the geothermal standard of 0.1–0.5 ppm of chloride to over 10 ppm chloride.

Steam purity is typically measured by the chloride content of the steam condensate. However, the chloride itself is seldom intrinsically a problem to the alloys employed in a geothermal steam turbine. Rather, chloride is a convenient measure of the co-contaminants that are much harder to measure: mostly silica, but other minerals as well. Where these minerals are carried in the steam to the turbine, they may precipitate primarily on the first-stage stationary blades, reducing efficiency and eventually restricting plant capacity as well. The consequences and treatment of these mineral deposits are further discussed in Section 51.6.5.

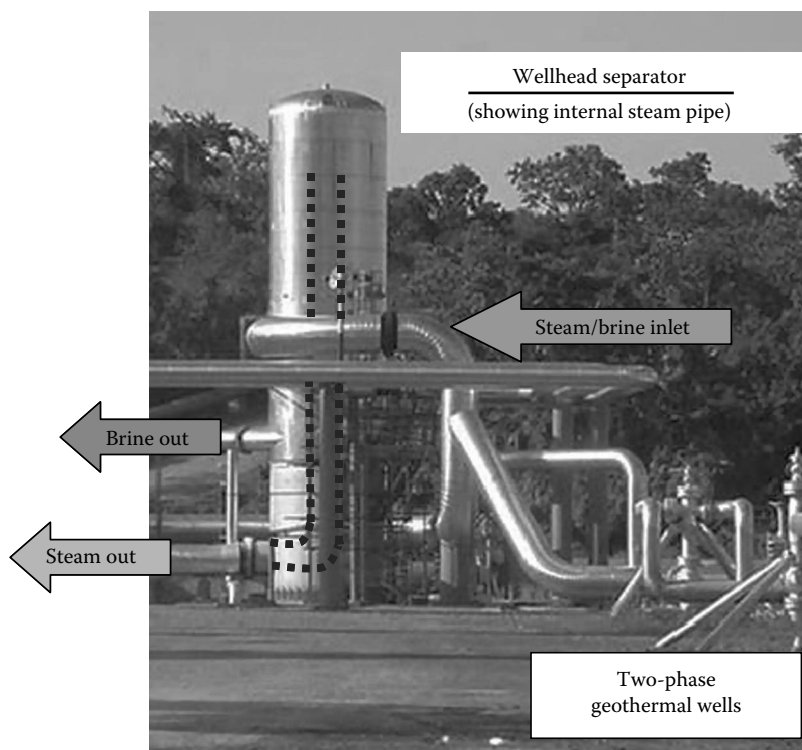

With typical geothermal brine chloride levels, the separators need to achieve over 99.5% dryness to achieve the lower steam chloride concentration objective. The greatest challenge in doing so is to minimize the pressure drop through the vessel. The pressure drop has two negative consequences. The first is that the pressure drop results in an unrecoverable loss of available energy (reduced efficiency). Second, it results in a higher pressure at the wellhead, which reduces flow from the well (moving the operating point toward “B” in [Figure 51.2](#)), thereby requiring more wells (greater capital cost) to supply a given steam demand.

Where high-chloride (high-silica) steam is produced from the separators, steam washing must be employed to clean the steam before admission to the turbine, with a consequent parasitic steam loss as described below. While the commitment to, and investment in, steam purity at the discharge of the flash separation vessel varies from field to field, it is, in fact, better in practice to “put a fence at the top of the cliff, than an ambulance at the bottom.”<sup>14</sup> In other words, the best practice in geothermal design is to first ensure high-efficiency separation (the fence) and not rely on the steam-washing system (the ambulance) at the power plant to prevent scaling of the turbine. Steam washing is defined and described below in Section 51.6.5.

[Figure 51.3](#) illustrates a modern high-efficiency, low-pressure-drop geothermal steam separator designed by Sinclair Knight Mertz Consultants.\* The two-phase mixture of steam and brine from the wells on the right enters the vessel through a special lemniscate entry (providing lower entrance turbulence than a tangential entry). The brine is separated

**FIGURE 51.3**  
Annotated photo of a high-efficiency steam separator.

by the centrifugal motion of the steam flowing upward. The steam enters an exit pipe at the top, flowing downward to exit through the bottom of the vessel. The brine exits tangentially through the vessel side-wall below the inlet.

### 51.6.2 Multipressure Steam Flash and Separation

The number of steam pressures (flashes) that are taken from the brine varies from field to field. Each time the brine is flashed, additional energy is extracted from the brine by delivering a supply of steam to the power plant at a lower pressure, but the concentration of minerals in the residual brine is increased. Many fields use only one flash to avoid silica saturation of the brine. Multiple flashes can quickly drive the brine past the silica saturation point by the combined effect of cooling and concentration due to the extraction of steam. Where multiple-flash separation is used, it is usually limited to two flash pressures. At the CalEnergy\* Salton Sea facilities, turbines are driven off of as many as three separate flashes, producing turbine inlet pressures of roughly 250, 100, and 10 psig (actual pressures vary among the various plants) with a final flash at atmospheric pressure that is vented, but a large silica precipitation facility is employed to desupersaturate the silica from the brine to prevent pipeline and injection well fouling.

Figure 51.4 illustrates a multistage steam separation and cleaning process from the well to the turbine inlets. Brine from the first separator is flashed to the lower pressure across

\* CalEnergy Generation, <http://www.calenergy.com>.

**FIGURE 51.4**

Geothermal double-flash process with steam cleaning.

the level control valve of the higher pressure separator. Commonly, each flow of steam is washed with geothermal steam condensate from the power plant before entering the turbine. Residual brine is injected.

### 51.6.3 Steam Pipeline Operation

Steam pressures used in geothermal power generation are often less than 120 psig at the turbine inlet, and the steam pipelines are sized to keep steam velocities low. Thus, on large-steam turbine installations, there may be many miles of 30–42 in. pipeline snaking along roads and hillsides to bring the steam to the power plant.

These long pipelines introduce various operational problems. The pressure drop that occurs over such long distances represents an unrecoverable loss of available energy.\* The long distances and the transport of saturated steam can also lead to considerable condensation in the pipelines, especially during windy, rainy, or snowy weather. Condensed steam must be removed from the pipeline either in knockout pots with steam traps, or in the steam scrubbing vessel near the turbine inlet to prevent water damage to the turbine.

### 51.6.4 Steam Washing Prior to Steam Turbine Admission

After the steam is brought to the edge of the power plant from the dry steam wells or the separators, the steam at many facilities is washed by injecting steam condensate from the power plant condenser into the steam line. Typical flow rates look to achieve a total moisture of 1%–2.5%, or about 10,000–25,000 lb/h (up to 50 gal/min) for a common 55 MW power plant using about 1 million lb/h of steam. For each 100 lb of condensate injected into the steam flow, approximately 22 lb of steam is condensed. This condensed steam also helps to scrub the vapor, but the condensation is essentially a parasitic load. In a large facility, with poor steam quality, the wash water can represent as much as one megawatt of steam flow. The condensation and any injected water are removed in the power plant moisture removal vessel that immediately precedes the turbine.

\* A wellhead separator pressure of 160 psia and a turbine inlet pressure of 110 psia are commonly seen. Assuming a constant condenser pressure of 101 mm Hg<sub>a</sub> (4 in.), this pressure drop between wellhead and turbine represents up to a 7% loss of available energy.

The moisture removal vessel can be either a centrifugal separator or a vane-type demister. Pad-type demisters are not used because they are prone to scaling. The Porta-Test Whirlscrub® V Gas Scrubber\* is used upstream of many United States and world-wide geothermal steam turbines to ensure low-moisture steam is delivered to the turbine.

When high-efficiency steam separation is successfully implemented for wells producing a two-phase mixture of steam and brine, steam washing is unnecessary on a continuous basis. Even if a high-efficiency separator is used, a moisture removal vessel is still required to protect the turbine from entrained water and/or solids that may originate in the pipeline between the separator and the moisture removal vessel.

### 51.6.5 Turbine Washing to Remove Scale Buildup

The consequence of insufficient steam purity and contaminant cleanup is that the turbine first-stage nozzle diaphragms will develop a layer of scale that restricts the steam passage. A schematic illustration of the turbine pressure and generation response to inlet nozzle scale build-up and removal through turbine washing is shown in Figure 51.5. As scaling occurs, the operator will allow the turbine inlet pressure to increase to maintain plant contracted output. As the scaling and pressure build up, the pressure limit of the turbine casing is eventually reached, and at that point, further scaling of the turbine results in reduction of the of turbine output due to decreased steam flow.

Turbine scaling occurs as the steam passes across the first-stage stationary blades. Entrained microdroplets of liquid with dissolved impurities evaporate as they cross the blades. The impurities are left behind, and scale buildup is the result.

Over the years, various experiments have been undertaken to remove the built-up scale with online turbine washing. Early efforts took the unit off-line and injected water at reduced rotating speeds. Later, low load injection of water into the turbine inlet was tried. Eventually, however, it became the widely accepted practice to inject water into the turbine at almost full-load to clean off scaling and restore design operating conditions. This practice has evolved in part by consideration of the actual operation of a low-pressure geothermal turbine. In normal operation, the saturated steam enters the turbine with condensation forming as the steam passes through the turbine to produce work. A typical

**FIGURE 51.5**

Response of turbine to scaling of the first stage nozzles and to an on-line turbine wash (schematic-not to scale).

\* <http://www.natcogroup.com/>.

geothermal steam turbine operating around 120 psia inlet pressure and 2 psia condenser pressure (4 in. Hg, absolute) has an exhaust moisture of 14%–16% less interstage moisture drains. Therefore, adding 1%–2% moisture to the steam entering the turbine for short periods of time does not represent a large deviation from normal operating conditions.

## 51.7 Geothermal Power Production—Steam Turbine Technologies

### 51.7.1 Overview of Geothermal Power Generation Technologies

Two conversion technologies dominate the geothermal power industry: Direct steam turbines in an open-loop Rankine cycle configuration, and binary power plants using a hydrocarbon (pentane or butane) in the boilers and turbines in a closed-loop organic Rankine cycle (ORC). Geothermal combined cycle (GCC) units marry the two technologies. Ammonia/water binary power plant technologies have been proposed as a potential third power cycle option, with one such plant having been built as of 2006, and additional plants planned for operation in the coming years. Table 51.7 lists the 2004 breakdown of worldwide installed capacity.

Steam turbines represent 95% of the installed capacity of geothermal power plants worldwide, including the steam turbines of the integrated steam turbine and binary power plants. Binary power plant technologies, discussed in Section 51.8, represent the remaining 5% of installed worldwide capacity.

### 51.7.2 Steam Turbine Conversion

Geothermal power plants using steam as the motive fluid are open-cycle systems in which geothermal energy in the form of steam is admitted to the power plant, the energy is extracted, and the residual brine and condensed steam are then discharged from the plant to surface disposal, or injection, as described above. Gases contained in the steam are vented to the atmosphere. Because there are no fuel handling systems, boilers, superheaters, ash systems, or other systems related to the burning of fuel, geothermal steam power plants

**TABLE 51.7**

Breakdown of Geothermal Power Technologies Worldwide

Resource Type	Power Plant Type	Installed Capacity (MW)	Number of Units
Dry steam	Steam turbine	2460	63
Flash steam	Steam turbine	5831	210
Pressurized brine, including residual brine from a flash steam plant	Organic Rankine cycle (ORC)	274	154
Steam/brine	Integrated steam turbine and ORC, or ORC only	306	39
Pressurized brine	Binary-Kalina cycle (ammonia)	2	1
	Total	8873	467

Source: DiPippo, R., *Geothermal Power Plants: Principles, Applications and Case Studies*, Elsevier Advanced Technology, Oxford, U.K., 2005, pp. 404–405.

are very simple. It is referred to as an “open” cycle because the condensed steam is not returned to a boiler in a closed-loop circuit. The steam from the geothermal resource is delivered to the turbine inlet and may originate from either dry steam wells or from the separated steam of wells producing a brine/steam mixture.

There are three main steam power processes in use around the world: steam turbines without condensers (atmospheric discharge), steam turbines with subatmospheric condensers, and steam turbines integrated with binary power plants.

In a few installations worldwide, the steam turbine may exhaust directly to atmosphere. It is an inefficient mode of operation since 50% of the available energy is lost when discharged at atmospheric pressure. From an economic perspective, the loss of 50% of the available energy does not justify long-term operation of atmospheric discharge turbines, because with only the addition of a condenser and cooling tower, the output of the facility can be roughly doubled with no additional resource development. However, atmospheric discharge turbines are sometimes used to prove reservoir capability because of rapid installation and low cost. In other places, they have been used when CO<sub>2</sub> content in the steam was over 5%. The use of atmospheric discharge turbines provides another example of the trade-offs that occur between long-term efficiency benefits and economic constraints as discussed in Section 51.5.3.

Geothermal combined-cycle steam/binary power plants also use a steam turbine that discharges at slightly above atmospheric pressure. However, instead of the steam venting to the atmosphere, the steam is condensed and energy recovered in the vaporizers and preheaters of the binary power plant. In this way, the energy of the exhaust steam is captured in the power conversion cycle of the binary power plant. More details on this process and advantages of this “combined cycle” technology are discussed in Section 51.8.4.

Most of the total installed worldwide geothermal generating capacity is from steam turbines in which the geothermal steam is admitted to the turbine at between 15 and 250 psia and exits the turbine at subatmospheric pressures of between 1.0 and 2.5 psia. The condenser is cooled by water from a cooling tower. The steam rate (pounds/kilowatt-hour) of the turbines is determined by the turbine efficiency (usually slightly better than 80%, including entrance and leaving losses), inlet pressure, and the condenser pressure. [Figure 51.6](#) is a photo of the world’s largest-capacity (110 MW net rated output) single shaft geothermal steam turbine, in the Fuji Electric\* shop before its installation at the Wayang Windu (Indonesia) geothermal power project. The design inlet and condenser pressures are 150 and 1.7 psia, respectively, using a 27 in. long last stage blade.<sup>15</sup>

### 51.7.3 Condensing Steam Turbine Process

[Figure 51.7](#) is a general illustrations of a dry steam power process. Steam is produced from the geothermal reservoir through multiple wells and delivered to the power plant through cross-country pipelines. The steam is always passed through a moisture removal vessel before entering the turbine to ensure that no particles or slugs of water reach the turbine. In many installations around the world, the steam is washed before entering this vessel to remove any impurities (see Section 51.6.4).

The basic process for a single-flash steam process is much the same, as shown in [Figure 51.8](#). The key difference is that a two-phase mixture of brine and steam are produced from the geothermal reservoir to the surface. A centrifugal separator removes the steam for delivery to the power plant (Section 51.6.1), and the brine is injected back into the reservoir.

**FIGURE 51.6**

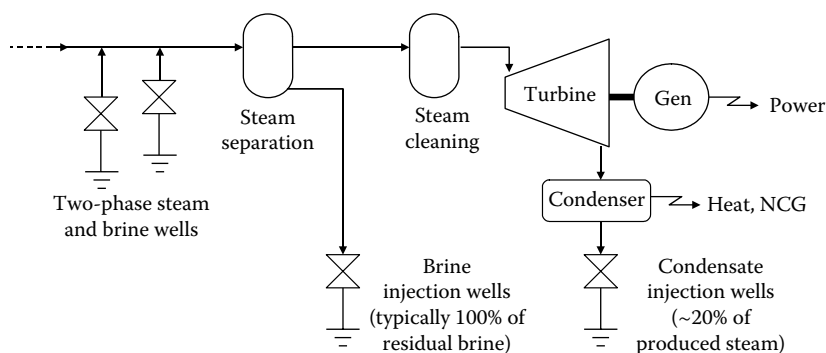

The Wayang Windu 110 MW geothermal turbine. (Photo courtesy of Fuji Electric Systems Co., Ltd., Tokyo, Japan.)

**FIGURE 51.7**

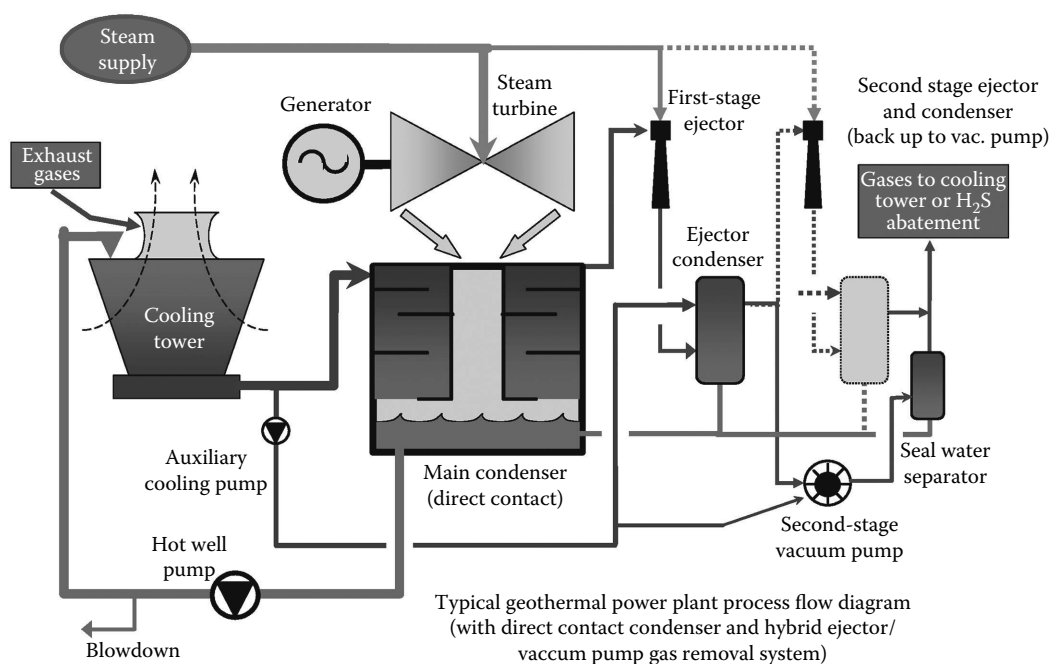

Geothermal dry steam power process (water cooled).

Figure 51.9 is a typical process-flow diagram for a geothermal power plant using a steam turbine and a condenser. In this illustration, steam is supplied from dry steam wells or a flash separation process at only one pressure (i.e., there is no low pressure turbine inlet). The steam is also used directly in the gas removal ejectors. Steam exiting the turbine is condensed in a direct contact condenser that is supplied with cold water from a cooling tower. The condensed steam and the cooling water are returned to the cooling tower. Approximately 80% of the steam to the power plant is evaporated in the cooling tower, and the remaining 20% forms the cooling tower blowdown. In hot arid climates, the amount of water evaporated can be greater than 100% during the hottest hours of the day and greater than 90% over a 24 h period. The steam contains noncondensable

**FIGURE 51.8**  
Geothermal single-flash steam power process (water cooled).

**FIGURE 51.9**  
Geothermal steam power plant with direct contact condenser. (From Williamson, K.H. et al., *Proc. IEEE*, 89(12), 1783, 2001.)

gases (NCG), primarily CO<sub>2</sub>, but also H<sub>2</sub>S and other trace gases. These gases must be removed from the condenser to keep a low turbine exhaust pressure.

In Figure 51.9, geothermal steam is used as the motive force for the first-stage ejector to compress the NCG. The ejector steam is condensed in the direct-contact ejector condenser (the intercondenser), with the condensed steam and cooling water being returned to the main condenser. The NCG from the intercondenser is compressed in a second stage to atmospheric pressure either by the vacuum pump or by a second-stage ejector with an aftercondenser. The amount of steam used by the ejector and the size of the vacuum pump motor is related to the size of the power plant and the NCG content of the steam.

The vacuum pump is the primary system because it is more efficient than an ejector. The second-stage ejector is shown as a backup system because it has lower capital costs than a standby stainless steel compressor. Stainless steel is required throughout the NCG system because of the corrosiveness of moist  $\text{CO}_2$  gases. The NCGs are dispersed using the cooling tower fans. If  $\text{H}_2\text{S}$  abatement is required, it is installed between the discharge of the second stage of compression and the cooling tower. The gas removal system is discussed in greater detail in Section 51.7.6.

#### 51.7.4 Design of Geothermal Turbines

Geothermal steam can be a virtual chemical soup that varies from field to field. In most cases, the steam is saturated as it enters the turbine, and has a moisture content approaching or even exceeding 15% as it leaves the turbine for subatmospheric discharge turbines. The combination of scaling tendency, potential corrosivity, and high moisture content heavily influences the design of geothermal turbines.

Geothermal turbines generally use the same alloys as low pressure turbines in fossil fuel power plants, but with small variations in the alloy composition of the blades and rotors to enhance the alloy's ability to withstand the corrosive environment of geothermal steam. Detailed design can be just as important as alloy selection. For example, by using long-radius transitions and avoiding notches in the design of geothermal turbine parts, especially in the blade attachment areas, the stresses are more evenly applied and the blades and rotors are much less susceptible to cracking and failure.

The last-stage turbine blades are exposed to high moisture content, which requires methods to minimize blade leading edge erosion. Both erosion-resistant alloy shields and blade-surface hardening are used to resist the impingement of water on the last-stage blades. In addition to moisture, the specter of corrosion once again strongly influences the design of geothermal turbines at the last stage.

Last-stage blade size is a key element in the maximum size geothermal turbine that can be built. Geothermal turbine last-stage blades are designed for lower combined stresses than equivalent blades in conventional power plants. Because a large portion of last-stage blades stresses is proportional to the steam flow, this results in lower steam flows (per square foot of exhaust area) than in conventional power plants. High moisture content—the result of using saturated steam at the turbine inlet—tends to limit blade size to about 660 mm (26 in.) for turbines operating at 3600 rpm (60 Hz power), and its equivalent of about 765 mm (30 in.) for turbines operating at 3000 rpm (50 Hz power). The combined effect of the limited blade length and the reduced flow rate per unit area limit the maximum size that can be achieved in a geothermal turbine/generator. Thus, it is common to see two to three 55–70 MW turbines installed in a single powerhouse, rather than a single 200 MW unit. As discussed above, the largest two-flow geothermal turbine/generator (two rows of last-stage blades with steam inlet in the middle) ever built was Wayang Windu in Indonesia, with a rated net output of 110 MW.

#### 51.7.5 Design of Heat-Rejection Systems

A second area affecting geothermal competitiveness is the heat-rejection system comprising the condenser, cooling tower, and cooling water pumps. The heat-rejection system of geothermal power plants can be up to eight times as large as a combustion-turbine combined-cycle power plant per kilowatt of output because of the low available energy per mass of steam at the inlet to the geothermal turbine. The heat-rejection system of any

geothermal power plant, whether for a steam turbine or binary plant, represents a very large capital cost burden for the project.

Where  $\text{H}_2\text{S}$  abatement is required, modern plants are most often built with shell-and-tube condensers. Thus, shell-and-tube is found in most steam condensers in United States geothermal power plants. Outside of the United States, the majority of geothermal steam condensers are direct-contact. In this system, steam exiting the turbine encounters either water sprayed from nozzles or droplets from trays. Heat transfer is much more efficient. The higher the gas content of the steam, the larger the advantage that direct-contact condensers bring. The disadvantages are that the cooling water is exposed to the  $\text{CO}_2$ ,  $\text{H}_2\text{S}$ , and ammonia, thereby providing substantial biological growth potential in the circulating water. Counteracting this is the high blowdown rate in a direct-contact geothermal cooling system.

Cooling tower make-up water comes from the condensed geothermal steam. In most circumstances, between 70% and 80% of the steam that enters the turbine is eventually evaporated in the cooling tower. The remaining 30%–20% steam is condensed and not evaporated, and is the source of the cooling system blowdown. Although the low cycles of concentration in the cooling water help control biological growth in the system, at the same time, the high blowdown rates result in it being relatively expensive to dose the water with biocides, since the biocides are quickly washed out of the system. Additionally, the presence of  $\text{H}_2\text{S}$  and  $\text{NH}_3$  in the cooling water substantially reduces the efficacy of conventional biocide treatments. Cooling tower blowdown is most commonly injected back into the geothermal reservoir.

### 51.7.6 Geothermal Condenser Gas-Removal Systems

In addition to the challenges of mechanical design of the steam turbine and the size of the cooling and condenser system, the steam also contains large quantities of noncondensable gases (NCG). Average NCG compositions for two fields in the Philippines are shown in Table 51.8.

As a consequence of high NCG content in the geothermal steam, the gas-removal systems of geothermal power plants dwarf the gas-removal systems of conventional power plants. For example, the power plants at Tiwi, with a gas content of about 3%, can use either a two-stage steam jet gas ejector that consumes 110,000 lb of steam/h, or a hybrid system of first-stage ejector and second-stage liquid ring vacuum pump (consuming 33,000 lb of steam/h and 0.6 MW of electrical load). This is summarized in tabular form in Table 51.9. The two systems were designed for different gas loads, but both systems place a tremendous parasitic load on the plant. The two-stage ejector consumes an additional 11% steam over that used by the turbine, while the ejector hybrid consumes only 3.4% of the turbine steam, but also consumes 1.2% of the net electric output of the facility.

**TABLE 51.8**

NCG Amount and Composition in Steam at Tiwi and Mak-Ban, Philippines

Field	Percent Gas in Steam (wt%)	Gas Composition (mol%)								
		$\text{CO}_2$	$\text{H}_2\text{S}$	$\text{NH}_3$	$\text{CH}_4$	$\text{H}_2$	$\text{N}_2$	$\text{O}_2$	He	As, Hg
Tiwi	2.8	97.9	1.24	0.04	0.05	0.31	0.45	0.04	0.001	Trace
Mak-Ban	0.5	88.7	6.9	0.08	0.22	1.24	2.61	0.10	0.006	Trace

**TABLE 51.9**

Parasitic Steam and Power for Condenser Gas Removal at Tiwi, Philippines, for One 55 MW Unit

Option	Design Gas Load % Steam	Parasitic Steam		Parasitic Power	
		Ejector Flow (lb/h)	% of Turbine Flow	kW	% of Rated Capacity
Two-stage ejector	2.8	110,000	11.1	Not applicable	
Ejector hybrid	2.8	33,000	3.4	635	1.2

The higher the NCG content is above 1% in the steam, the greater the incentive to cut the parasitic steam usage with mechanical gas compression. This may take the form of ejector hybrids, as discussed above, or to eliminate the ejector altogether using an all-mechanical compressor. As in most aspects of geothermal design, a variety of solutions is employed.

Whatever the particular compressor system used, the additional cost of compressor systems is usually justified by the reduction of production wells required to supply the ejectors with steam, by an increase in the turbine steam supply at a geothermal field that is short of steam, or looking to maximize installed capacity. However, the electric parasitic load can have considerable negative implications on plant revenue, and for this reason, it is sometimes avoided on newer installations. The reason that the electric loads of mechanically driven compressors can have large impacts on revenue is found in the size limitation of the geothermal turbine, as discussed above. If the turbine size is limited (e.g., by last-stage blade size), then adding parasitic electric load reduces the power that can be sold, and hence reduces revenue. This is, once again, an example of the need to sacrifice efficiency in the short term to obtain higher net present value in a discounted cash flow calculation.

## 51.8 Geothermal Power Production—Binary Power Plant Technologies

Section 51.7 presented the technologies and strategies of the geothermal power plant that directly uses geothermal steam in the turbine. In Section 51.8, the use of geothermal steam and brine as an energy source but not as the power plant working fluid (that which drives the turbine) is discussed. The power plants that use these two fluids are known as *binary power plants*. All of the closed-loop working fluid cycles used in geothermal energy production, with a few exceptions, are Rankine cycles with a hydrocarbon as the working fluid.

### 51.8.1 Binary Power Plant Advantages

If one were to consider an idealized geothermal system in which the thermodynamics of pure water and steam played the dominant role in decision-making, there may not be a large role for the binary geothermal power plant. However, one does not have to delve too far into the reality of geothermal development before the advantages of the binary geothermal power plant in some applications become apparent. Some of these reasons have already been discussed in the preceding pages. Two of the most important answers to the question “Why binary?” are provided below.

### **51.8.1.1 Silica Solubility**

As noted in several earlier sections, avoiding the precipitation of silica is a requirement for successful long-term geothermal well and pipeline operations. The precipitation of silica is a function of three factors: time, concentration, and temperature. Time is easily extended by the addition of acid to the geothermal brine, but for inexplicable reasons, this straightforward and easy solution is widely ignored. That leaves concentration and temperature as the factors within the control of the power process designer.

A brine that starts out at 450°F in the reservoir, when introduced into a steam separator at a pressure of 135 psia, will flash off approximately 12% of the initial water mass as steam. If there is a second flash at 35 psia, the total water mass flashed to steam is 21%. In such a flash process, two factors are at work increasing the potential of forming silica scale: mineral concentration in the brine and lower brine temperature. The physical properties that inhibit scale precipitation are that amorphous silica solubility is greater than the quartz silica solubility, and the often-slow kinetics of amorphous silica precipitation.

In contrast, the geothermal heat is transferred to the working fluid in a binary power plant without concentrating the silica by flashing off steam from the brine. Therefore, the temperature of the brine can be lowered further before the amorphous silica precipitation temperature is reached. Because of the silica solubility limit, the binary power plant can extract more energy from the produced brine (lower temperature) than a flash plant is capable of, especially where pH modification of the brine (acid addition) is not used. This can be true either on wells that are pumped and in which pressurized brine is delivered to the power plant, or after the brine has been flashed once and the binary plant is then installed to make use of the heat in the residual brine.

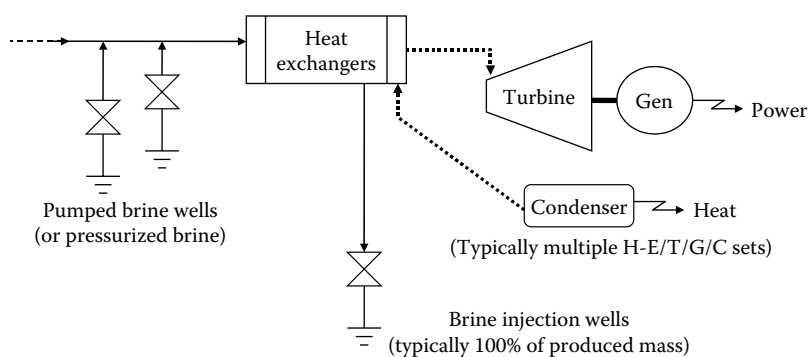

### **51.8.1.2 Lower Parasitics vs. Cycle Inefficiency**

In a binary plant, a heat exchanger must be used to transfer the heat from the geothermal fluid to the power plant working fluid. As such, there is an inherent loss of efficiency from the process, as well as the capital cost of the heat exchanger itself. There is also a cycle feed pump, a significant power consumer that has no counterpart at all in a geothermal steam turbine power plant. On the other hand, in a plant directly using geothermal steam, the process of removing NCGs from the condenser is also an inherent loss of efficiency and a significant capital cost that does not exist in a binary power plant. How the two options balance out is dependent on site-specific factors, but conceptually, there are offsetting advantages and disadvantages, making the thermodynamic and economic balance closer than it might appear at first glance.

The exception to the offsetting advantages of binary plants versus direct steam plants occurs when the use of binary also forces the use of air-cooled condensers instead of water-cooled condensers and evaporative cooling towers. The water-cooled direct contact condenser has lower capital cost, higher efficiency, and lower parasitic loads than an air-cooled condenser system in all but the coldest climates.

### **51.8.1.3 Compactness**

Binary power plants operate with working pressures much higher than those used for low-temperature flash power plants. This translates to smaller pipes and eliminates flash separators and scrubbers on pressurized brine systems; additionally, the condensers have smaller volumes because of the much higher condenser pressures of the working fluids.

**FIGURE 51.10**

Pressurized brine binary power process (air or water cooled).

### 51.8.2 Types of Binary Systems

There are two types of binary power systems currently in use, both of which are based on hydrocarbons, and a third currently under development that is based on using an ammonia–water mixture as the working fluid. A fourth binary power system based on commercial refrigeration equipment is also under development, with a 200 kW demonstration project starting operation in Alaska at Chena Hot Springs in 2006. All of these power cycles are similar to that shown in Figure 51.10.

#### 51.8.2.1 Subcritical Pentane Binary Power Plants

The geothermal fluids (brine or steam) are used to boil pentane as the power cycle working fluid in an ORC. The pentane passes through a turbine coupled to a generator and is then condensed. The cooled geothermal fluid is injected back into the geothermal reservoir.

The use of pressurized geothermal water from pumped wells in a subcritical pentane-based power plant is the most prevalent method to utilize geothermal resources from 280°F to 320°F. This system is also used to extract additional energy and power from the residual brine from single-flash flash plants all around the world.

Where two-phase geothermal fluid is available instead of pressurized brine, the two-phase fluids can be used in one of two ways. In some instances, both the steam and the brine are used in the vaporizers and preheaters. On larger facilities, it is more common to see a mixture of steam turbines and ORC plants. This type of integrated facility is made up of a pressurized brine facility of the type described above and a geothermal combined-cycle facility. In the geothermal combined-cycle facility, geothermal steam is first passed through a steam turbine and then condensed in a binary power plant.

#### 51.8.2.2 Supercritical Hydrocarbon Binary Power Plants

Several hydrocarbon-based binary power plants have been built that use supercritical isobutane as the working fluid in an ORC. The pinch point is eliminated in the vaporizer in the supercritical regime. Although there is a theoretical thermodynamic benefit to a supercritical power cycle, the market has not embraced these plants because they tend to be much more expensive than the subcritical plants.

### 51.8.2.3 Ammonia–Water Binary Power Plants

Several different power cycles have been proposed based on ammonia-water systems. The potential advantages and disadvantages that all ammonia systems share over hydrocarbon-based binary systems include:

- Higher heat-capacity fluid means smaller heat exchangers and less parasitic load from the working fluid cycle feed pumps.
- Higher pressures result in smaller vapor equipment components.
- The boiling point changes with water/ammonia concentration, providing a boiling point glide instead of a single pinch point temperature, increasing thermodynamic efficiency.
- Condensation temperature changes with concentration, again providing a glide instead of a pinch point and a higher thermodynamic efficiency.
- The design of the heat exchangers is more complex to achieve the glides.
- There is a tradeoff of ammonia toxicity for hydrocarbon flammability.
- Ammonia has been used in refrigeration cycles for a century, providing a wealth of practical operating knowledge, even though few ammonia-based power plants exist.
- Ammonia vapor and steam have similar molecular weights (17 and 18 g/mol, respectively), which theoretically means that conventional steam turbines could be used, with little modification; if true, it would allow a rapid step up in turbine size to 30 MW or more and for the competitive bidding for supply of the turbine.
- Ammonia cycles are more complex, with more exchangers and cycle pumps.

In spite of the net benefit of the potential advantages, only one 2 MW geothermal plant has been installed to date, in Husavik, Iceland, using one of many Kalina cycle ammonia–water technologies. Plans to install additional Kalina cycle plants at Salt Wells, Nevada, and a 42 MW plant at Cove Fort, Utah, have been announced.

### 51.8.3 Binary Power Plants for Pressurized Geothermal Brine

Ormat Technologies\* has developed a binary power plant approach, using subcritical pentane-based Rankine cycle technology, that commercially dominates the pressurized brine market. Because of that dominance, their technology will be used to illustrate the principles of the binary power plant design in this section. The technology has also been used in some instances in which the wells produce a mixture of steam and brine. These same basic power plants are now also being used to generate power from natural gas pipeline compressors exhaust gas waste heat.

Ormat started out designing and building small binary plants. One of their first installations was at the East Mesa field in California near the Mexican border. The ORMESA I plant began operation in 1987 and was comprised of 26 individual boiler/turbine/condenser units, with a total output of 24 MW. Since the East Mesa installation, Ormat has steadily increased the size of their units in the pursuit of both economy of scale and efficiency, and hence, lower installed cost (\$/kW). Initially, Ormat technology was based on a modular design, in which the economy of scale of a single large plant was traded off in

---

\* Ormat Technologies, <http://www.ormat.com>.

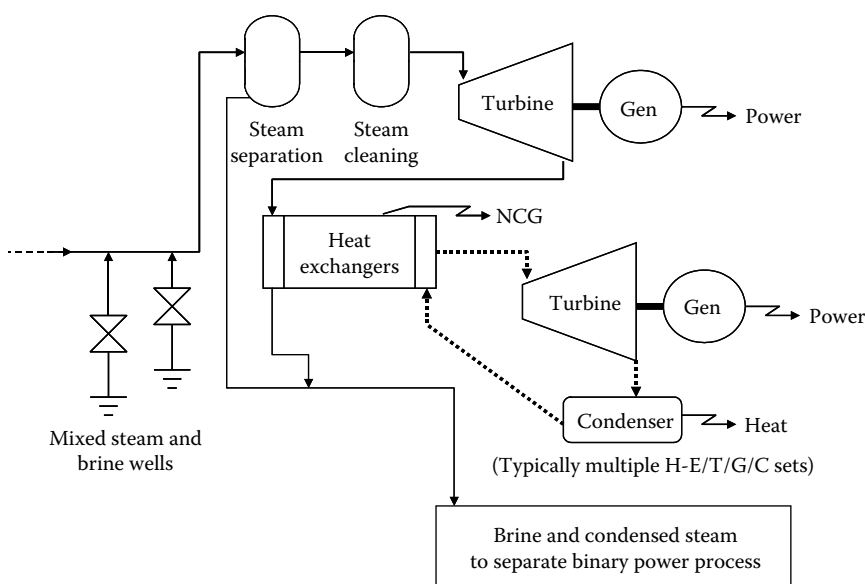

The basic ORC process design used by Ormat is illustrated in Figure 51.11. The hot pressurized geothermal brine, whether from a pumped well or as residual brine from a flash plant, enters the high-pressure (HP) vaporizer to generate HP pentane vapor for the HP turbine. The geothermal fluid exits the HP turbine and enters the low-pressure (LP) vaporizer, which generates vapor for the LP turbine. From the LP vaporizer, the geothermal fluid splits between the preheaters of the LP and HP vaporizers. The pentane for the LP turbine is pumped out of the condenser to the preheaters and into the vaporizers. Pentane vapor passes through the turbine and into the condenser. The HP pentane cycle is similar, except that the pentane from the condenser is first pumped to a desuperheater located between the turbine discharge and the condenser.

Binary power plants have been installed to capture the waste energy of several geothermal power plant hot brine discharges. Examples include Brady Hot Springs (Nevada), Mak-Ban (Philippines), Los Azufres (Mexico), Miravalles (Costa Rica), and Wairakei (New Zealand). There also remain many locations where binary power plants could be installed on existing steam flash plants.

#### 51.8.4 Integrated Steam Turbine and Binary Power Plants

In other locations, steam turbine(s) and binary power units have been combined into a single facility. Integrated facilities are installed at fields where the geothermal fluid is produced to the surface as a mix of steam and brine, rather than pumped and pressurized brine.

**FIGURE 51.12**

Integrated brine steam combined cycle binary power process (air cooled).

The largest integrated facilities are those of Ormat Technologies, and are based on the integration of the pressurized brine ORC and what is referred to as GCC plants. See Figure 51.12.

#### 51.8.4.1 The Geothermal Combined Cycle Process

The brine/steam mix flows from the production well to a separator. Brine from the separator is directed to a pressurized brine binary power plant, as described above.

Steam from the separator is cleaned and delivered to a steam turbine. The steam turbine faces the same inlet steam quality issues as were discussed in Section 51.8. However, because the turbine discharges at near-atmospheric pressures, the previously discussed concerns about last-stage blade length and moisture-induced erosion are eliminated. With the elimination of these two issues, cycle optimization of the geothermal resource can be undertaken without a cap on the maximum turbine inlet pressure. The available mass and the optimized pressure of the steam result in varying steam turbine sizes and outputs at different geothermal fields.

At the larger GCC units (see Table 51.10), the steam that discharges from the steam turbine is divided among multiple binary units. Each binary unit condenses the steam in a process of heating and vaporizing the binary unit working fluid. The condensed steam is mixed back into the brine to reduce silica scaling potential. In some instances, small steam turbines are coupled to one end of a generator, with the steam discharged used in a binary plant with the pentane turbine coupled to the other end of the generator. In most cases, the condensers for the binary power plant are air-cooled.

#### 51.8.4.2 Silica Solubility Limits

In fields with a steam/brine mix, the GCC competes directly with multistage flash steam technology. The GCC can produce greater output where flash plants have elected to use a

**TABLE 51.10**

Examples of Ormat Geothermal Combined Cycle Projects

Year	Project Name and Location	Project Net Output (MW)	Description of the Air-Cooled Power Plant
1996	Upper Mahiao, Leyte, Philippines	125	Four geothermal steam turbines that feed multiple binary units for 120 MW of net output. An additional 5 MW of power are generated by other binary units using the geothermal brine
2000	Mokai, New Zealand	60	One geothermal steam turbine that feeds multiple binary units for 50 MW of net output. Ten megawatts of power are generated by binary units using the geothermal brine

single flash to control silica ( $\text{SiO}_2$ ) scaling, resulting in a brine discharge temperature of 300°F or greater. The same temperature limitation of the single-flash technology does not apply to the GCC, so the GCC is able to capture more energy from a given brine flow and therefore generate more power. Although it may at first seem counter-intuitive, the hotter the resource and thus the more steam that is produced in the flash process, the more advantage the GCC will have.

In a flash process, hotter brine results in a greater silica concentration in the reservoir fluid. Hotter brine also results in more flash, and therefore more concentration of the silica. The silica solubility limit controls the separated brine temperature, and therefore the minimum allowable flash pressure and temperature. Thus, because of the silica concentration, higher geothermal resource temperatures also result in a higher brine temperature that must be discharged from the flash plant.

Although the integrated binary plant also uses the initial flash in the steam turbine of the GCC, the condensed steam is mixed back into the brine flow. As a result, the final brine temperature can be lower without risking silica scaling. Consequently, more energy is available to the integrated binary power plant than is available to the flash-only plant. The binary plant advantage would be reduced if more geothermal operators were willing to use acid to slightly lower the pH of the brine and retard the kinetics of the silica precipitation.

#### **51.8.4.3 Compare and Contrast**

The GCC technology has some additional advantages and disadvantages over a single- or multiple-flash plant when compared side-by-side for a particular geothermal resource. The large advantage that the GCC obtains in greater energy availability due to the silica solubility limits is discussed in the paragraph above. The larger units that Ormat has developed in recent years will also help to make them more competitive through an economy of scale. Another advantage is obtained by discharging the steam turbine at slightly above atmospheric pressure. In this way, the NCGs are vented without the cost or parasitic load of the gas removal equipment that is needed when the steam turbine exhaust is at sub-atmospheric pressure, as occurs with the steam flash process. Since the steam condensate is mixed back into the brine with the GCC, the cost of an oxygenated fluid disposal well may be eliminated.

The advantages that the steam-turbine process holds over the GCC are: (1) the ability to use large equipment (up to a single 110 MW turbine); (2) no need for large heat exchangers (vaporizers and preheaters) and the intrinsic thermodynamic and capital cost penalty they entail; and (3) the steam flash process uses wet cooling from the condensed steam, whereas the GCC uses dry cooling, resulting in a higher final condenser temperature.

Thus, the steam process regains some of the thermodynamic disadvantage incurred by the silica solubility limit and the gas removal system parasitic steam load by having a lower power plant heat-rejection temperature and, thereby, greater available energy.

---

## 51.9 Environmental Impact

The generation of electric power will have an environmental impact, regardless of the energy source used. A large unregulated strip mine and unabated emissions from an old coal plant would probably represent the extreme negative end of the spectrum in its environmental impact to land, water, and air, but would not be particularly relevant to discussions of environmental impacts of power generation in the United States. Understanding the other end of the spectrum is much more complex. Solar and wind generation would seem to have zero emissions, but both of these require fossil-fired generation to back them up during periods when these generation technologies are unavailable or erratic. These “firming” requirements increase emissions from fossil-fired plants, and result in them not being the zero-emission technology that they might otherwise seem to be. What this shows is that even renewable technologies have negative environmental consequences. Society’s need for new sources of electric power generation, which cannot be served by conservation and efficiency, will result in negative environmental impacts.

Like other renewable technologies, geothermal power generation must be evaluated on a site-specific basis to accurately determine its environmental impacts. Two areas of environmental impact relevant to the use of geothermal energy, emissions and land use, are discussed below.

### 51.9.1 Geothermal Power Plant Emissions

Air emissions and clean air are the most-discussed environmental benefits of renewable-energy electric power generation, especially with the concern of the effect of greenhouse gases on global warming. Like other renewable energy sources, the emissions from geothermal power are generally low compared to fossil-fired generation. However, certain geothermal resources with high gas content may approach that of a natural gas fired power plant with regards to CO<sub>2</sub> emissions, but this is a rare exception. The concentrated CO<sub>2</sub> discharged from such units does make CO<sub>2</sub> capture feasible. The actual emissions from geothermal power plants are dependent on the highly variable gas content of the geothermal fluids that are being produced and the nature of the geothermal power process. [Table 51.11](#) gives representative emissions of geothermal power plants compared to fossil-fired generation sources.

Pumped binary power plants have no emissions, except for fugitive leaks of the working fluid. As discussed above, the gases are still present in the brine, but because the pressure is never lowered below the bubble pressure of the gases, they remain in solution and are injected back into the geothermal resource.

#### 51.9.1.1 CO<sub>2</sub> Emissions

Flash-steam power plants have emissions on the order of magnitude described, but vary according to the particular resource characteristics and whether the power process is

TABLE 51.11

Emissions from Generation Sources

	Emissions Rate (lb/MW h)				
Plant/Fuel	NO <sub>x</sub>	SO <sub>2</sub>	CO <sub>2</sub>	Particulates	Notes
<i>Conventional power plants</i>					
Coal	4.3	10.4	2190	2.2	
Coal—life cycle	7.4	14.8	—	20.3	— <sup>a</sup>
Natural gas	3.0	0.2	1210	0.1	— <sup>b</sup>
Avg. of all U.S. plants	3.0	6.0	1390	—	[18]
<i>Geothermal power plants</i>					
Pumped geothermal brine	0	0	0	Negligible	— <sup>c</sup>
Geothermal flash steam plants	0	Negligible with abatement to 0.35	60 (avg.) some plants <120 to >900	Negligible	— <sup>d</sup>
Dry steam resources	Trace	Negligible with abatement	90 (Geysers) some plants <120 to >900	Negligible	

Source: Kagel, A. et al., *A Guide to Geothermal Energy and the Environment*, Geothermal Energy Association, Washington, DC, 2005, p. 39.

<sup>a</sup> Kagel reports that this includes the emissions from the mining and transportation of coal to the power plant.

<sup>b</sup> Kagel reports as an average of direct fired, combined cycle, and simple cycle plants.

<sup>c</sup> Cooling tower drift only, if water cooling is used. Air-cooled plants have zero particulate emissions.

<sup>d</sup> 150–900 lb/MW h of CO<sub>2</sub> is added to Kagel's reported numbers for both flash and steam plants. It is based on 0.7%–5% CO<sub>2</sub> in the geothermal steam and 18–20 klb/MW h steam usage in the power plant. These are realistic, though nonproject-specific, values for some high-gas geothermal resources worldwide.

single-flash, double-flash, or coupled to a binary system. Most geothermal flash steam resources have NCG content of between 0.5% and 2% in the steam, which, when coupled with either double flash or a binary system, results in the reported values. However, for those systems that operate with only a single flash and have NCG content of up to 5% in the steam, the CO<sub>2</sub> emissions can reach the 900 lb/MW h reported in the above table.

Like the flash steam plants, the emissions from a dry steam power plant are dependent on the particular resource being considered.

### 51.9.1.2 H<sub>2</sub>S and SO<sub>x</sub> Emissions

For geothermal power plants with some form of H<sub>2</sub>S abatement, sulfur emissions are negligible to very low, as shown in the table. For those plants without H<sub>2</sub>S abatement, the released H<sub>2</sub>S eventually converts to SO<sub>2</sub>, and can be on the same order of magnitude as U.S. coal plant emissions for geothermal resources with high-H<sub>2</sub>S content in the NCGs.

Except for California and the western United States, few geothermal plants worldwide operate H<sub>2</sub>S abatement systems. Stretford<sup>TM</sup> and Lo-Cat<sup>TM</sup> are the most common H<sub>2</sub>S abatement technologies for gas-phase H<sub>2</sub>S emissions. The use of bioreactors is an emerging technology for abatement, one in which sulfur-loving bacteria are used to convert the H<sub>2</sub>S to sulfate. Bioreactors have been independently developed and put into operation at the Salton Sea, California, and in Wairakei, New Zealand.

### 51.9.1.3 NO<sub>x</sub> Emissions

The reason NO<sub>x</sub> emissions are reported as “negligible” instead of zero for the dry steam plants is a consequence of the early H<sub>2</sub>S abatement technology installed at The Geysers

**TABLE 51.12**

30-Year Land Use

Energy Source	Land Use (m <sup>2</sup> /GW h)
Coal, including mining	3642
Solar thermal	3561
Central station photovoltaic	3237
Wind, including roads	1335
Geothermal, including roads and pipelines	404

Source: Brophy, P., *Renewab. Energy*, 10, 374, 1997.

that incinerates the H<sub>2</sub>S and then scrubs it out of the gas stream using the cooling water. The incineration also produces small amounts of nitrogen oxides. Since those early efforts at H<sub>2</sub>S abatement, the geothermal industry has primarily used a cold catalytic conversion of H<sub>2</sub>S to elemental sulfur, which has no NO<sub>x</sub> emissions.

#### 51.9.1.4 Particulate Emissions

Air-cooled plants have no particulate emissions, whereas water-cooled plants have only the evaporated minerals remaining from cooling tower drift, the quantity of which will be a function of the TDS in the cooling water. This quantity of particulate is negligible.

#### 51.9.2 Land Use

Compared to other renewable energy sources, geothermal power developments have low land use and visual impact. The total geothermal development of wells and power plant may occur over many square miles, but the actual land occupied by the facilities is small. Some negative impacts may be attributed when a geothermal development occurs in a roadless area. There is a visual impact from the pipelines running from wells to power plant, and from the cooling tower steam plume on a cold day. When an air-cooled power cycle is used, geothermal power generation achieves its minimum visual impact. The fenced area of the power plant itself may be no larger than a couple of acres for up to 20 MW of net generation. The height of the air-cooled condenser, the highest point in the plant, is less than 25 ft above ground level. Overall, the land-use impact of geothermal development is small. Table 51.12 provides the total land use of various renewable and coal power technologies.

### 51.10 Additional Information on Geothermal Energy

This chapter has touched on only some of the many topics in the field of geothermal energy—a subject to which entire books have been devoted. Some additional geothermal energy information sources are provided in this section.

For a broad view on the subject of geothermal energy, including many direct-use applications such as aquaculture, district heating, industrial heat use, environmental issues and financing, a recent book, *Geothermal Energy—Utilization and Technology*, edited by Mary Dickson and Mario Fanelli, is an excellent resource. Each chapter has been written by an

expert of geothermal subject matter. At the end of each chapter are questions, answers, and references regarding the particular subject matter of that chapter.

Another recent book, *Geothermal Power Plants: Principles, Applications and Case Studies*, authored by Ronald DiPippo, provides some coverage of geothermal exploration, drilling, and reservoir engineering, with a primary focus on geothermal power generation. The book covers the conversion technologies, thermodynamics, equipment, and operation, and includes several detailed case studies of particular geothermal power plant developments.

In addition, there are a number of excellent geothermal resources on the World Wide Web.

Geo-Heat Center, <a href="http://geoheat.oit.edu/">http://geoheat.oit.edu/</a>	Focus is direct use. Excellent online library. Software and databases
Geothermal Resources Council, <a href="http://www.geothermal.org/">www.geothermal.org/</a>	GRC bulletin and transaction articles. Must be a member of the GRC to download articles
Geothermal Energy Association, <a href="http://www.geo-energy.org">www.geo-energy.org</a>	The U.S. geothermal industry trade association several excellent broad research articles available for download including three papers on Geothermal Energy Costs, Environmental Impact, and Employment
International Geothermal Association, <a href="http://iga.igg.cnr.it/index.php">http://iga.igg.cnr.it/index.php</a>	Downloadable papers from the last two world geothermal conferences

## 52.1 Introduction

Energy carriers are a convenient form of stored energy. Electricity is one type of carrier that can be produced from various sources, transported over large distances, and distributed to the end user. Hydrogen is another type of energy carrier. If produced from clean sources, it constitutes a clean and versatile carrier. Liquid hydrogen is already used for space shuttles and rockets and is also proposed for the future hypersonic or supersonic space vehicles. However, at present, there is increased interest from governments in the development of hydrogen as a fuel for other applications such as transportation and stationery power from off-peak storage. This chapter provides the information about hydrogen and the status of hydrogen technologies. The topics covered include hydrogen production, storage, distribution, conversion, and safety.

## 52.2 Properties of Hydrogen

Hydrogen is an odorless, colorless gas. With a molecular weight of 2.016, hydrogen is the lightest element. Its density is about 14 times less than air (0.08376 kg/m<sup>3</sup> at standard temperature and pressure). Hydrogen is liquid at temperatures below 20.3 K (at atmospheric pressure). Hydrogen has the highest energy content per unit mass of all fuels—higher heating value is 141.9 MJ/kg, almost three times higher than gasoline. However, because of its low density, its heating value on volumetric basis is almost one-third of natural gas. Some important properties of hydrogen are compiled in Table 52.1. It exists in three isotopes: protium, deuterium, and tritium. A standard hydrogen atom (protium) is the simplest of all the elements and consists of one proton and one electron. Molecular hydrogen (H<sub>2</sub>) exists in two forms: *ortho*- and *para*-hydrogen. Both forms have identical chemical

**TABLE 52.1**

Properties of Hydrogen (at Normal Temperature and Pressure)

Molecular weight		2.016
Density	kg/m <sup>3</sup>	0.0838
Higher heating value	MJ/kg	141.90
	MJ/m <sup>3</sup>	11.89
Lower heating value	MJ/kg	119.90
	MJ/m <sup>3</sup>	10.05
Boiling temperature	K	20.3
Density as liquid	kg/m <sup>3</sup>	70.8
Critical point

Specific heat (c <sub>p</sub> )	kJ/(kg K)	14.89

properties, but due to different spin orientation have somewhat different physical properties. At room temperature, hydrogen consists of approximately 75% *ortho*- and 25% *para*-hydrogen. Since *para*-hydrogen is more stable at lower temperatures, its concentration increases at lower temperatures, reaching virtually 100% at liquid hydrogen temperatures.

## 52.3 Hydrogen Production Methods

While hydrogen is the most plentiful element in the universe, making up about three quarters of all matter, free hydrogen is scarce. The atmosphere contains trace amounts of it (0.07%), and it is usually found in small amounts mixed with natural gas in crustal reservoirs. A few wells, however, have been found to contain large amounts of hydrogen, such as some wells in Kansas that contain 40% hydrogen, 60% nitrogen, and trace amounts of hydrocarbons [1]. The Earth's surface contains about 0.14% hydrogen (10th most abundant element), most of which resides in chemical combination with oxygen as water. Hydrogen, therefore, must be produced. Logical sources of hydrogen are hydrocarbon (fossil) fuels ( $C_xH_y$ ) and water ( $H_2O$ ). Presently, hydrogen is mostly being produced from fossil fuels (natural gas, oil, and coal). However, except for the space program, hydrogen is not being directly used as a fuel or an energy carrier. It is being used in refineries to upgrade crude oil (hydrotreating and hydrocracking), in the chemical industry to synthesize various chemical compounds (such as ammonia and methanol), and in metallurgical processes (as a reduction or protection gas). The total annual hydrogen production worldwide in 1996 was about 40 million tons (5.6 EJ) [2]. Less than 10% of that amount was supplied by industrial gas companies; the rest is being produced at consumer-owned and operated plants (so-called captive production), such as refineries, and ammonia and methanol producers. Production of hydrogen as an energy carrier would require an increase in production rates by several orders of magnitude.

A logical source for large-scale hydrogen production is water, which is abundant on Earth. Different methods of hydrogen production from water have been, or are being, developed. They include electrolysis, thermochemical processes, photolysis, photoelectrochemical (PEC), and photocatalysis. Biomass is another important renewable resource for producing hydrogen. Some of these methods are described in what follows (Table 52.2).

### 52.3.1 Electrolysis

Electrolysis appears to be the only method developed to date, which can be used for large-scale hydrogen production in a post-fossil fuel era. Production of hydrogen by water electrolysis is a mature technology; based on a fundamentally simple process, it is very efficient, and does not involve moving parts.

**TABLE 52.2**

Hydrogen Production Cost

Technology	Cost of $H_2$ (\$/GJ)	Cost of $H_2$ (\$/kg)
Direct biomass gasification	12.5–21.6	1.51–2.59
Steam reforming of bio-oil	10.3–19.9	1.24–2.38

Sources: Spath, P.L. et al., Update of hydrogen from biomass—Determination of the delivered cost of hydrogen, National Renewable Energy Laboratory, Golden, CO, NREL/MP-510-33112, 2000; Craig, K.R. and Mann, M.K., Cost and performance analysis of biomass based integrated gasification combined cycle BIGCC power systems, National Renewable Energy Laboratory, Golden, CO, NREL/TP-430-21657, 1996, 70 pp.

The following reactions take place at the electrodes of an electrolysis cell filled with a suitable electrolyte (aqueous solution of KOH or NaOH or NaCl) upon the application of a potential:

The reversible decomposition potential ( $E_{\text{rev}} = \Delta G/nF$ ) of the earlier reaction is 1.229 V at standard conditions. The total theoretical water decomposition potential is 1.480 V corresponding to hydrogen's enthalpy (since  $\Delta H = \Delta G + T\Delta S$ ). Due to irreversible processes occurring at the anode and the cathode, including the electrical resistance of the cell, the actual potentials are always higher, typically between 1.75 and 2.05 V. This corresponds to the efficiencies of 72%–82%.

Several advanced electrolyzer technologies are being developed such as follows:

- Advanced alkaline electrolysis, which employs new materials for membranes and electrodes that allow further improvement in efficiency—up to 90% [3,4].
- Solid polymer electrolytic process, which employs a proton-conducting ion exchange membrane as electrolyte and as membrane that separates the electrolysis cell. This type of electrolyzers can operate at very high current densities (up to 2 A/cm<sup>2</sup>, which is about one order of magnitude higher than standard electrolyzers with alkaline liquid electrolyte). The water to be dissociated does not require dissolved electrolytes to increase its conductivity, and is added solely to the anode side [4,5].
- High-temperature steam electrolysis operates between 700°C and 1000°C, which employs oxygen ion-conducting ceramics as electrolyte. Electrical energy consumption is reduced since part of the energy required for water dissociation is supplied in the form of heat. The water to be dissociated is entered on the cathode side as steam, which forms a steam–hydrogen mixture during electrolytic dissociation. The O<sup>2−</sup> ions are transported through the ceramic material to the anode, where they are discharged as oxygen [6].

An electrolysis plant can operate over a wide range of capacity factors and is convenient for a wide range of operating capacities, which makes this process interesting for coupling with renewable energy sources, particularly with photovoltaics (PVs). PV generates low-voltage direct current, exactly what is required for the electrolysis process.

The performance of PV–electrolyzer systems has been studied extensively both in theory and in practice [7–10]. Several experimental PV–electrolysis plants are currently operating all over the world, such as follows:

- Solar–Wasserstoff–Bayern pilot plant in Neunburg vorm Wald, Germany [11]
- HYSOLAR project in Saudi Arabia [12]

- Schatz Energy Center, Humboldt State University, Arcata, California [13]
- Helsinki University of Technology, Helsinki, Finland [14]
- INTA Energy Laboratory, Huelva, Spain [15]

### 52.3.2 Thermochemical Processes

Thermochemical hydrogen production is a means of splitting water via a series of chemical reactions. All chemical intermediates are recycled internally within the process so that water is the only raw material and hydrogen and oxygen are the only products. The maximum temperature requirements for most thermochemical cycles lie within a temperature range of 650°C–1100°C [16], thus eliminating use of lower temperature heat sources. High-concentration solar collectors and nuclear reactors are the possible sources of heat for these cycles. Figure 52.1 illustrates the concept of splitting of water by a thermochemical cycle.

According to Wendt [17], 2000–3000 different theoretical cycles have been proposed and evaluated. However, out of all the possible thermochemical cycles, Mark 1, Mark 15, ZnO/Zn, UT-3, Fe<sub>3</sub>O<sub>4</sub>/FeO, and iodine–sulfur processes are the only few, which have been studied extensively. The following cycles are under active research around the world.

#### 52.3.2.1 ZnO/Zn Cycle

ZnO/Zn cycle is a two-step water-splitting cycle based on the thermal redox pairs of metal oxides. As shown, in the following reactions, the process relies on the endothermic thermal dissociation of ZnO followed by the exothermic hydrolysis of Zn:

Theoretical conversion efficiencies are of the order of 50% [18]. This cycle is under active research [19]. The current work is focused on the quenching step and decomposition rate measurements. The success of this cycle will depend on the development of an efficient mechanism for the separation of Zn–H<sub>2</sub> mixture.

**FIGURE 52.1**

Schematic diagram of thermochemical cycle. (From Casper, M.S., *Hydrogen Manufacture by Electrolysis, Thermal Decomposition and Unusual Techniques*, Noyes Data Corporation, Park Ridge, NJ, 1978.)

### 52.3.2.2 UT-3 Cycle

The UT-3 cycle invented at the University of Tokyo consists of Ca, Fe, and Br compounds. It involves the use of solid and gaseous phases of reactants and products. The predicted first- and second-law efficiencies of the adiabatic UT-3 cycle are 49% and 53%, respectively [20]. This cycle is composed of the following reactions:

The reactants  $\text{CaBr}_2$ ,  $\text{CaO}$ ,  $\text{Fe}_3\text{O}_4$ , and  $\text{FeBr}_2$  are solids and stay within the four reactors while  $\text{Br}_2$ ,  $\text{H}_2\text{O}$ , and  $\text{HBr}$  are gases that move from one reactor to the next. Once the reactions in the forward direction are complete, the flow of gaseous reactants is reversed. Substantial amount of research work including bench-scale laboratory tests [21], solid reactants' development [22,23], and reaction kinetic measurements [24] have been performed on this cycle.

### 52.3.2.3 Iodine–Sulfur Cycle

Iodine–sulfur process is a three-step thermochemical cycle for decomposing water into  $\text{H}_2$  and  $\text{O}_2$ . The cycle proposed by General Atomic (GA) Co. is one of the extensively studied cycles. It proceeds by the formation of  $\text{H}_2\text{SO}_4$  and  $\text{HI}$  from  $\text{SO}_2$ ,  $\text{I}_2$ , and  $\text{H}_2\text{O}$ . It is followed by the decomposition of  $\text{HI}$  and  $\text{H}_2\text{SO}_4$  that produces  $\text{H}_2$  and  $\text{I}_2$ , respectively. The chemical reactions involved in the process are shown in the following equations [25]:

The maximum hydrogen production efficiency as estimated by GA was around 50% [26]. Practical implementation of this cycle has been limited by the effective separation of  $\text{HI}$  and  $\text{H}_2$  from  $\text{HI-I}_2\text{-H}_2\text{O}$  and  $\text{H}_2\text{-H}_2\text{O-HI-I}_2$  mixtures, respectively.

Due to the numerous thermochemical cycles and limited data for each of these cycles, it is difficult to choose an optimal thermochemical process. Material problems at high temperatures have also hindered the development of efficient scalable reactor concepts. The problems associated with the separation of hydrogen and oxygen, the depletion of intermediate products, and matching the reaction rates of the individual steps have further limited the practical implementation of thermochemical cycles. So far, only one cycle has been demonstrated on a bench scale, and none of them have been demonstrated at a larger scale.

### 52.3.3 Photoelectrochemical Hydrogen Production

PEC systems combine both PV and electrolysis into a one-step water-splitting process. These systems use a semiconductor electrode exposed to sunlight in combination with a metallic or semiconductor electrode to form a PEC cell. A schematic illustration of a PEC hydrogen production driven by solar energy is shown in Figure 52.2. In general, the semiconductor electrode (photoanode) is activated by solar radiation, which drives the reaction in aqueous solution. Due to bandgap illumination, electrons and holes are formed in the conduction and valence bands, respectively, at the photoanode.

The photogenerated holes at the anode split the water molecules into hydrogen ions and oxygen. Hydrogen ions released hence migrate to the cathode through the aqueous electrolyte.

Electrons generated at photoanode are transferred over the external circuit to the cathode, where they reduce hydrogen ions into gaseous hydrogen:

Ideally, electrochemical decomposition of water takes place when the electromotive force of the cell is equal to 1.23 eV. If we consider internal losses in the PEC, a minimum bandgap of 1.8 eV is required to run the reaction [28]. Photoelectrochemically stable semiconductors such as  $\text{TiO}_2$  and  $\text{SrTiO}_3$  have a wide bandgap and hence are limited in the UV region of the solar spectrum, whereas narrow bandgap semiconductors such as GaP and GaAs are often photoelectrochemically unstable [29]. The way to address the problem of low light absorption is to enlarge the spectral response of the PEC cells. The techniques used to solve the problem are dye adsorption, metal incorporation, and use of multijunction cells.

**FIGURE 52.2**

Schematic representation of photoelectrochemical (PEC) cell. (From Bak, T. et al., *Int. J. Hydrogen Energy*, 27, 991, 2002.)

### 52.3.4 Photochemical Hydrogen Production

Photochemical systems differ from PEC systems in the fact that they use a semiconductor suspension instead of individual electrodes to induce the reactions. Photochemical systems have photosensitizer particles suspended in an aqueous solution where a photosensitizer is an organic or semiconductor molecule that can absorb sunlight and induce photochemical reactions for the hydrogen production. The reduction and oxidation reactions occur simultaneously at the surface of the suspended photosensitizer particles. Since absorption of a single photon can at most cause the transfer of one electron, a catalyst is required along with light to induce the redox reaction.

Figure 52.3 illustrates the schematic of a general photochemical reaction to generate hydrogen. No photochemical system has been able to reach an efficiency of 10%.

### 52.3.5 Hydrogen Production from Biomass

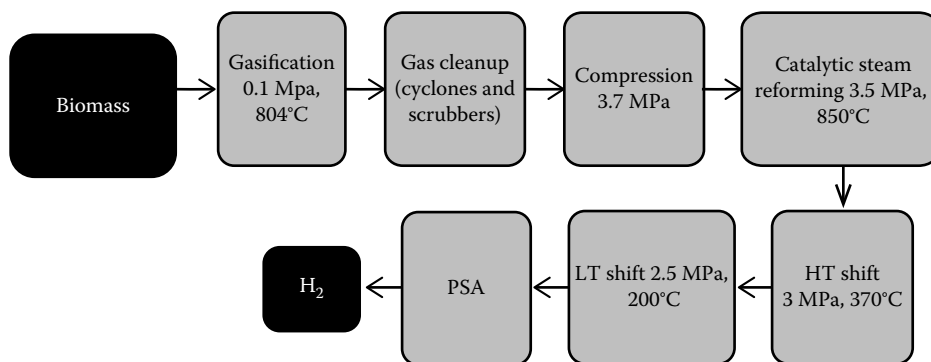

Biomass represents a large potential feedstock resource for environmentally clean hydrogen production. It lends itself to both biological and thermal conversion processes. In the thermal path, hydrogen can be produced in two ways, viz., direct gasification and pyrolysis to produce liquid bio-oil followed by steam reforming.

Direct gasification of biomass is in many ways similar to coal gasification. The process occurs broadly in three steps: Biomass is first gasified (using steam or air) to produce an impure syngas mixture composed of hydrogen, CO, CO<sub>2</sub>, CH<sub>4</sub>, small amounts of higher hydrocarbons, tar, and water vapor. The gas may also contain particulate matter, which is removed using cyclones and scrubbers. The particulate free gas is compressed and then catalytically steam-reformed to eliminate the tars and higher hydrocarbons. This is followed by high- and low-temperature shift conversions to convert the CO to CO<sub>2</sub> and thereby produce additional hydrogen. Finally, the hydrogen is separated from other products by pressure swing adsorption [31]. Figure 52.4 illustrates

**FIGURE 52.3**

Minimal scheme for the photochemical splitting of water. S is a photochemical sensitizer. (From Bolton, J.R., Solar photoproduction of hydrogen, International Energy Agency Technical Report, IEA/H2/TR-96, 1996a.)

**FIGURE 52.4**

Gasification followed by steam reforming. (From Spath, P.L. et al., Update of hydrogen from biomass—Determination of the delivered cost of hydrogen, National Renewable Energy Laboratory, Golden, CO, NREL/MP-510-33112, 2000.)

the sequence of processes. The main reactions taking place in biomass gasification are as follows:

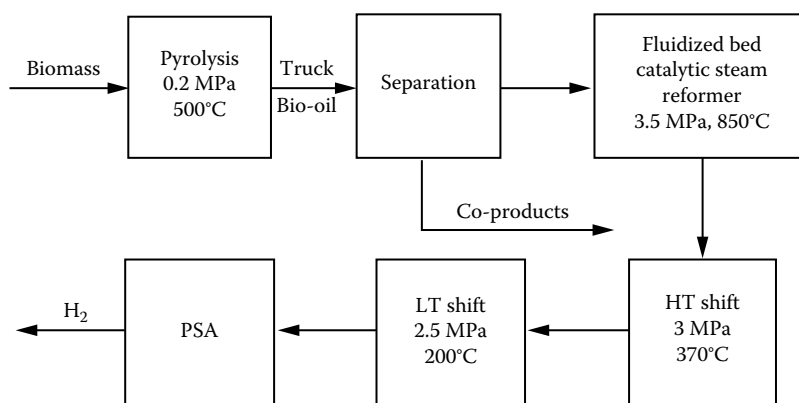

Biomass typically contains about 6% hydrogen by weight. However, in the presence of hydrogen-bearing species (steam), the hydrogen yield can be considerably improved above the 6% minimum [32]. Gasification temperatures encountered are typically in the range 600°C–850°C, which is lower than many thermochemical water-splitting cycles thereby making biomass gasification an attractive technology to produce hydrogen. Steam gasification of biomass is endothermic, and the energy required for the process is supplied by burning part of the biomass feedstock or uncombusted char. Tars are polyaromatic hydrocarbons produced during gasification of biomass. Tars are undesirable coproducts as they clog filters, pipes, and valves and damage downstream equipments such as engines and turbines. Efforts are being made to minimize or reform the tars to additional product hydrogen [33,34].

Hydrogen can alternately be produced by reforming the biomass to a liquid bio-oil in a process called pyrolysis. Pyrolysis is an endothermic thermal decomposition of biomass carried out in an inert atmosphere at 450°C–550°C [35]. The bio-oil so produced is a liquid composed of 85% oxygenated organics and 15% water. The bio-oil is then steam-reformed in the presence of a nickel-based catalyst at 750°C–850°C followed by shift conversion to convert CO to CO<sub>2</sub> [36]. Figure 52.5 illustrates the sequence of processes. The reactions can be written as follows:

A number of research groups around the world are involved in research on hydrogen production from a variety of biomass resources, including wood, municipal solid waste,

**FIGURE 52.5**

Pyrolysis followed by steam reforming. (From Spath, P.L. et al., Update of hydrogen from biomass—Determination of the delivered cost of hydrogen, National Renewable Energy Laboratory, Golden, CO, NREL/MP-510-33112, 2000.)

and residues from industries [34,37–44]. There are currently no commercial biomass gasification processes for hydrogen production, but there are several demonstration plants of biomass gasifiers for producing electricity or other chemicals [45]. The FERCO SilvaGas process employs low-pressure Battelle Columbus gasification, which consists of two physically separate reactors—a gasification reactor in which biomass is converted into a medium-heating-value gas and residual char at a temperature of 850°C–1000°C and a combustion reactor that burns residual char to provide heat for gasification. A typical product gas using wood chips consists of about 21% H<sub>2</sub> (using steam/biomass ratio of 0.45). The Fast Internal Circulation Fluidized Bed (FICFB) process is another example. In FICFB, there is a single reactor with two zones—a gasification zone and a combustion zone; biomass is gasified in the gasification zone with steam at 850°C–950°C followed by circulation to the combustion zone where char is burned to supply thermal energy. A demonstration plant producing 2 MW electrical power was constructed in Europe in 2001 (details in [45]).

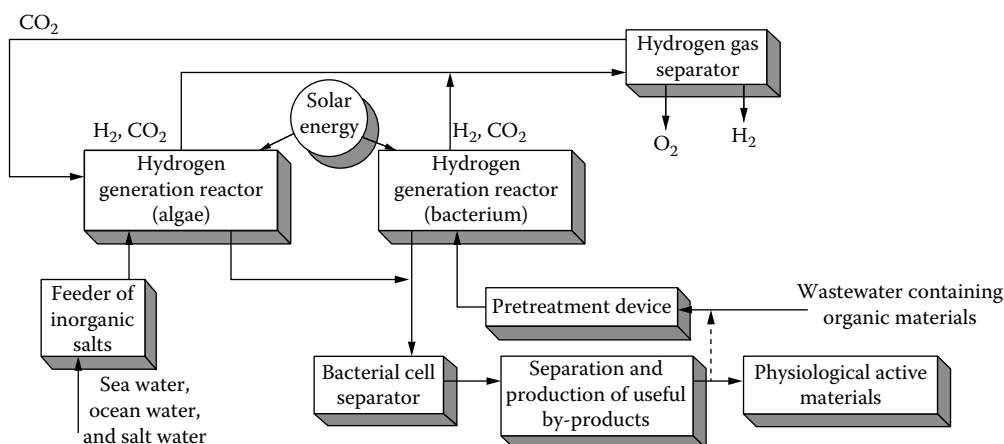

Biomass resources have the advantage of being renewable and hence can make an important contribution to renewable hydrogen production. However, an important factor that prohibits commercialization is the difficulty of transporting large amounts of low-energy-density biomass feedstocks over long distances. The cost associated with growing, harvesting, and transporting biomass may be up to 40% of the total biomass plant operating cost [31,46].

Additional technical and economic considerations for capture and storage of CO<sub>2</sub> may also be necessary as both gasification and pyrolysis produce carbon dioxide.

### 52.3.6 Biological Methods

Hydrogen may also be obtained from biological processes involving organic compounds. One of the techniques used for hydrogen production using biological means is shown in Figure 52.6.

The two fundamental ways of biological hydrogen production are (1) *fermentation of the bacteria*, which is an anaerobic process that converts organic substances like starch, cellobiose, sucrose, and xylose to H<sub>2</sub> and CO<sub>2</sub> without the need of sunlight and oxygen, and (2) *biophotolysis*, a process that uses microalgae—cyanobacteria and green algae to produce hydrogen in the presence of sunlight and water. Both of these processes are being researched.

**FIGURE 52.6**

Concept of biological hydrogen production. (Adapted from Miyake, J. et al., *J. Biotechnol.*, 70, 89, 1999, Figure 1.)

## 52.4 Hydrogen Storage Methods

### 52.4.1 Gaseous Hydrogen Storage

Because of hydrogen's low density, its storage always requires relatively large volumes and is associated with either high pressures (thus requiring heavy vessels), or extremely low temperatures, and/or combination with other materials (much heavier than hydrogen itself). Table 52.3 shows achievable storage densities with different types of hydrogen storage methods. Some novel hydrogen storage method may achieve even higher storage densities, but have yet to be proven in terms of practicality, cost, and safety.

**TABLE 52.3**

Hydrogen Storage Types and Densities

H <sub>2</sub> Storage Method	kg H <sub>2</sub> /kg	kg H <sub>2</sub> /m <sup>3</sup>
<i>Large volume storage (10<sup>2</sup>–10<sup>4</sup> m<sup>3</sup> geometric volume)</i>		
Underground storage		5–10
Pressurized gas storage (aboveground)	0.01–0.014	2–16
Metal hydride	0.013–0.015	50–55
Liquid hydrogen	~1	65–69
<i>Stationary small storage (1–100 m<sup>3</sup> geometric volume)</i>		
Pressurized gas cylinder	0.012	~15
Metal hydride	0.012–0.014	50–53
Liquid hydrogen tank	0.15–0.50	~65
<i>Vehicle tanks (0.1–0.5 m<sup>3</sup> geometric volume)</i>		
Pressurized gas cylinder	0.05	15
Metal hydride	0.02	55
Liquid hydrogen tank	0.09–0.13	50–60

Depending on storage size and application, several types of hydrogen storage may be differentiated:

1. *Stationary large storage systems*: These are typically storage devices at the production site or at the start or end of pipelines and other transportation pathways.
2. *Stationary small storage systems*: At the distribution or final user level, for example, a storage system to meet the demand of an industrial plant.
3. *Mobile storage systems for transport and distribution*: These include both large-capacity devices, such as a liquid hydrogen tanker—bulk carrier—and small systems, such as a gaseous or liquid hydrogen truck trailer.
4. *Vehicle tanks*: To store hydrogen used as fuel for road vehicles.

#### **52.4.1.1 Large Underground Hydrogen Storage**

Underground storage of hydrogen in caverns, aquifers, depleted petroleum and natural gas fields, and man-made caverns resulting from mining and other activities is likely to be technologically and economically feasible [48]. Hydrogen storage systems of the same type and the same energy content will be more expensive by approximately a factor of 3 than natural gas storage systems, due to hydrogen's lower volumetric heating value. Technical problems, specifically for the underground storage of hydrogen other than expected losses of the working gas in the amount of 1%–3% per year, are not anticipated. The city of Kiel's public utility has been storing town gas with a hydrogen content of 60%–65% in a gas cavern with a geometric volume of about 32,000 m<sup>3</sup> and a pressure of 80–160 bar at a depth of 1,330 m since 1971 [49]. Gaz de France (the French National Gas Company) has stored hydrogen-rich refinery by-product gases in an aquifer structure near Beynes, France. Imperial Chemical Industries of Great Britain stores hydrogen in the salt mine caverns near Teesside, United Kingdom [50].

#### **52.4.1.2 Aboveground Pressurized Gas Storage Systems**

Today, pressurized gas storage systems are used in natural gas business in various sizes and pressure ranges from standard pressure cylinders (50 L, 200 bar) to stationary high-pressure containers (over 200 bar) or low-pressure spherical containers (>30,000 m<sup>3</sup>, 12–16 bar). This application range will be similar for hydrogen storage.

#### **52.4.1.3 Vehicular Pressurized Hydrogen Tanks**

Storage of hydrogen in automobiles has been enabled by the development of ultralight but strong new composite materials. Pressure vessels that allow hydrogen storage at pressures >200 bars have been developed and are used in automobiles (e.g., Daimler-Benz NECAR II). A storage density higher than 0.05 kg of hydrogen/1 kg of total weight is easily achievable [51].

### **52.4.2 Liquid Hydrogen Storage**

At present, liquid hydrogen is primarily used as a rocket fuel and is predestined for supersonic and hypersonic space vehicles primarily because it has the lowest boiling point density and the highest specific thrust of any known fuel. Its favorable characteristics include

its high heating value per unit mass, its wide ignition range in hydrogen/oxygen or air mixtures, as well as its large flame speed and cooling capacity due to its high specific heat, which permits very effective engine cooling and cooling of the critical parts of the outer skin [52,53]. Liquid hydrogen has some other important uses such as in high-energy nuclear physics and bubble chambers. The transport of hydrogen is vastly more economical when it is in liquid form even though cryogenic refrigeration and special dewar vessels are required. Although liquid hydrogen can provide a lot of advantages, its uses are restricted in part because liquefying hydrogen by existing conventional methods consumes a large amount of energy (around 30% of its heating value). Liquefying 1 kg of hydrogen in a medium-size plant requires 10–13 kW h of energy (electricity) [53]. In addition, boil-off losses associated with the storage, transportation, and handling of liquid hydrogen can consume up to 40% of its available combustion energy. It is therefore important to search for ways that can improve the efficiency of the liquefiers and diminish the boil-off losses.

#### 52.4.2.1 Hydrogen Liquefaction

Production of liquid hydrogen requires the use of liquefiers that utilize different principles of cooling. In general, hydrogen liquefiers may be classified as conventional, magnetic, or hybrid. Many types of conventional liquefiers exist such as the Linde–Hampson liquefiers, the Linde dual-pressure liquefiers, the Claude liquefiers, the Kapitza liquefiers, the Heylandt liquefiers, and those liquefiers utilizing the Collins cycle, just to name a few. Conventional liquefiers generally comprise compressors, expanders, heat exchangers, and Joule–Thomson valves. Magnetic liquefiers, on the other hand, utilize the magnetocaloric effect. This effect is based on the principle that some magnetic materials experience a temperature increase upon the application of a magnetic field and a temperature drop upon lifting the magnetic field. The magnetic analog of several conventional liquefiers includes the Brayton liquefiers, the Stirling liquefiers, and the active magnetic regenerative liquefier. Additional information on liquid hydrogen production methods can be found in Sherif et al. [55].

Hydrogen is usually transported in large quantities by truck tankers of 30–60 m<sup>3</sup> capacity, by rail tank cars of 115 m<sup>3</sup> capacity, and by barge containers of 950 m<sup>3</sup> capacity [55]. Liquid hydrogen storage vessels are usually available in sizes ranging from 1 L dewar flasks used in laboratory applications to large tanks of 5000 m<sup>3</sup> capacity. The National Aeronautics and Space Administration typically uses large tanks of 3800 m<sup>3</sup> capacity (25 m in diameter) [48]. The total boil-off rate from such dewars is approximately 600,000 LPY (liters per year), which is vented to a burn pond. The contributing mechanisms to boil-off losses in cryogenic hydrogen storage systems are (1) *ortho*–*para* conversion, (2) heat leak (shape and size effect, thermal stratification, thermal overfill, insulation, conduction, radiation, and cooldown), (3) sloshing, and (4) flashing.

#### 52.4.3 Solid-State Hydrogen Storage

Hydrogen can be packed and stored in the solid state by forming metal hydride. During the formation of the metal hydride, hydrogen molecules are dissociated into H-atoms, and the hydrogen atoms are inserted in interstitial spaces inside the lattice of intermetallic compounds and/or alloys. In such a way, effective storage comparable to the density of liquid hydrogen is created. However, when the mass of the metal or alloy is taken into account, the metal hydride gravimetric storage density is comparable to the storage of pressurized hydrogen. The best achievable gravimetric storage density is about 0.07 kg of H<sub>2</sub>/kg of metal, for a high-temperature hydride such as MgH<sub>2</sub> as shown in

**TABLE 52.4**

Theoretical Capacities of Hydriding Substances as Hydrogen Storage Media

Medium	Hydrogen Content(kg/kg)	Hydrogen Storage(Capacity (kg/L of vol.)	Energy Density (kJ/kg)	Energy Density (kJ/L of vol.)
MgH <sub>2</sub>	0.070	0.101	9,933	14,330
Mg <sub>2</sub> NiH <sub>4</sub>	0.0316	0.081	4,484	11,494
VH <sub>2</sub>	0.0207		3,831	
FeTiH <sub>1.95</sub>	0.0175	0.096	2,483	13,620
TiFe <sub>0.7</sub> Mn <sub>0.2</sub> H <sub>1.9</sub>	0.0172	0.090	2,440	12,770
LaNi <sub>5</sub> H <sub>7.0</sub>	0.0137	0.089	1,944	12,630
R.E.Ni <sub>5</sub> H <sub>6.5</sub>	0.0135	0.090	1,915	12,770
Liquid H <sub>2</sub>	1.00	0.071	141,900	10,075
Gaseous H <sub>2</sub> (100 bar)	1.00	0.0083	141,900	1,170
Gaseous H <sub>2</sub> (200 bar)	1.00	0.0166	141,900	2,340
Gasoline	—	—	47,300	35,500

Table 52.4, which gives a comparison of some hydriding substances with liquid hydrogen, gaseous hydrogen, and gasoline [56].

An overview of hydrogen storage alloys has been discussed by Sandrock [57] from the solid–gas reaction point of view. There are a number of important properties that must be considered in metal hydride storage. Some of the most important ones are (1) ease of activation, (2) heat transfer rate, (3) kinetics of hydriding and dehydriding, (4) resistance to gaseous impurities, (5) cyclic stability, (6) safety, and (7) weight and cost. Although metal hydrides can theoretically store large amounts of hydrogen in a safe and compact way, the practical gravimetric hydrogen density is limited to <3 mass%. Another stumbling block for this storage method is the low practical cyclic stability achieved so far.

#### 52.4.3.1 Metal Hydrides

The potential to use hydrides for energy storage and applications has stimulated extensive theoretical and experimental research on the fundamental aspects of hydrogen sorption and several reversible storage intermetallics [58] such as FeTi [59], LaNi<sub>5</sub>, MmNi<sub>4.5</sub>Al<sub>0.5</sub> [60], and Mg<sub>2</sub>Ni [61]. Since the maximum weight percentage storage for these intermetallics is ~1.8 wt.% at ambient conditions and ~3.8 wt.% at high temperature (300°C–400°C), there is an ongoing research to find better hydride materials with higher storage capacity at ambient as well as high-temperature conditions. To achieve this, two prominent routes are being followed: first, to modify and optimize the present storage materials such as FeTi, LaNi<sub>5</sub>, and the high-temperature hydride Mg<sub>2</sub>Ni, and second, to develop altogether new storage materials, for example, transition metal complexes, composite materials, nanoparticle and nanostructured materials, and new carbon variants (fullerenes, C<sub>60</sub>, and other higher versions, graphitic nanofibers and nanotubes).

Magnesium (Mg) has the highest theoretical hydrogen storage capacity of ~7.6 wt.%. However, it has two significant disadvantages: (1) the Mg–H<sub>2</sub> reaction has poor kinetics, and (2) the resulting hydride is not reversible under ambient or moderate temperature and pressure conditions [62]. A possible way to achieve Mg-like storage capacity but with reversible hydrogenation characteristics is to form composites with Mg as one of the components. The other component may be one of the known hydrogen storage intermetallic alloys [63].

An important feature of the metallic hydrides is the high volumetric density of the hydrogen atoms present in the host atomic lattice [64]. The highest theoretical volumetric hydrogen density known today is 150 kg/m<sup>3</sup> for Mg<sub>2</sub>FeH<sub>6</sub> and Al(BH<sub>4</sub>)<sub>3</sub>. The Mg<sub>2</sub>FeH<sub>6</sub> hydride belongs to the family of Mg–transition metal complex hydrides with [FeH<sub>6</sub>]<sup>4−</sup> octahedral surrounded by Mg atoms in cubic configuration [65]. Interestingly, iron does not form intermetallic compounds with Mg, but it readily combines with hydrogen and Mg to form ternary hydride Mg<sub>2</sub>FeH<sub>6</sub> according to these reactions:

During the storage process (charging or absorption), heat is released, which must be removed in order to achieve the continuity of the reaction. During the hydrogen release process (discharging or desorption), heat must be supplied to the storage tank. The thermodynamic aspects of hydride formation from gaseous hydrogen are described by means of pressure–composition isotherms as shown in Figure 52.7. While the solid solution and hydride phase coexist, the isotherms show a flat plateau, the length of which determines the amount of H<sub>2</sub> stored. The stability of metal hydrides is usually presented in the form of Van't Hoff equation (52.23):

$$\ln P_{\text{H}_2} \text{ (atm)} = \frac{2\Delta H_f}{\text{SRT}} + C \quad (52.24)$$

where

$P_{\text{H}_2}$  is the plateau pressure at a particular temperature  $T$

$C$  is the constant of integration

$R$  is the universal gas constant

The enthalpy of formation,  $\Delta H_f$ , of the hydride is calculated from the slope of the straight line obtained plotting  $\ln P_{\text{H}_2}$  versus  $1/T$  (see Figure 52.7).

**FIGURE 52.7**  
P–C isotherms and Van't Hoff curve for the LaNi<sub>5</sub> metal hydride.

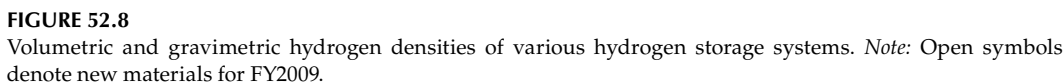

Figure 52.8 demonstrates various complex hydrides synthesized and having gravimetric hydrogen storage capacities at particular operating temperature. The following subsections discuss different potential complex hydrides and their reversible chemical reactions for hydrogen storage.

MAIH<sub>4</sub>, MBH<sub>4</sub>, and N(AlH<sub>4</sub>)<sub>2</sub> (M = Na, Li, K; N = Mg) are emerging as promising hydrogen storage materials because of their high-potential storage capacity. However, they are generally characterized by irreversible dehydriding or extremely slow hydrogen cycling kinetics. The breakthrough discovery of doping with a few mole percent of Ti-catalyst has enhanced the dehydrogenation kinetics of NaAlH<sub>4</sub> at low operating temperatures (<150°C) and was the starting point in reinvestigating these complex hydride systems for hydrogen storage [67]. However, reduced availability of reversible hydrogen (~4–5 wt.%), poor cyclic stability, and loss of the catalytic function of Ti-species necessitate the search for new and efficient complex hydride systems [68]. There are about 234 complex chemical hydrides that have been reported with theoretical hydrogen storage capacity [69]. Table 52.5 lists the complex chemical hydrides and their available capacities and operating temperatures.

© 2016 Taylor & Francis Group, LLC

**TABLE 52.5**

Theoretical Hydrogen Storage Capacities of Complex Hydrides

No.	Complex Chemical Hydride	Theoretical Capacity (wt.%)	Reversible Capacity (wt.%)	Operating Temperature (°C)	Remarks
1.	Ti-doped NaAlH <sub>4</sub>	7.5	5.5	100–150	High rehydrogenation pressure, poor life cycle, loss of catalytic activity, less available capacity
2.	Undoped and Ti-doped LiAlH <sub>4</sub>	10.5	6.3	120–170	Problems with reversibility and reduced thermodynamic stability
3.	Undoped and doped LiBH <sub>4</sub>	18.2	9.0	200–400	High operating temperature, rehydrogenation problem, possible borane evolution
4.	Mg(AlH <sub>4</sub> ) <sub>2</sub>	9.3	6.6	200–250	High operating temperature, thermodynamic stability
5.	NaBH <sub>4</sub> /H <sub>2</sub> O	10.5	9.2	Ambient	Hydrolysis reaction, irreversibility, one-time use
6.	Li <sub>3</sub> N (LiNH <sub>2</sub> /LiH)	11.3	6.5–7.0	255–285	High operating temperature, possible ammonia evolution
7.	B–H–Li–N	10.0		80–150	Rehydrogenation problem
8.	AlH <sub>3</sub>	10.5		150	Ball milling–induced decomposition, irreversible
9.	H <sub>3</sub> BNH <sub>3</sub>	18.3	12.6		Ammonia evolution, irreversible

However, the addition of a few mole concentrations of titanium species to NaAlH<sub>4</sub> eases the release of hydrogen at moderate temperatures and ambient pressure [67]. The decomposition of Ti-doped NaAlH<sub>4</sub> proceeds in two steps with the total released hydrogen of ~5.5 wt.% at 100°C–150°C as follows:

Following this breakthrough discovery, an effort was initiated in the U.S. DOE hydrogen program to develop NaAlH<sub>4</sub> and related alanates as hydrogen storage materials [70,71]. Another complex hydride, Mg(AlH<sub>4</sub>)<sub>2</sub>, contains 9.6 wt.% of hydrogen that decomposes below 200°C [72]. Some of the new complex hydrides and their theoretical capacities are listed in Table 52.6.

Borohydride complexes with suitable alkali or alkaline earth metals are a promising class of compounds for hydrogen storage. The hydrogen content can reach values of up to 18 wt.% for LiBH<sub>4</sub> [73]. The total amount of hydrogen desorbed up to 600°C is 9 wt.%. Mixing LiBH<sub>4</sub> with SiO<sub>2</sub> powder lowers the desorption temperature, so that 9 wt.% of hydrogen is liberated below 400°C. Recently, Chen et al. reported a new hydrogen storage system, lithium nitride (Li<sub>3</sub>N), which absorbs 11.5 wt.% of hydrogen reversibly [74,75]. The hydrogenation of lithium nitride is a two-step reaction as shown in the following equations:

TABLE 52.6

New Complex Hydrides and Their Hydrogen Storage Capacity

Serial Number	Complex Hydride	Theoretical Capacity (wt.%)	Temperature, T <sub>dec</sub> (°C)
1.	LiAlH <sub>2</sub> (BH <sub>4</sub> ) <sub>2</sub>	15.2	
2.	Mg(BH <sub>4</sub> ) <sub>2</sub>	14.8	260–280
3.	NH <sub>4</sub> Cl + LiBH <sub>4</sub>	13.6	>Ambient
4.	Ti(BH <sub>4</sub> ) <sub>3</sub>	12.9	~25
5.	Fe(BH <sub>4</sub> ) <sub>3</sub>	11.9	–30 to –10
6.	Ti(AlH <sub>4</sub> ) <sub>4</sub>	9.3	–85
7.	Zr(BH <sub>4</sub> ) <sub>3</sub>	8.8	<250
8.	Zn(BH <sub>4</sub> ) <sub>2</sub>	8.4	85

Li<sub>3</sub>N absorbs 5.74 wt.% of hydrogen in the first step and 11.5 wt.% in the second step. Since the hydrogen pressure for the reaction corresponding to the first step is very low (about 0.01 bar at 255°C), only the second step reaction of Li<sub>2</sub>NH (lithium imides) with H<sub>2</sub> leads to the reversible storage capacity. According to Chen et al., the plateau pressure for imides hydrogenation is 1 bar at the relatively high temperature of 285°C [74]. However, the temperature of this reaction can be lowered to 220°C with magnesium substitution, although at higher pressures [76]. Further research on this system may lead to additional improvements in operating conditions with improved capacity.

Zn(BH<sub>4</sub>)<sub>2</sub> is a ternary complex metal borohydride with a decomposition temperature of around 85°C [77]. Its theoretical hydrogen capacity is about 8.5 wt.%, and it can be synthesized by metathesis reaction of NaBH<sub>4</sub> and ZnCl<sub>2</sub> in diethyl ether [78]. A recent report from Jeon and Cho [79] indicates that zinc borohydride was successfully synthesized by ball milling zinc chloride and sodium borohydride without the use of a solvent as follows:

An example of the decomposition of a borohydride (Zn(BH<sub>4</sub>)<sub>2</sub>) is given in the following [77]:

which shows Zn(BH<sub>4</sub>)<sub>2</sub> thermally decomposing into the constituent elements with the release of hydrogen. The main reason that complex hydride compounds have not been considered for hydrogen storage before is their reported lack of reversibility.

### 52.4.3.3 Chemical Hydrogen Storage

The term *chemical hydrogen storage* is used to describe storage technologies in which hydrogen is generated through a chemical reaction. Common reactions involve chemical hydrides with water or alcohols. Typically, these reactions are not easily reversible onboard a vehicle. Hence, the “spent fuel” or by-products must be removed from the vehicle and regenerated off board.

#### 52.4.3.3.1 Hydrolysis Reactions

Hydrolysis reactions involve the oxidation reaction of chemical hydrides with water to produce hydrogen. The reaction of sodium borohydride has been the most studied to date. This reaction is

In the first embodiment, slurry of an inert stabilizing liquid protects the hydride from contact with moisture and makes the hydride pumpable. At the point of use, the slurry is mixed with water, and the consequent reaction produces high-purity hydrogen. The reaction can be controlled in an aqueous medium via pH and the use of a catalyst. Although the material hydrogen capacity can be high and the hydrogen release kinetics fast, the borohydride regeneration reaction must take place off board. Regeneration energy requirements cost and life cycle impacts are the key issues currently being investigated.

Millennium cell has reported that its  $\text{NaBH}_4$ -based hydrogen-on-demand system possesses a system gravimetric capacity of about 4 wt.% [80]. Similar to other material approaches, issues include system volume, weight, and complexity and water availability.

Another hydrolysis reaction currently being investigated by Safe Hydrogen is the reaction of  $\text{MgH}_2$  with water to form  $\text{Mg(OH)}_2$  and  $\text{H}_2$  [81]. In this case, particles of  $\text{MgH}_2$  are contained in nonaqueous slurry to inhibit premature water reactions when hydrogen generation is not required. Material-based capacities for the  $\text{MgH}_2$  slurry reaction with water can be as high as 11 wt.%. However, as with the sodium borohydride approach, water must be carried onboard the vehicle in addition to the slurry, and the  $\text{Mg(OH)}_2$  must be regenerated off board.

#### 52.4.3.3.2 New Chemical Approach

A new chemical approach may provide hydrogen generation from ammonia–borane materials by the following reactions:

The first reaction, which occurs at  $<120^\circ\text{C}$ , releases 6.1 wt.% hydrogen, while the second reaction, which occurs at approximately  $160^\circ\text{C}$ , releases 6.5 wt.% hydrogen [82]. Recent studies indicate that hydrogen-release kinetics and selectivity are improved by incorporating ammonia–borane nanosized particles in a mesoporous scaffold.

#### 52.4.3.4 Carbonaceous Materials

Carbonaceous materials are attractive candidates for hydrogen storage because of a combination of adsorption ability, high specific surface, pore microstructure, and low mass density. In spite of extensive results available on hydrogen uptake by carbonaceous materials, the actual mechanism of storage still remains a mystery. The interaction may either be based on van der Waals attractive forces (physisorption) or on the overlap of the highest occupied molecular orbital of carbon with occupied electronic wave function of the hydrogen electron, overcoming the activation energy barrier for hydrogen dissociation (chemisorption).

The physisorption of hydrogen limits the hydrogen-to-carbon ratio to less than one hydrogen atom per two carbon atoms (i.e., 4.2 mass%). While in chemisorption, the ratio of two hydrogen atoms per one carbon atom is realized, as in the case of polyethylene [83,84]. Physisorbed hydrogen has a binding energy normally of the order of 0.1 eV, while chemisorbed hydrogen has C–H covalent bonding, with a binding energy of more than 2–3 eV.

Dillon et al. presented the first report on hydrogen storage in carbon nanotubes and triggered a worldwide tide of research on carbonaceous materials [85]. Hydrogen can be physically adsorbed on activated carbon and be “packed” on the surface and inside the carbon structure more densely than if it has just been compressed. The best results

**FIGURE 52.9**

Schematic of a hydrogen-filled hollow glass microsphere.

achieved with carbon nanotubes to date confirmed by the National Renewable Energy Laboratory is hydrogen storage density corresponding to about 10% of the nanotube weight [86].

Hydrogen can be stored in glass microspheres of approximately 50  $\mu\text{m}$  diameter. The microspheres can be filled with hydrogen by heating them to increase the glass permeability to hydrogen (see Figure 52.9) [87]. At room temperature, a pressure of approximately 25 MPa is achieved, resulting in a storage density of 14% mass fraction 10 kg  $\text{H}_2/\text{m}^3$  [88]. At 62 MPa, a bed of glass microspheres can store 20 kg  $\text{H}_2/\text{m}^3$ . The release of hydrogen occurs by reheating the spheres to again increase the permeability.

#### 52.4.3.5 Polymer Nanostructures

Novel nanocomposite materials consist primarily of polyaniline, a conducting polymer, which has conductivity on the order of 1 S/cm [89]. Figure 52.10 shows the chemical structure of polyaniline in its emeraldine form. The salt form of the polyaniline has anions, which allow hydrogen ions to bond to the material very well. Due to its porosity, the surface area of the conducting polymeric matrix material will allow for additional hydrogen binding in the form of physisorption.

Conducting polymer nanostructures combine the advantages of organic conductors and low-dimensional systems having interesting physicochemical properties [90–93] and useful applications [94–96]. Among the conducting polymers, polyaniline is considered important because of its extraordinary properties of electrical and optical behavior. It was recently reported that polyaniline can store as much as 6–8 wt.% of hydrogen [97], which was later refuted by Panella et al. [98]. Though many controversial results were reported in terms of hydrogen uptake [99–102] in polymer nanocomposites, there are still a number of parameters, tailor-made properties, surface morphologies, and their correlation with hydrogen sorption behavior to be investigated before these materials can be commercially deployed for onboard hydrogen storage. Similarly, nanotubes [103] or

**FIGURE 52.10**

Chemical structure of polyaniline (emeraldine) in its salt and base form.

nanofibers [104] have attracted more interest because of their novel properties and wide potential application for nanometer-scale engineering applications. It is known that the nanofibrillar morphology significantly improves the performance of polyaniline in many conventional applications involving polymer interactions with its environment [105]. This leads to faster and more responsive chemical sensors [106], new organic/polyaniline nanocomposites [107], and ultrafast nonvolatile memory devices [108]. Nanofibers with diameters of tens of nanometers appear to be an intrinsic morphological unit that was found to naturally form in the early stage of chemical oxidative polymerization of aniline. In conventional polymerization, nanofibers are subject to secondary growth of irregularly shaped particles that form the final granular agglomerates. The key to producing pure nanofibers is to suppress secondary growth. Based on this, two methods (interfacial polymerization and rapidly mixed reactions) have been developed that can readily produce pure nanofibers by slightly modifying the conventional chemical synthesis of polyaniline without the need for any template or structural directing material. With this nanofiber morphology, dispensability and processability of polyaniline are now greatly improved. On the other hand, the template synthesis method is an effective way to grow the nanotubes of various conducting polymers [109]. The preparation conditions and their effect on morphology, size, and electrical properties of nanofibers have been reported by Zhang and Wang [110]. We have recently observed excellent hydrogen sorption characteristics in polyaniline nanofibers [111,112] prepared by an electrospinning process as shown in Figure 52.11.

Hydrogen uptake of 10 wt.% followed by the coexistence of physisorption and chemisorptions, during hydrogen release, has been correlated with unique nanofibrous morphologies (see Figure 52.12). Though the initial hydrogen storage capacity and kinetics are

**FIGURE 52.11**

Hydrogen absorption and desorption cycling of electrospun polyaniline nanofiber at around 100°C.

**FIGURE 52.12**

Surface morphology of electrospun polyaniline nanofiber as obtained from SEM.

excellent in these materials, they diminish in consecutive cycles; fundamental gas–solid reaction and the rate-limiting factors are currently under investigation.

Additive materials, such as carbon nanotubes and fullerenes, as well as catalyst materials will also allow the formation of chemical and physical bonds at the matrix material. By combining various carbon structures in a nanocomposite, a new hydrogen storage system can be developed that exceeds the performance of the existing state-of-the-art materials and facilitates rapid commercialization of high-energy-density hydrogen storage devices. These new catalyst-enhanced hydrogen storage materials can be described as porous nanocomposites of a conducting polymer with modified fullerene compounds and carbon nanotubes, as well as kinetics enhancing catalyst materials. The combination of the high surface area of carbon nanotubes and modified fullerenes [113] with the tunable redox behavior of the conducting polymer potentially offers enhanced performance as a hydrogen storage system.

#### **52.4.3.6 High-Surface-Area Sorbents and New Materials Concepts**

There is a pressing need for the discovery and development of new reversible materials. One new area that may be promising is that of high-surface-area hydrogen sorbents based on microporous metal-organic frameworks. Such materials are synthetic, crystalline, and microporous, and are composed of metal/oxide groups linked together by organic struts. Hydrogen storage capacity at 78 K (–195°C) has been reported as high as 4 wt.% via an adsorptive mechanism, with a room temperature capacity of approximately 1 wt.% [114]. However, due to the highly porous nature of these materials, the volumetric capacity may still be a significant issue.

Another class of materials for hydrogen storage may be clathrates, which are primarily hydrogen-bonded H<sub>2</sub>O frameworks [115]. Initial studies have indicated that significant amounts of hydrogen molecules can be incorporated into the sII clathrate. Such materials may be particularly viable for off-board storage of hydrogen without the need for high pressure or liquid hydrogen tanks.

## 52.5 Hydrogen Transportation and Distribution

It is envisaged that from the production plants and/or storage, hydrogen will be transmitted to consumers by means of underground pipelines (gaseous hydrogen) and/or super-tankers (liquid hydrogen). Presently, hydrogen transportation through pipelines is used either in links between nearby production and utilization sites (up to 10 km) or in more extensive networks (roughly 200 km). Table 52.7 lists the principal existing hydrogen pipelines [116]. Future developments will certainly entail greater flow rates and distances. For hydrogen pipelines, it is necessary to use steel less prone to embrittlement by hydrogen under pressure (particularly for very pure hydrogen >99.5% purity). Reciprocating compressors used for natural gas can be used for hydrogen without major design modifications. However, special attention must be given to sealing (to avoid hydrogen leaks) and to materials selection for the parts subject to fatigue stress. Use of centrifugal compressors for hydrogen creates more problems due to hydrogen's exceptional lightness.

As a rule, hydrogen transmission through pipelines requires larger diameter piping and more compression power than natural gas for the same energy throughput. However, due to lower pressure losses in the case of hydrogen, the recompression stations would need to be spaced twice as far apart. In economic terms, most of the studies found that the cost of large-scale transmission of hydrogen is about 1.5–1.8 times that of natural gas transmission.

In order to match the consumption demand, hydrogen can be regionally transported and distributed, both as a gas and as a liquid, by pipelines or in special cases in containers by road and rail transportation. Gaseous (and liquid) hydrogen carriage is subject to strict regulations ensuring public safety, which in some countries is very constraining. Transportation of gaseous or liquid hydrogen in a discontinuous mode is currently employed by occasional or low-volume users. The cost of discontinuous transport is very high (it can be as high as two to five times the production cost). In the future energy system, discontinuous transportation of hydrogen would see little use, except for special users (mainly nonenergy related). Hydrogen in the gas phase is generally transported in pressurized cylindrical vessels (typically at 200 bar) arranged in frames adapted to road transport. The unit capacity of these frames or skids can be as great as 3000 m<sup>3</sup>. Hydrogen gas distribution companies also install such frames at the user site to serve as a stationary storage.

**TABLE 52.7**

Some Major Hydrogen Pipelines

Location	Years of Operation	Diameter (mm)	Length (km)	Pressure (MPa)	Purity
AGEC, Alberta, Canada	Since 1987	273	3.7	3.79	99.9%
Air Liquide, France	Since 1966	Various	290	6.48–10	Pure and raw

## 52.6 Hydrogen Conversion Technologies

Hydrogen as an energy carrier can be converted into useful forms of energy in several ways, namely,

- Combustion in internal combustion engines
- Combustion with pure oxygen to generate steam
- Catalytic combustion to generate heat
- Electrochemical conversion to electricity
- Metal hydride conversions

### 52.6.1 Hydrogen Combustion in Internal Combustion Engines

Hydrogen may be directly used as a fuel for internal combustion engines. The ideal thermal efficiency of an internal combustion engine is

$$\eta = 1 - \left( \frac{1}{r} \right)^{k-1} \quad (52.33)$$

where

$r$  is the compression ratio

$k$  is the ratio of specific heats ( $C_p/C_v$ )

This equation shows that the thermal efficiency can be improved by increasing either the compression ratio or the specific heat ratio. In hydrogen engines, both ratios are higher than in a comparable gasoline engine due to hydrogen's lower self-ignition temperature and ability to burn in lean mixtures. Therefore, hydrogen-powered internal combustion engines are on average about 20% more efficient than comparable gasoline engines.

However, the use of hydrogen in internal combustion engines results in loss of power due to lower energy content in a stoichiometric mixture in the engine's cylinder. A stoichiometric mixture of gasoline and air, and gaseous hydrogen and air, premixed externally occupies ~2% and 30% of the cylinder volume, respectively. Under these conditions, the energy of the hydrogen mixture is only 85% of the gasoline mixture, thus resulting in about 15% reduction in power. Therefore, the same engine running on hydrogen will have ~15% less power than when operated with gasoline. The power output of a hydrogen engine can be improved by using more advanced fuel injection techniques or liquid hydrogen. For example, if liquid hydrogen is premixed with air, the amount of hydrogen that can be introduced in the combustion chamber can be increased by approximately one-third [117].

One of the most important advantages of hydrogen as a fuel for internal combustion engines is that hydrogen engines emit by far fewer pollutants than comparable gasoline engines. Basically, the only products of hydrogen combustion in air are water vapor and small amounts of nitrogen oxides. Hydrogen has a wide flammability range in air (5%–75% vol.), and therefore, high excess air can be utilized more effectively. The formation of nitrogen oxides in hydrogen/air combustion can be minimized with excess air.  $\text{NO}_x$  emissions can also be lowered by cooling the combustion environment using techniques such as water injection, exhaust gas recirculation, or using liquid hydrogen. The emissions of

NO<sub>x</sub> in hydrogen engines are typically one order of magnitude smaller than emissions from comparable gasoline engines. Small amounts of unburned hydrocarbons, CO<sub>2</sub>, and CO have been detected in hydrogen engines due to lubrication oil [117].

The low ignition energy and fast flame propagation of hydrogen have led to problems of preignition and backfire. These problems have been overcome by adding hydrogen to the air mixture at the point where and when the conditions for preignition are less likely, such as delivering the fuel and air separately to the combustion chamber and/or injecting hydrogen under pressure into the combustion chamber before the piston is at the top dead center and after the intake air valve has been closed. Water injection and exhaust gas recirculation techniques are also used in hydrogen engines to help control premature ignition. It should be noted that most of the research on hydrogen combustion in internal combustion engines has been conducted with modifications of existing engines designed to burn gasoline. Redesign of the combustion chamber and coolant systems to accommodate hydrogen's unique combustion properties could be the most effective method of solving the problems of preignition and knocking [117].

Hydrogen use in turbines and jet engines is similar to use of conventional jet fuel. The use of hydrogen avoids the problems of sediments and corrosion on turbine blades, which prolongs life and reduces maintenance. Gas inlet temperatures can be pushed beyond normal gas turbine temperatures of 800°C, thus increasing the overall efficiency. The only pollutants from the use of hydrogen in turbines and jet engines are nitrogen oxides.

### 52.6.2 Steam Generation by Hydrogen/Oxygen Combustion

Hydrogen combusted with pure oxygen results in pure steam, that is,

This reaction creates temperatures in the flame zone above 3000°C; therefore, additional water has to be injected so that the steam temperature can be regulated at a desired level. Both saturated and superheated vapor can be produced.

The German Aerospace Research Establishment (DLR) has developed a compact hydrogen/oxygen steam generator [118]. The steam generator consists of the ignition, combustion, and evaporation chambers. In the ignition chamber, a combustible mixture of hydrogen and oxygen at a low oxidant/fuel ratio is ignited by means of a spark plug. The rest of the oxygen is added in the combustion chamber to adjust the oxidant/fuel ratio exactly to the stoichiometric one. Water is also injected in the combustion chamber after it has passed through the double walls of the combustion chamber. The evaporation chamber serves to homogenize the steam. The steam's temperature is monitored and controlled. Such a device is very efficient, since there are no emissions other than steam and very little thermal losses.

The hydrogen steam generator can be used to generate steam for spinning reserve in power plants, for peak load electricity generation, for industrial steam supply networks, and as a micro-steam generator in medical technology and biotechnology [118].

### 52.6.3 Catalytic Combustion of Hydrogen

Hydrogen and oxygen in the presence of a suitable catalyst may be combined at temperatures significantly lower than flame combustion (from ambient to 500°C). This principle can be used to design catalytic burners and heaters. Catalytic burners require considerably more surface area than conventional flame burners. Therefore, the catalyst is typically dispersed

in a porous structure. The reaction rate and resulting temperature are easily controlled, by controlling the hydrogen flow rate. The reaction takes place in a reaction zone of the porous catalytic sintered metal cylinders or plates in which hydrogen and oxygen are mixed by diffusion from opposite sides. A combustible mixture is formed only in the reaction zone and assisted with a (platinum) catalyst to burn at low temperatures (Figure 52.2). The only product of catalytic combustion of hydrogen is water vapor. Due to low temperatures, there are no nitrogen oxides formed. The reaction cannot migrate into the hydrogen supply, since there is no flame and hydrogen concentration is above the higher flammable limit (75%). Possible applications of catalytic burners are in household appliances such as cooking ranges and space heaters. The same principle is also used in hydrogen sensors.

#### 52.6.4 Electrochemical Conversion (Fuel Cells)

Hydrogen can be combined with oxygen without combustion in an electrochemical reaction (reverse of electrolysis) and produce electricity (DC). The device where such a reaction takes place is called the electrochemical fuel cell or just fuel cell [119,120]. Fuel cells are described in more detail in the next chapter and will not be covered here.

---

### 52.7 Hydrogen Safety

Like any other fuel or energy carrier, hydrogen poses risks if not properly handled or controlled. The risk of hydrogen, therefore, must be considered relative to the common fuels such as gasoline, propane, or natural gas. The specific physical characteristics of hydrogen are quite different from those common fuels. Some of those properties make hydrogen potentially less hazardous, while other hydrogen characteristics could make it more dangerous in certain situations.

Since hydrogen has the smallest molecule, it has a greater tendency to escape through small openings than other liquid or gaseous fuels. Based on properties of hydrogen such as density, viscosity, and diffusion coefficient in air, the propensity of hydrogen to leak through holes or joints of low-pressure fuel lines may be only 1.26–2.8 times faster than a natural gas leak through the same hole (and not 3.8 times faster as frequently assumed based solely on diffusion coefficients). Experiments have indicated that most leaks from residential natural gas lines are laminar [121]. Since natural gas has over three times the energy density per unit volume, a natural gas leak would result in more energy release than a hydrogen leak.

For very large leaks from high-pressure storage tanks, the leak rate is limited by the sonic speed. Due to higher sonic velocity (1308 m/s), hydrogen would initially escape much faster than natural gas (sonic velocity of natural gas is 449 m/s). Again, since natural gas has more than three times the energy density than hydrogen, a natural gas leak will always contain more energy.

Some high-strength steels are prone to hydrogen embrittlement. Prolonged exposure to hydrogen, particularly at high temperatures and pressures, can cause the steel to lose strength, eventually leading to failure. However, most other construction, tank, and pipe materials are not prone to hydrogen embrittlement. Therefore, with proper choice of materials, hydrogen embrittlement safety risks could be avoided.

If a leak should occur for whatever reason, hydrogen will disperse much faster than any other fuel, thus reducing the hazard levels. Hydrogen is both more buoyant and

**TABLE 52.8**

Properties and Leak Rates of Hydrogen and Natural Gas

	Hydrogen	Natural Gas
<i>Flow parameters</i>		
Diffusion coefficient (cm <sup>2</sup> /s)	0.61	0.16
Viscosity (μ-poise)	87.5	100
Density (kg/m <sup>3</sup> )	0.0838	0.651
Sonic velocity (m/s)	1308	449
<i>Relative leak rates</i>		
Diffusion	3.80	1
Laminar flow	1.23	1
Turbulent flow	2.83	1
Sonic flow	2.91	1

more diffusive than gasoline, propane, or natural gas. Table 52.8 compares some properties and leak rates for hydrogen and natural gas.

Hydrogen/air mixture can burn in relatively wide volume ratios, between 4% and 75% of hydrogen in air. The other fuels have much lower flammability ranges, viz., natural gas 5.3%–15%, propane 2.1%–10%, and gasoline 1%–7.8%. However, the range has little practical value. In many actual leak situations, the key parameter that determines if a leak would ignite is the lower flammability limit, and hydrogen's lower flammability limit is 4 times higher than that of gasoline, 1.9 times higher than that of propane, and slightly lower than that of natural gas.

Hydrogen has a very low ignition energy (0.02 mJ), about one order of magnitude lower than other fuels. The ignition energy is a function of fuel/air ratio, and for hydrogen, it reaches a minimum at about 25%–30%. At the lower flammability limit, hydrogen ignition energy is comparable with that of natural gas [122]. Hydrogen has a flame velocity seven times faster than that of natural gas or gasoline. A hydrogen flame would therefore be more likely to progress to a deflagration or even a detonation than other fuels. However, the likelihood of a detonation depends in a complex manner on the exact fuel/air ratio, the temperature, and particularly the geometry of the confined space. Hydrogen detonation in the open atmosphere is highly unlikely.

The lower detonability fuel/air ratio for hydrogen is 13%–18%, which is 2 times higher than that of natural gas and 12 times higher than that of gasoline. Since the lower flammability limit is 4%, an explosion is possible only under the most unusual scenarios, for example, hydrogen would first have to accumulate and reach 13% concentration in a closed space without ignition, and only then an ignition source would have to be triggered. Should an explosion occur, hydrogen has the lowest explosive energy per unit stored energy in the fuel, and a given volume of hydrogen would have 22 times less explosive energy than the same volume filled with gasoline vapor.

Hydrogen flame is nearly invisible, which may be dangerous, because people in the vicinity of a hydrogen flame may not even know there is a fire. This may be remedied by adding some chemicals that will provide the necessary luminosity. The low emissivity of hydrogen flames means that nearby materials and people will be much less likely to ignite and/or hurt by radiant heat transfer. The fumes and soot from a gasoline fire pose a risk to anyone inhaling the smoke, while hydrogen fires produce only water vapor (unless secondary materials begin to burn).

Liquid hydrogen presents another set of safety issues, such as risk of cold burns and the increased duration of leaked cryogenic fuel. A large spill of liquid hydrogen has some characteristics of a gasoline spill; however, it will dissipate much faster. Another potential danger is a violent explosion of a boiling liquid expanding vapor in case of a pressure relief valve failure.

In conclusion, hydrogen appears to pose risks of the same order of magnitude as other fuels. In spite of public perception, in many aspects, hydrogen is actually a safer fuel than gasoline and natural gas. As a matter of fact, hydrogen has a very good safety record, as a constituent of the “town gas” widely used in Europe and the United States in the nineteenth and early twentieth centuries, as a commercially used industrial gas and as a fuel in space programs. There have been accidents, but nothing that would characterize hydrogen as more dangerous than other fuels.

### 53.1 Introduction

A fuel cell is an electrochemical device that directly converts the chemical energy of a fuel and oxidant into electric energy. Such a direct one-step conversion avoids the inefficient multistep processes involved in heat engines via combustion, thus eliminating the emission of chemical pollutants. Besides being efficient and clean, fuel cell is also compatible with renewable energy sources and carriers for sustainable development and energy security. Fuel cell offers additional advantages for both mobile and stationary applications, including quiet operation without vibration and noise, thus capable of on-site applications. Its inherent modularity allows for simple construction and operation with possible applications for dispersed, distributed, and portable power generation. Its fast response to the changing load condition while maintaining high efficiency makes it ideally suited to load following applications. Its potential high efficiency also represents less chemical, thermal, and carbon dioxide emissions for the same amount of energy conversion and power generation. Hence, fuel cell is often regarded as one of the advanced energy technologies of the future.

At present, fuel cells are being used routinely in space applications and have been under intensive development for terrestrial use, such as for utilities and zero-emission vehicles. There exist a variety of fuel cells, which are classified based on their operating temperature such as low- and high-temperature fuel cells, and the type of ion migrating through the electrolyte, etc. However, the choice of electrolyte defines the properties of a fuel cell. Hence, fuel cells are often named by the nature of the electrolyte used. There are presently six major fuel cell technologies at varying stages of development and commercialization. They are alkaline, phosphoric acid, polymer electrolyte membrane (PEM), molten carbonate, solid oxide, and direct methanol fuel cells (DMFCs). This chapter provides a

summary of fundamentals and the state-of-the-art technology for these types of fuel cell, while detailed information regarding their electrochemical reactions, operation principles, construction and design, and specific areas of applications can be found elsewhere [1–7].

### 53.2 Principle of Operation for Fuel Cells

A fuel cell is composed of three active components: a fuel electrode (anode), an oxidant electrode (cathode), and an electrolyte sandwiched in-between. Figure 53.1 illustrates the basic operational principle of fuel cells with a typical acid electrolyte fuel cell, where it is seen that molecular hydrogen is delivered from a gas flow stream to one of the electrodes, often named anode (or fuel electrode), and it reacts electrochemically in the anode as follows:

The hydrogen (fuel) is oxidized at the anode/electrolyte interface into hydrogen ion or proton  $\text{H}^+$  and an electron  $\text{e}^-$ . The protons migrate through the (acid) electrolyte, while the electrons are forced to transfer through an external circuit, both arriving at another electrode that is often referred to as cathode (or oxidant electrode). At the cathode, the protons and electrons react with the oxygen supplied from an external gas flow stream, forming water:

Thus, oxygen is reduced into water at the cathode by combining with  $\text{H}^+$  and  $\text{e}^-$ . Now both the electric current and the mass transfer form a complete circuit. The electrons go

**FIGURE 53.1**  
Schematic of a typical acid electrolyte fuel cell.

through the external electric circuit and do work on the electric load, constituting the useful electric energy output from the fuel cell. At the same time, waste heat is also generated due to the electrochemical reactions occurring at the anode and the cathode, as well as due to protons migrating through the electrolyte and electrons transporting in the solid portion of the electrodes and the external circuit. As a result, the overall cell reaction can be obtained by summing these two half-cell reactions to yield

where  $W$  stands for the useful electric energy output from the fuel cell. Although the half-cell reactions may be quite different in different types of fuel cells, to be described later, the overall cell reaction remains exactly the same as the equation shown earlier.

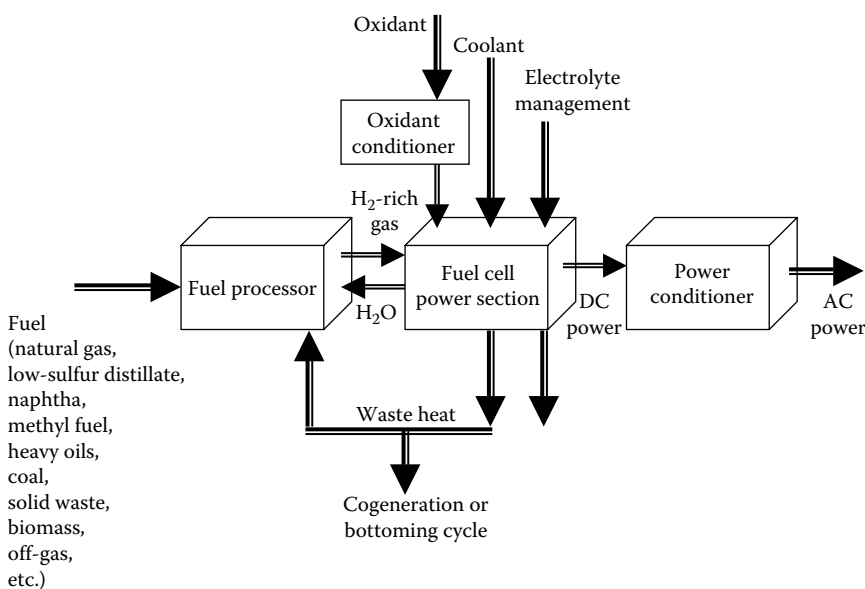

Therefore, the by-products of the electrochemical reactions described earlier are water and waste heat. They should be continuously removed from the cell in order to maintain its continuous isothermal operation for electric power generation. This need for the continuous removal of water and heat results in the so-called water and heat (thermal) management, which may become the two critical issues for the design and operation of some types of fuel cells. In general, they are not easy tasks to accomplish.

---

### 53.3 Typical Fuel Cell Systems

In general, a fuel cell power system involves more than just fuel cell itself because fuel cell needs a steady supply of qualifying fuel and oxidant as reactants for continuous generation of electric power. The oxidant is usually pure oxygen for specialized applications like in space and some military applications, and is almost invariably air for terrestrial and commercial applications. Depending on the specific types of fuel cells, both fuel and oxidant streams need to meet certain impurity requirements before being qualified as adequate for fuel cell operations. Therefore, a fuel cell power system is usually composed of a number of subsystems for fuel processing, oxidant conditioning, electrolyte management, cooling or thermal management, and reaction product removal, etc. A schematic of a typical rudimentary fuel cell system is illustrated in [Figure 53.2](#). Normally, a power-conditioning unit is required to convert the DC electric power into AC power because fuel cell generates DC power while most of electric equipment operates on AC. The waste heat produced in the fuel cell power section is often integrated through a series of heat exchangers into the fuel cell system for better energy efficiency, and it is also possible for some types of fuel cells to use the waste heat as the heat source for either cogeneration or bottoming cycles for additional electric energy generation. The cogeneration of heat and hot water (and sometimes steam) along with electricity increases the overall energy efficiency of the fuel cell system to as much as 85% or more. Heat is critical to human survival, for example, for space heating and household use. Both heat and steam are significantly important commodity in industrial processes, in addition to many other practical applications.

The DC-to-AC inverter is a fairly mature technology, due to the incorporation of semiconductor and integrated circuit technology, and its conversion efficiency is very high, as much as 96% for megawatt-size power plants. The fuel processor converts the primary and/or portable fuel (such as natural gas, low-sulfur distillate, naphtha, methyl fuel—mostly

**FIGURE 53.2**

Schematic of a typical rudimentary fuel cell system.

methanol, heavy oils, coal, solid waste, biomass, etc.) into  $H_2$  and  $CO$ . These secondary fuels ( $H_2$  and  $CO$ ) are considerably more electrochemically active in the electrochemical cell stack than the primary fuels. Even though fuel processing technology is highly advanced and efficient, it typically accounts for a third of the power plant size, weight, and cost for the hydrocarbon-fuelled fuel cell power plants; roughly, the electrochemical fuel cell stack accounts another third of the size, weight, and cost, while the ancillary components and subsystems associated with air supply, thermal management, water recovery and treatment, cabinet ventilation, and system control and diagnostics (or often referred to as the balance of the plant) accounts for the remaining third. In fuel cell systems, the most important subsystem is the electrochemical fuel cell stack, and fuel processor is the second major subsystem if hydrocarbon fuels are used as the primary fuel.

### 53.4 Performance of Fuel Cells

Although numerous studies have been conducted, aiming at developing fuel cell as a practical source of power, some confusion and misconception exist about the thermodynamic performance of fuel cell and its comparison with heat engines [2,8–10]. In this section, the fundamental principles, the first and second laws of thermodynamics, will be used to derive the idealized best possible performance, namely, the reversible cell potential and the reversible energy conversion efficiency of fuel cell. The effect of the operating conditions on the cell performance will be given, such as temperature, pressure, and reactant concentrations. The maximum possible efficiency for fuel cell will be compared with the Carnot efficiency, the maximum possible efficiency for heat engines against which fuel cell is competing for commercial success. Then, the possibility of over 100% efficiency for fuel cell will

be analyzed and ruled out based on the fundamental principles. Finally, various energy loss mechanisms in a fuel cell will be described, including both reversible and irreversible losses; the amount and rate of heat generation in an operating fuel cell will be derived; various forms of efficiency for fuel cell will be defined; and further energy losses in operating fuel cells will be considered as the Nernst loss due to limited utilization (or stoichiometry) of the reactants supplied to the cell.

### 53.4.1 Reversible Cell Potential

In a fuel cell, the chemical energy of a fuel and an oxidant is directly converted into electrical energy, which is exhibited in terms of cell potential and electrical current output. The maximum possible electrical energy output and the corresponding electrical potential difference between the cathode and the anode are achieved when the fuel cell is operated under thermodynamically reversible conditions. This maximum possible cell potential is called reversible cell potential, one of the important parameters for fuel cells, and it is derived in this section.

A thermodynamic system\* model is shown in Figure 53.3 for the analysis of fuel cell performance. It is a control volume system for the fuel cell to which fuel and oxidant streams enter and product or exhaust stream exits. The fuel cell is located inside a thermal bath in order to maintain the desired system temperature  $T$ . The reactant streams (fuel and oxidant) and the exhaust stream are considered to have the same temperature  $T$  and

**FIGURE 53.3**

A thermodynamic model of fuel cell system.

\* A thermodynamic system, or simply system, is a collection of matter under study (or analysis) in thermodynamics, whereas the jargon “fuel cell system” in fuel cell literature usually denotes the fuel cell power plant that consists of fuel cell stack(s) and auxiliary equipment (also called balance of the plant)—see Section 53.3, for example. In this chapter, a fuel cell system may imply both meanings. However, the context will tell which it is meant to be.

pressure  $P$ . It is assumed that the fuel and oxidant inflow and the exhaust outflow are steady; the kinetic and gravitational potential energy changes are negligible. Further, the overall electrochemical reactions occurring inside the fuel cell system boundary is described as follows:

where

$\dot{W}$  is the rate of work done by the system

$\dot{Q}$  is the rate of heat transferred into the system from the surrounding constant temperature thermal bath, which may, or may not, be in thermal equilibrium with the fuel cell system at the temperature  $T$  and pressure  $P$

For hydrogen/oxygen fuel cells, the reaction product is water. Then, the first and second laws of thermodynamics can be written, respectively, for the present fuel cell system, as

$$\frac{dE_{\text{C.V.}}}{dt} = [(\dot{N}h)_{\text{F}} + (\dot{N}h)_{\text{Ox}}]_{\text{in}} - [(\dot{N}h)_{\text{Ex}}]_{\text{out}} + \dot{Q} - \dot{W} \quad (53.5)$$

$$\frac{dS_{\text{C.V.}}}{dt} = [(\dot{N}s)_{\text{F}} + (\dot{N}s)_{\text{Ox}}]_{\text{in}} - [(\dot{N}s)_{\text{Ex}}]_{\text{out}} + \frac{\dot{Q}}{T} + \dot{\phi}_s \quad (53.6)$$

where

$\dot{N}$  is the molar flow rate

$h$  is the (absolute) enthalpy per unit mole

$s$  is the specific entropy on a mole basis

$\dot{\phi}_s$  is the rate of entropy generation due to irreversibilities

The subscripts “F,” “Ox,” and “Ex” stand for fuel, oxidant, and exhaust stream, respectively. “KE” and “PE” denote kinetic and gravitational potential energies that are being carried in and out of the system by the mass flow.

For a steady process, there are no temporal changes in the amount of energy  $E_{\text{C.V.}}$  and entropy  $S_{\text{C.V.}}$  within the control volume system, hence,  $dE_{\text{C.V.}}/dt = 0$  and  $dS_{\text{C.V.}}/dt = 0$ . Therefore, Equations 53.5 and 53.6 can be simplified as follows:

$$\dot{N}_{\text{F}}(h_{\text{in}} - h_{\text{out}}) + \dot{Q} - \dot{W} = 0 \quad (53.7)$$

$$\dot{Q} = -T\dot{\phi}_s - \dot{N}_{\text{F}}T(s_{\text{in}} - s_{\text{out}}) \quad (53.8)$$

where

$$h_{\text{in}} = \left( h_{\text{F}} + \frac{\dot{N}_{\text{Ox}}}{\dot{N}_{\text{F}}} h_{\text{Ox}} \right)_{\text{in}} \quad \text{and} \quad h_{\text{out}} = \frac{\dot{N}_{\text{Ex}}}{\dot{N}_{\text{F}}} h_{\text{Ex}} \quad (53.9)$$

where

$h_{\text{in}}$  is the amount of enthalpy per mole of fuel carried into the system by the reactant inflow

$h_{\text{out}}$  is the amount of enthalpy per mole of fuel taken out of the system by the exhaust stream

Similarly,

$$s_{\text{in}} = \left( s_{\text{F}} + \frac{\dot{N}_{\text{Ox}}}{\dot{N}_{\text{F}}} s_{\text{Ox}} \right)_{\text{in}} \quad \text{and} \quad s_{\text{out}} = \frac{\dot{N}_{\text{Ex}}}{\dot{N}_{\text{F}}} s_{\text{Ex}} \quad (53.10)$$

are the amount of entropy per mole of fuel brought into, and carried out of, the system by the reactant inflow, and the outgoing exhaust stream containing the reaction products, respectively.

Substitution of Equation 53.8 into Equation 53.7 yields

$$\dot{W} = \dot{N}_{\text{F}}(h_{\text{in}} - h_{\text{out}}) - \dot{N}_{\text{F}}T(s_{\text{in}} - s_{\text{out}}) - T\dot{\wp}_s \quad (53.11)$$

Let

$$w = \frac{\dot{W}}{\dot{N}_{\text{F}}}, \quad q = \frac{\dot{Q}}{\dot{N}_{\text{F}}}, \quad \text{and} \quad \wp_s = \frac{\dot{\wp}_s}{\dot{N}_{\text{F}}} \quad (53.12)$$

represent, respectively, the amount of work done, heat transferred, and entropy generated per unit mole of fuel. Equations 53.8 and 53.11 then become

$$q = -T\wp_s - T(s_{\text{in}} - s_{\text{out}}) = T\Delta s - T\wp_s \quad (53.13)$$

$$w = (h_{\text{in}} - h_{\text{out}}) - T(s_{\text{in}} - s_{\text{out}}) - T\wp_s \quad (53.14)$$

Because the enthalpy and entropy changes for the fuel cell reaction are defined as

$$\Delta h = h_{\text{out}} - h_{\text{in}} \quad \text{and} \quad \Delta s = s_{\text{out}} - s_{\text{in}} \quad (53.15)$$

Equation 53.14 can also be expressed as

$$w = -\Delta h + T\Delta s - T\wp_s = -[(h - Ts)_{\text{out}} - (h - Ts)_{\text{in}}] - T\wp_s \quad (53.16)$$

From the definition of the Gibbs function (per mole of fuel)  $g = h - Ts$ , Equation 53.14 or 53.16 can also be written as

$$w = -(g_{\text{out}} - g_{\text{in}}) - T\wp_s = -\Delta g - T\wp_s \quad (53.17)$$

Because by the second law of thermodynamics, entropy can be generated but can never be destroyed, we know  $\wp_s \geq 0$ , and also the absolute temperature (in Kelvin scale)  $T > 0$  by the third law of thermodynamics, the maximum possible work (i.e., useful energy) output from the present system occurs when  $\wp_s = 0$ , or under the thermodynamically reversible condition, since the change in the Gibbs function is usually negative for useful fuel cell reaction. Therefore, from Equation 53.17, it is clear that the maximum possible work output from the present fuel cell system is equal to the decrease in Gibbs function, or

$$w_{\text{max}} = -\Delta g \quad (53.18)$$

for all reversible processes, regardless of the specific type of fuel cells involved. In fact, it might be pointed out that in the derivation of Equations 53.17 and 53.18, no specifics about the control volume system have been stipulated; hence, they are valid for any energy conversion systems.

For a fuel cell system, the electrical energy output is conventionally expressed in terms of the cell potential difference between the cathode and the anode. Since the (electrical) potential is the (electrical) potential energy per unit (electrical) charge, its SI unit is J/C, which is more often called volt or simply V. Potential energy is defined as the work done when a charge is moved from one location to another in the electrical field, normally external circuits. For the internal circuit of fuel cells, such as the one shown in [Figure 53.3](#), electromotive force is the terminology often used, which is also defined as the work done by transferring 1 C (coulomb) positive charge from a low to a high potential. Hence, electromotive force also has the SI unit of J/C, or V. We shall adopt the terminology of cell potential, instead of electromotive force, from now on, and we shall use the notation  $E$  to represent the cell potential. Because normally electrons are the particles transferred that carry electrical charge, we may express the work done by a fuel cell as follows:

$$w \text{ (J/mol fuel)} = E \times (\text{Coulombs of electron charge transferred/mol fuel})$$

or

$$w = E \times (nN_0e) = E \times (nF) \quad (53.19)$$

where

$n$  is the number of moles of electrons transferred per mole of fuel consumed

$N_0$  is the Avogadro's number ( $=6.023 \times 10^{23}$  number of electrons/mol electron)

$e$  is the electric charge per electron ( $=1.6021 \times 10^{-19}$  C/electron)

Since  $N_0e = 96,487$  C/mol electron  $= F$  is known as the Faraday constant, the cell potential becomes, from Equation 53.17,

$$E = \frac{w}{nF} = \frac{-\Delta g - T\phi_s}{nF} \quad (53.20)$$

Hence, the maximum possible cell potential, or the reversible cell potential  $E_r$ , becomes

$$E_r = -\frac{\Delta g}{nF} \quad (53.21)$$

From the reversible cell potential given earlier, Equation 53.20 can also be rewritten as

$$E = E_r - \frac{T\phi_s}{nF} = E_r - \eta \quad (53.22)$$

where

$$\eta = \frac{T\phi_s}{nF} \quad (53.23)$$

is the cell voltage loss due to irreversibilities (or entropy generation). Clearly, the actual cell potential can be calculated by subtracting the cell voltage loss from the reversible cell potential. Alternatively, the amount of entropy generation per mole of fuel consumed can be determined as

$$\phi_s = \frac{nF\eta}{T} = \frac{nF(E_r - E)}{T} \quad (53.24)$$

Thus, the amount of entropy generation, representing the degree of irreversibilities (the degree of deviation from the idealized reversible condition), for the fuel cell reaction process can be measured once the cell potential  $E$  and the cell operating temperature  $T$  are known.

Note that the Gibbs function is a thermodynamic property, determined by state variables such as temperature and pressure. Hence, the change in the Gibbs function for the fuel cell reaction discussed here

$$\Delta g = \Delta h - T\Delta s \quad (53.25)$$

is also a function of the system temperature  $T$  and pressure  $P$ , as is the reversible cell potential. The specific effect of the operating conditions, such as temperature, pressure, and reactant concentrations, on the reversible cell potential will be presented in the next section. If the reaction occurs at the standard reference temperature and pressure (25°C and 1 atm), the resulting cell potential is usually called the standard reversible cell potential  $E_r^\circ$ ,\* or

$$E_r^\circ(T_{\text{ref}}) = -\frac{\Delta g(T_{\text{ref}}, P_{\text{ref}})}{nF} \quad (53.26)$$

If pure hydrogen and oxygen are used as reactants to form product water, then  $E_r^\circ(25^\circ\text{C}) = 1.229\text{ V}$  for the product water in liquid form, and  $E_r^\circ(25^\circ\text{C}) = 1.185\text{ V}$  for the product water in vapor form. The difference in  $E_r^\circ$  corresponds to the energy required for the vaporization of water. It might be pointed out that any fuel containing hydrogen (including hydrogen itself, hydrocarbons, alcohols, and to a lesser extent coal) has two values for  $\Delta g$  and  $\Delta h$ , one higher and one lower, depending on whether the product water is in the form of liquid or vapor. Hence, care should be taken when referring to reversible cell potential and energy efficiency to be discussed later in Section 53.4.3.

The standard reversible cell potential,  $E_r^\circ$ , can be determined for any other electrochemical reactions. Some of the potential fuel cell reactions and the resulting  $E_r^\circ$  are shown in Table 53.1 along with other relevant parameters. From this table, it might be noted that  $E_r^\circ$  should be approximately above 1 V in order for the reaction to be realistic for fuel cell application. This is because if  $E_r^\circ$  is  $\ll 1\text{ V}$ , and considering the cell voltage loss that inevitably occurs in practical fuel cells due to irreversibilities, the actual cell potential might become too small to be useful for practical applications. Therefore, the rule of thumb is, for any proposed fuel and oxidant, to calculate  $E_r^\circ$  and to see if  $E_r^\circ$  is on the order of 1 V or larger before proceeding to any further work on it.

### 53.4.2 Effect of Operating Conditions on Reversible Cell Potential

The most important operating conditions that influence fuel cell performance are the operating temperature, pressure, and reactant concentrations. For many useful electrochemical reactions, the entropy change is negative and is almost constant with the change of temperature to a good approximation, provided the temperature change

\* In the literature, the superscript “°” sometimes denotes the value at the standard reference condition of 25°C and 1 atm, and sometimes it also refers to parameters evaluated at 1 atm. The latter meaning has been adopted in this chapter.

**TABLE 53.1**

Standard Enthalpy and Gibbs Function of Reaction for Candidate Fuels and Oxidants, and Corresponding Standard Reversible Cell Potential as well as Other Relevant Parameters (at 25°C and 1 atm)

Fuel	Reaction	<i>n</i>	−Δ <i>h</i> (kJ/mol)	−Δ <i>g</i> (kJ/mol)	<i>E</i> <sub><i>r</i></sub> <sup>°</sup> (V)	η <sup>a</sup> (%)

<sup>a</sup> Energy conversion efficiency.

<sup>b</sup> There is a conceptual problem with these efficiency data; see Section 53.4.3.5 for explanation.

$T - T_{\text{ref}}$  is not too large. Then, the effect of temperature on the reversible cell potential may be written as [1]

$$E_r(T, P) = E_r(T_{\text{ref}}, P) + \left( \frac{\Delta s(T_{\text{ref}}, P)}{nF} \right) (T - T_{\text{ref}}) \quad (53.27)$$

It must be emphasized that the expression given in Equation 53.27 is an approximation. Strictly speaking, the reversible cell potential at any temperature and pressure should be determined from Equation 53.21 by calculating first the property changes for the particular fuel cell reaction involved. Such a procedure has been followed for the hydrogen and oxygen reaction to form gaseous water, and the results are presented in Figure 53.4. Clearly, the reversible cell potential indeed decreases almost linearly as temperature is increased over a large temperature range. However, it is noticed that the reversible cell potential is larger for product water as liquid at low temperatures, but it decreases much faster than the gaseous water as product when temperature is increased. So that at temperatures slightly above about 373 K, the reversible cell potential for liquid water product actually becomes smaller. This may seem odd, but it is because at such high-temperature pressurization is necessary to keep the product water in liquid form as the reactants, hydrogen and oxygen, are fed at 1 atm. Also notice that the critical temperature for water is about 647 K, beyond which distinct liquid state does not exist for water, hence the shorter curve shown for the liquid water case in Figure 53.4.

**FIGURE 53.4**

Effect of temperature on the reversible cell potential of a hydrogen–oxygen fuel cell for the reaction of  $\text{H}_2 + 1/2\text{O}_2 \rightarrow \text{H}_2\text{O}$  at the pressure of 1 atm.

As pointed out earlier, the entropy change for most of fuel cell reactions is negative; consequently, the reversible cell potential decreases as temperature is increased as shown in Figure 53.4. However, for some reactions such as

the entropy change is positive, for example,  $\Delta s = 89 \text{ J}/(\text{mol fuel K})$  at the standard reference temperature and pressure. As a result, the reversible cell potential for this type of reactions will increase with temperature, which is clearly seen in Figure 53.5 for the reversible cell potential as a function of temperature for a number of important fuel cell reactions.

The effect of pressure on reversible cell potential can be expressed as [1]

$$E_r(T, P) = E_r(T, P_{\text{ref}}) - \frac{\Delta N \mathcal{R} T}{nF} \ln \left( \frac{P}{P_{\text{ref}}} \right) \quad (53.28)$$

where  $\Delta N$  represents the total number of mole changes for all the gaseous species involved in the fuel cell reaction. This equation indicates that the pressure dependence of the reversible cell potential is a logarithmic function, and hence the dependence becomes weaker as pressure  $P$  is increased. Figure 53.6 shows the effect of pressure on the reversible cell potential for hydrogen/oxygen fuel cell for both liquid and vapor water as the reaction product. It is seen that the reversible cell potential increases with pressure, very fast for low-pressure values, gradually slowing down for higher-pressure values. Also, the pressure effect is larger for liquid water as the product, because of the larger coefficient arising from the larger change in the number of moles between the product and the reactant,  $\Delta N$ .

It might be also emphasized that the pressure effect is small on the reversible cell potential at low temperatures, as shown in the earlier example. However, this effect increases

**FIGURE 53.5**

Standard reversible cell potential,  $E^\circ$ , as a function of temperature for the most important fuel cell reactions at the pressure of 1 atm. (From Barendrecht, E., *Electrochemistry of fuel cells*, in: Blomen, L.J. M.J. and Mugerwa, M.N., eds., *Fuel Cell Systems*, Plenum Press, New York, 1993.)

**FIGURE 53.6**

Standard reversible cell potential,  $E^\circ$ , as a function of pressure for the fuel cell reaction of  $\text{H}_2(\text{g}) + 1/2\text{O}_2 \rightarrow \text{H}_2\text{O}$  at the temperature of 25°C.

significantly at high temperatures because the pressure effect coefficient,  $-\Delta N\mathcal{R}T/(nF)$ , is directly proportional to temperature.

It might be pointed out that for high-temperature fuel cells, the dependence of the actual cell potential  $E$  on the pressure follows closely the results given in Equation 53.28, whereas a significant deviation occurs for the low-temperature fuel cells. The difference arises from

the fact that at high temperatures, the reaction kinetics are very fast and pressurization primarily increases the reactant concentration, hence better performance directly. At low temperatures, the reaction kinetics are slow, and higher reactant concentration does not yield a proportional increase in the cell potential due to the significant cell potential loss associated with the slow kinetics.

When the fuel, oxidant, and exhaust streams contain chemically inert gas species, the reversible cell potential will be lowered due to the dilution effect of the inert species and can be derived as [1]

$$E_r(T, P_i) = E_r(T, P) - \frac{\mathcal{R}T}{nF} \ln K \quad (53.29)$$

where  $P_i$  is the partial pressure of the reactant in the fuel and oxidant streams, and

$$K = \prod_{i=1}^{N_g} \left( \frac{P_i}{P} \right)^{(v_i'' - v_i')} \quad (53.30)$$

is defined similar to the equilibrium constant for partial pressure (but they are not the same);  $N_g$  is the total number of gas species in the reacting system, excluding the solid and liquid species;  $v_i'$  and  $v_i''$  are the number of moles of species  $i$  in the reactant and product mixtures, respectively. Equation 53.29 is the general form of the Nernst equation, representing the effect of the reactant and product concentrations on the reversible cell potential. When the reactant streams contain inert diluents for a given operating temperature and pressure, the diluents will cause a voltage loss for the reversible cell potential, and the amount of loss is generally called the Nernst loss, and its magnitude is equal to the second term on the right-hand side of Equation 53.29.

### 53.4.3 Energy Conversion Efficiency

#### 53.4.3.1 Definition of Energy Conversion Efficiency

The efficiency for any energy conversion process or system is often defined as\*

$$\eta = \frac{\text{Useful energy obtained}}{\text{Energy available for conversion that's an expense}} \quad (53.31)$$

Based on this definition, it is well known that 100% energy conversion efficiency is possible by the first law of thermodynamics, but is not possible by the second law of thermodynamics for many energy conversion systems that produce power output, such as steam and gas turbines, internal combustion engines, which involve irreversible losses of energy. These thermal energy conversion systems are often referred to as heat engines.

\* Note that in literature  $\eta$  is commonly used as efficiency in thermodynamics, whereas it is also conventionally used as overpotential, or voltage loss, for fuel cell analysis, as in electrochemistry. In this chapter,  $\eta$  is used for both efficiency and overpotential in order to be consistent with the respective convention, and its meaning would become clear from the context.

### 53.4.3.2 Reversible Energy Conversion Efficiency for Fuel Cells

For the present fuel cell system described in Figure 53.3, the energy balance equation, Equation 53.5, can be written, on a per unit mole of fuel basis, as

$$h_{\text{in}} - h_{\text{out}} + q - w = 0 \quad \text{or} \quad h_{\text{in}} - h_{\text{out}} = -q + w \quad (53.32)$$

which indicates that the enthalpy change,  $-\Delta h = h_{\text{in}} - h_{\text{out}}$ , provides the energy available for conversion into the useful energy exhibited as work here, and it is the expense to be paid for the useful work output. At the same time, waste heat,  $q$ , is also generated, which would represent a degradation of energy. The amount of waste heat generated can be determined from the second law expression, Equation 53.6 or 53.13, as

$$q = T\Delta s - T\phi_s \quad (53.33)$$

and the useful energy output as work is, from Equation 53.17 or combining Equations 53.32 and 53.33

$$w = -\Delta g - T\phi_s \quad (53.34)$$

Therefore, the energy conversion efficiency for the fuel cell system described in Figure 53.3 becomes, according to Equation 53.31,

$$\eta = \frac{w}{-\Delta h} = \frac{\Delta g + T\phi_s}{\Delta h} \quad (53.35)$$

Note that both  $\Delta h$  and  $\Delta g$  are negative for power generation systems, including fuel cells as it is clearly shown in Table 53.1. By the second law, the entropy generation per unit mole of fuel is

$$\phi_s \geq 0 \quad (53.36)$$

and the equality holds for all reversible processes, whereas entropy is always generated for irreversible processes. Therefore, the maximum possible efficiency allowed by the second law is, when the process is reversible (i.e.,  $\phi_s = 0$ ),

$$\eta_r = \frac{w_{\text{max}}}{-\Delta h} = \frac{\Delta g(T, P)}{\Delta h(T, P)} \quad (53.37)$$

Since both the enthalpy and Gibbs function changes depend on the system temperature and pressure, the same holds for the energy conversion efficiency. It should be pointed out that in the earlier derivation, no assumption specifically related to fuel cell has been made; the only assumption made is that the energy conversion system for power production is reversible for all processes involved. Thus, Equation 53.37 is valid for any power production system, be it electrochemical converter like fuel cells or conventional thermal energy converter like heat engines, as long as the process is reversible. Hence, it may be called the *second law or reversible efficiency*, since it is the maximum possible efficiency that is allowed by the second law of thermodynamics. In what follows, we will demonstrate that the maximum possible efficiency for conventional heat engines, the well-known Carnot efficiency, is really the second law efficiency applied specifically to the conventional thermal power cycles, thus is equivalent to Equation 53.37.

### 53.4.3.3 Carnot Efficiency: The Reversible Energy Conversion Efficiency for Heat Engines

Consider a heat engine operating between two temperature thermal energy reservoirs (TER), one at a high temperature  $T_H$  and the other at a low temperature  $T_L$ , as shown in Figure 53.7. The heat engine obtains energy from the high-temperature TER in the form of heat with the quantity  $q_H$ ; a portion of this heat is converted to work output  $w$ , and the remainder is rejected to the low-temperature TER in the amount of  $q_L$  as waste heat. Applying the first and second laws to the heat engine, we have

$$\text{First law:} \quad w = q_H - q_L \quad (53.38)$$

$$\text{Second law:} \quad \wp_{s,\text{HE}} = \frac{q_L}{T_L} - \frac{q_H}{T_H} \quad (53.39)$$

where  $\wp_{s,\text{HE}}$  represents the amount of entropy production during the energy conversion process by means of the heat engine. From Equation 53.39, the amount of heat rejection can be determined as

$$q_L = \frac{T_L}{T_H} q_H + T_L \wp_{s,\text{HE}} \quad (53.40)$$

The efficiency for the heat engine is, by the definition of Equation 53.31,

$$\eta = \frac{w}{q_H} \quad (53.41)$$

Substituting Equations 53.38 and 53.40 into 53.41 yields

$$\eta = 1 - \frac{T_L}{T_H} - \frac{T_L}{q_H} \wp_{s,\text{HE}} \quad (53.42)$$

As pointed out earlier, the second law of thermodynamics dictates that the entropy generation within the heat engine can never be negative; at most, it can vanish under the

**FIGURE 53.7**

Thermodynamic system model of heat engines operating between two temperature thermal energy reservoirs.

thermodynamically reversible condition. Therefore, the maximum possible efficiency for the heat engine is achieved if the process is reversible ( $\mathcal{G}_{s,HE} = 0$ ):

$$\eta_{r,HE} = 1 - \frac{T_L}{T_H} \quad (53.43)$$

This is the familiar Carnot efficiency, giving the upper bound for the efficiency of all heat engines. Because  $T_L < T_H$ , the low-temperature  $T_L \neq 0$  by the third law of thermodynamics, and the high-temperature  $T_H$  is finite, 100% efficiency is not possible by the second law for any energy conversion system that produces power output using heat engines, such as steam and gas turbines and internal combustion engines, because of the second law requirement that the entropy generation term must never be negative. In contrast, 100% efficiency is possible by the first law, which merely states the principle of energy conservation.

#### 53.4.3.4 Equivalency of Carnot and Fuel Cell Reversible Efficiency

As shown earlier, both the Carnot efficiency and the reversible energy conversion efficiency for fuel cell, Equation 53.37, are the maximum possible efficiency allowed by the second law; the former is applied specifically to heat engines, while the latter is derived for fuel cells. Therefore, they must be related somehow as they both are the maximum possible efficiency dictated by the second law. In this section, we demonstrate that they are actually equivalent, just expressed in a different form, under a suitable condition for the comparison.

Suppose, for a heat engine, the high-temperature TER is maintained at  $T_H$  by the combustion of a fuel with an oxidant, both reactants are originally at the temperature of  $T_L$ , as shown schematically in Figure 53.8. It is assumed that both the fuel and the oxidant are the same as used in Figure 53.3 for the derivation of fuel cell performance; the combustion process is carried out at the same system pressure  $P$  in a controlled manner such that the combustion products leave the TER at the pressure  $P$  and temperature  $T_L$ . Neglecting

**FIGURE 53.8**

Thermodynamic system model of high-temperature thermal energy reservoir (TER) maintained by combustion process of a fuel/oxidant mixture.

the changes in the kinetic and gravitational potential energy, the first and second laws become, for the high-temperature TER,

$$\text{First law:} \quad q_H = h_R - h_P = -\Delta h(T_L, P) \quad (53.44)$$

$$\text{Second law:} \quad \wp_{s, \text{TER}} = (s_P - s_R) + \frac{q_H}{T_H} = \Delta s(T_L, P) + \frac{q_H}{T_H} \quad (53.45)$$

After rearranging, Equation 53.45 gives the temperature  $T_H$  resulting from the combustion process

$$T_H = \frac{q_H}{\wp_{s, \text{TER}} - \Delta s(T_L, P)} \quad (53.46)$$

Substitution of Equations 53.44 and 53.46 into 53.42 leads to

$$\eta = \frac{\Delta g(T_L, P)}{\Delta h(T_L, P)} + \frac{T_L}{\Delta h(T_L, P)} (\wp_{s, \text{HE}} + \wp_{s, \text{TER}}) \quad (53.47)$$

where  $\Delta g(T_L, P) = \Delta h(T_L, P) - T_L \Delta s(T_L, P)$  is the change in the Gibbs function between the reaction product and the reactant. If all the processes within the heat engine and high-temperature TER are reversible ( $\wp_{s, \text{HE}} = 0$  and  $\wp_{s, \text{TER}} = 0$ ), then Equation 53.47 reduces to

$$\eta_r = \frac{\Delta g(T_L, P)}{\Delta h(T_L, P)} \quad (53.48)$$

which is exactly the same as Equation 53.37—the efficiency expression derived for fuel cells. Note that in order for the combustion process to be reversible (i.e.,  $\wp_{s, \text{HE}} = 0$ ) theoretically, there should be no product dissociations and no incomplete combustion products or by-products (such as pollutants) formed, and the perfect combustion products should consist of stable chemical species only, as would be obtained from an ideal and complete stoichiometric reaction. Therefore, it may be stated that any reversible heat engine operating under the maximum temperature limit allowed by a *perfect* combustion of a fuel/oxidant mixture has the same efficiency as that of a reversible isothermal fuel cell using the same fuel and oxidant and operating at the same temperature as that of the low-temperature TER. Or simply stated, the maximum possible efficiency is the same for both fuel cells and heat engines.

It should be emphasized that combustion process is inherently irreversible, and other irreversibilities occur in the heat engine as well so that the actual efficiency for heat engine is much lower than the maximum allowed by the second law. Similarly, fuel cells can never achieve, although it is quite possible to achieve very closely the maximum possible efficiency allowed by the second law. Therefore, the actual energy efficiency for fuel cells is typically much higher than the heat engine. The various mechanisms of irreversible losses in fuel cells will be described later in this chapter.

#### 53.4.3.5 Possibility of Over 100% Fuel Cell Efficiency: Is It Real or Hype?

It is well known that no heat engine could have efficiency of 100% or more, including the ideal Carnot efficiency, as discussed earlier. However, it has been reported that the ideal

fuel cell efficiency,  $\eta_r$ , according to Equation 53.37, could be over 100% in principle for some special fuel cell reactions (e.g., [2,8]), even though it is unachievable in practice. This has also sometimes been used as evidence that fuel cells could have higher energy efficiency than the competing heat engines. Is this realistic even under the thermodynamically reversible condition? The answer is negative! With the following analysis, we can show that this is really due to a conceptual error in stretching the application of Equation 53.37 beyond its validity range.

Consider the thermodynamic model system used for fuel cell analysis, as shown in Figure 53.3. The amount of heat transfer from the surrounding thermal bath to the fuel cell system is given in Equation 53.33 for practical fuel cells. Under the thermodynamically reversible condition, the amount of heat transfer becomes

$$q = T\Delta s = \Delta h - \Delta g \quad (53.49)$$

For most of fuel cell systems,  $\Delta s$  is negative (i.e.,  $\Delta s < 0$  just like  $\Delta h$  and  $\Delta g$ ), indicating that heat is actually transferred from the fuel cell to the ambient environment, or heat is lost from the fuel cell system, rather than the other way around. Hence, the second law efficiency, according to Equation 53.37,

$$\eta_r = \frac{\Delta g}{\Delta h} = \frac{\Delta h - T\Delta s}{\Delta h} = 1 - \frac{T\Delta s}{\Delta h} < 1 \quad (53.50)$$

is <100%, as it should be by the common perception of the parameter called efficiency.

However, for some special reactions, such as

the entropy change  $\Delta s$  is positive. Physically, it indicates that the fuel cell absorbs heat from the ambient and converts it completely into electrical energy along with the chemical energy of the reactants. This is equivalent to stating that the less useful form of energy, heat, is converted completely into the more useful form of energy, electric energy, without the generation of entropy (i.e., reversible condition) during the conversion process when Equation 53.37 is used for the efficiency calculation—such a process is clearly a violation of the second law. Therefore, the second law efficiency for this particular fuel cell reaction becomes larger than 100%, that is, a physically impossible result, when Equation 53.37 is utilized for the efficiency calculation for this type of fuel cell reactions. According to Equation 53.37, the reversible fuel cell efficiency for the reaction shown in Equation 53.51 would be equal to  $\eta_r = 124\%$  at the standard temperature and pressure, 163% at 500°C and 1 atm, and 197% at 1000°C and 1 atm.

The root of the problem from the straightforward application of Equation 53.37 leading to the physically impossible result of over 100% energy efficiency is as follows. At atmospheric temperature for fuel cell operations, the energy from the thermal bath (or the atmosphere) as heat may be free. But at elevated temperatures, external means must be employed to keep the thermal bath at temperatures above the ambient atmospheric temperature, which constitutes an expense. Therefore, the heat from the thermal bath to the fuel cell system is no longer a free energy input; rather, it is part of the energy input that has to be paid for. By definition, Equation 53.31, the efficiency definition for fuel cells, has to be modified accordingly, such that the ideal reversible efficiency will be no longer over 100% for fuel cells. Thus, we conclude that the reversible fuel cell

efficiency shown in Equation 53.37 is valid only for fuel cell reactions where the entropy change between the product and reactant is negative (hence, heat is lost from the fuel cell), and it cannot be applied for reactions with positive entropy change, such as the one given in Equation 53.51.

#### 53.4.4 Practical Fuel Cell Efficiency and Energy Loss Mechanisms

From the preceding analysis, it is clear that energy loss in fuel cells occurs under both reversible and irreversible conditions. We will describe each type of energy loss mechanisms and associated expression for energy conversion efficiency in fuel cells.

##### 53.4.4.1 Reversible Energy Loss and Reversible Energy Efficiency

The energy loss in fuel cells under reversible conditions is equal to the heat transferred (or lost) to the environment, as given:

$$q = T\Delta s = \Delta h - \Delta g \quad (53.49)$$

because of the negative entropy change for the fuel cell reaction. The associated energy conversion efficiency, which has been called the reversible energy conversion efficiency, has been derived and given in Equation 53.37 or 53.50. Combining Equation 53.49 with 53.50 yields

$$\eta_r = \frac{\Delta g}{\Delta h} = \frac{\Delta g}{\Delta g + T\Delta s} \quad (53.52)$$

Dividing the numerator and the denominator by the factor ( $nF$ ), and utilizing Equations 53.21 and 53.52 becomes [1]

$$\eta_r = \frac{E_r}{E_r - T(\partial E_r / \partial T)_p} \quad (53.53)$$

Therefore, when the entropy change is negative, as described earlier, the reversible efficiency,  $\eta_r$ , is <100%, and the reversible cell potential decreases with temperature; and according to Equation 53.53, the reversible efficiency,  $\eta_r$ , also decreases with temperature. For example, for  $H_2$  and  $O_2$  reaction forming gaseous water at 1 atm pressure,

$$\left( \frac{\partial E_r}{\partial T} \right)_p = -0.2302 \times 10^{-3} \text{ V/K}$$

at 25°C, and the reversible efficiency is about 95% at 25°C, and it becomes 88% at 600 K and 78% at 1000 K. [Figure 53.9](#) illustrates the reversible efficiency as a function of temperature for the hydrogen and oxygen reaction with gaseous water as the reaction product. It is seen that the reversible efficiency decreases almost linearly. For most fuel cell reactions,

$$\left( \frac{\partial E_r}{\partial T} \right)_p = -(0.1-1.0) \times 10^{-3} \text{ V/K}$$

at 25°C and 1 atm; hence, the reversible efficiency is typically around 90%.

**FIGURE 53.9**

The reversible fuel cell efficiency (based on LHV) as a function of temperature for the reaction of  $\text{H}_2 + 1/2\text{O}_2 \rightarrow \text{H}_2\text{O}(\text{g})$  occurring at 1 atm pressure.

However, for the reaction of carbon and oxygen to form carbon monoxide, as shown in Equation 53.51, the entropy change is positive, and the reversible cell potential increases with temperature, as presented previously; hence, the reversible efficiency will also increase with temperature, according to Equation 53.53. But as discussed previously, the efficiency expression, Equation 53.52 or 53.53, is not valid for such reactions.

From the reversible energy efficiency, Equation 53.37, and dividing the numerator and the denominator by the factor  $(nF)$ , we have, after utilizing the reversible cell potential, Equation 53.21

$$\eta_r = \frac{E_r}{(-\Delta h/nF)} = \frac{E_r}{E_{tn}} \quad (53.54)$$

where

$$E_{tn} = -\frac{\Delta h}{nF} \quad (53.55)$$

is called thermoneutral voltage (or potential), a voltage a fuel cell would have if all the chemical energy of the fuel and oxidant is converted to electric energy (i.e., 100% energy conversion into electricity). For example, for the reaction

$E_{tn} = 1.48 \text{ V}$ , and the corresponding reversible efficiency is  $\eta_r = 83\%$  at  $25^\circ\text{C}$  and 1 atm, whereas at the same temperature and pressure, for the reaction

$E_{tn} = 1.25 \text{ V}$ , and the corresponding reversible efficiency is  $\eta_r = 95\%$ .

From this discussion, it is noted that for hydrogen and oxygen reaction, the reversible cell efficiency can differ by as much as 14%, depending on whether the product water is liquid or vapor, or whether the higher (HHV) or lower heating value (LHV) is used for the efficiency calculation under identical operating conditions. For most of the hydrocarbon fuels that contain hydrogen (including hydrogen itself, hydrocarbons, alcohols, and to a lesser extent coal), there exist two values for the change in the enthalpy and Gibbs function, for example,

$$\text{For natural gas (methane, CH}_4\text{): } \frac{\text{LHV}}{\text{HHV}} = 0.90$$

$$\text{For coals of typical hydrogen and water content: } \frac{\text{LHV}}{\text{HHV}} = 0.95 \text{ } 0.98$$

Therefore, different efficiency values result, depending on which heating value ( $-\Delta h$ ) is used for the efficiency calculation. Typically, in fuel cell analysis, the HHV is used unless stated otherwise, and this convention will be used throughout this chapter unless explicitly stated otherwise.

It should be emphasized that from the preceding analysis, it is known that for most fuel cell reactions, the reversible efficiency,  $\eta_r$ , decreases as the fuel cell operating temperature is increased. This effect is important in considering high-temperature fuel cells, namely, the molten carbonate fuel cells (MCFCs) and the solid oxide fuel cells (SOFCs). For example, Figure 53.9 indicates that the reversible cell efficiency is reduced to lower 70% (based on LHV) for hydrogen and oxygen reaction at the typical operating temperature of 1000°C for SOFCs, as opposed to around 95% at 25°C as discussed earlier. This significant reduction in the reversible cell efficiency seems to work against high-temperature fuel cells. However, the irreversible losses, to be described later, decrease drastically as temperature is increased, so that the practical fuel cell performance (such as efficiency and power output under practical operating condition) increases. Therefore, further analysis should be done for efficiency under practical operating condition rather than the idealized reversible condition, which is the focus of the following discussion.

#### 53.4.4.2 Mechanism of Irreversible Energy Losses

For fuel cells, the reversible cell potential and the corresponding reversible efficiency are obtained under the thermodynamically reversible condition, implying that there is no rigorous occurrence of continuous reaction or electrical current output. For practical applications, a useful amount of work (electrical energy) is obtained only when a reasonably large current  $I$  is drawn from the cells because the electrical energy output is through the electrical power output, which is defined as

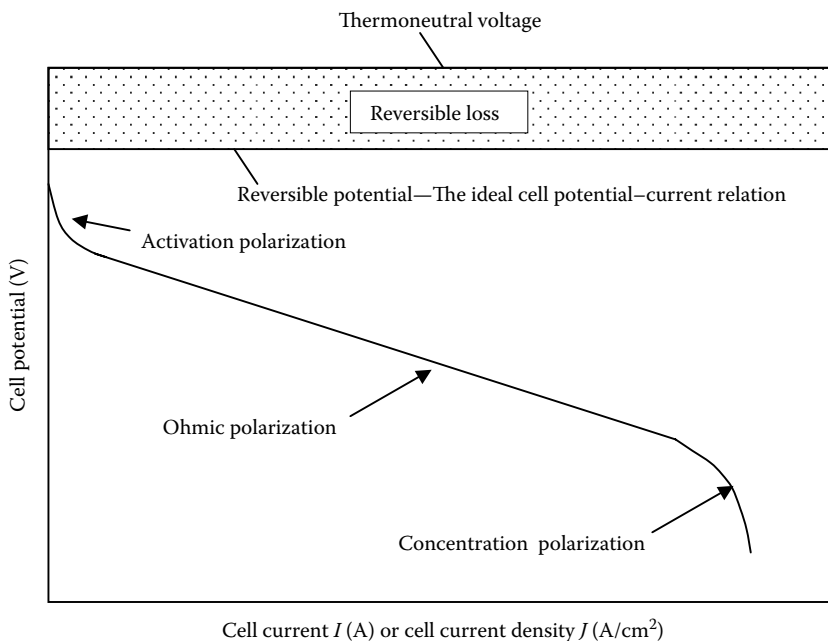

$$\text{Power} = EI \quad \text{or} \quad \text{Power Density} = EJ \quad (53.56)$$

However, both the cell potential and efficiency decrease from its corresponding (equilibrium) reversible values because of irreversible losses when current is increased. These irreversible losses are often called polarization, overpotential, or overvoltage\* in

\* The terms “polarization,” “overpotential,” and “overvoltage” have been loosely used in the literature to denote cell potential (or voltage) loss. However, they do have some subtle differences [1] that are neglected here so that these words can be used interchangeably.

literature, and they originate primarily from three sources: activation, ohmic, and concentration polarization. The actual cell potential as a function of current is the result of these polarizations; therefore, a plot of the cell potential vs. current output is conventionally called a polarization curve. It should be noticed that the magnitude of electrical current output depends largely on the active cell area; therefore, a better measure is the current density,  $J$  ( $\text{A}/\text{cm}^2$ ) instead of current,  $I$ , itself, and the unit  $\text{A}/\text{cm}^2$  is often used rather than  $\text{A}/\text{m}^2$  as the unit for the current density because square meter is too large to be used for fuel cell analysis.

A typical polarization curve is illustrated in Figure 53.10 for the cell potential as a function of current density. The ideal cell potential–current relation is independent of the current drawn from the cell, and the cell potential remains equal to the reversible cell potential. The difference between the thermoneutral voltage and the reversible cell potential represents the energy loss under the reversible condition (the reversible loss). However, the actual cell potential is smaller than the reversible cell potential and decreases as the current drawn is increased due to the three mechanisms of irreversible losses: activation, ohmic, and concentration polarization. The activation polarization,  $\eta_{\text{act}}$ , arises from the slow rate of electrochemical reactions, and a portion of the energy is lost (or spent) on driving up the rate of electrochemical reactions in order to meet the rate required by the current demand. The ohmic polarization,  $\eta_{\text{ohm}}$ , arises due to electrical resistance in the cell, including ionic resistance to the flow of ions in the electrolyte and electronic resistance to the flow of electrons in the rest of the cell components. Normally, the ohmic polarization is linearly dependent on the cell current. Concentration polarization,  $\eta_{\text{conc}}$ , is caused by the slow rate of mass transfer resulting in the depletion of reactants in the vicinity of active reaction sites and the overaccumulation of reaction products

**FIGURE 53.10**

Schematic of a typical polarization curve. The cell potential for a fuel cell decreases as the current drawn from the cell is increased due to activation, ohmic, and concentration polarizations.

that block the reactants from reaching the reaction sites. It usually becomes significant, or even prohibitive, at high current density when the slow rate of mass transfer is unable to meet the high demand required by the high current output. As shown in Figure 53.10, concentration polarization is often the cause of rapid cell potential decrease to zero. The current (density) corresponding to the zero cell potential is often called the limiting current (density), and evidently, it is controlled by the concentration activation. From Figure 53.10, it is also clear that activation polarization is dominant at small current densities, while concentration polarization is predominant at high current densities. The linear drop in the cell potential due to resistance loss occurs at intermediate current densities, and practical fuel cell operation is almost always located within the ohmic polarization region. It should be emphasized that these three loss mechanisms actually occur simultaneously in an operating cell, despite their different influences at the different current density conditions.

Figure 53.10 also indicates that even at zero current output from the fuel cell, the actual cell potential is smaller than the idealized reversible cell potential. This small difference in cell potential is directly related to the chemical potential difference between the cathode and the anode. So that even at zero external load current, there are electrons delivered to the cathode, where oxygen ions are formed, and migrate through the electrolyte to the anode where they deionize to release electrons. The electron released migrates back to the cathode to continue the process or *exchange*. The ionization/deionization reactions proceeding at a slow rate yield an extremely small current, often called exchange current  $I_0$  or exchange current density  $J_0$ , and the cell potential is reduced below the reversible cell potential. Therefore, exchange current arises from the electrons migrating through the electrolyte rather than through the external load, and about 0.1–0.2 V of cell potential loss results from the exchange process. Consequently, the efficiency of a real fuel cell is about 8%–16% lower than the reversible cell efficiency,  $\eta_r$ , even at close to zero current output.

The exchange current density  $J_0$  is very small; it is at least about  $10^{-2}$  A/cm<sup>2</sup> for H<sub>2</sub> oxidation at the anode, and about  $10^{-5}$  times slower for O<sub>2</sub> reduction at the cathode. In comparison, the O<sub>2</sub> reduction process at the cathode is so slow that competing anodic reactions play a significant role, such as oxidation of electrocatalyst, corrosion of electrode materials, and oxidation of organic impurities in the anode structure. All these anodic reactions result in the corrosion of electrodes, thereby limiting the cell life unless appropriate countermeasures are taken.

It should be pointed out that the cell potential loss resulting from the exchange current diminishes when the current drawn through the external load is increased beyond a certain critical value. As the external current is increased, the cell potential decreases as shown in Figure 53.10; thus, the driving force for the exchange current is reduced, leading to a smaller exchange current—this is the only form of energy loss that decreases when the external current is increased.

#### 53.4.4.3 Amount and Rate of Waste Heat Generation

From the earlier discussion, it becomes clear that the actual cell potential  $E$  is lower than the reversible cell potential  $E_r$ , and the difference is due to the potential losses arising from the earlier irreversible loss mechanisms. Therefore,

$$E = E_r - (\eta_{\text{act}} + \eta_{\text{ohm}} + \eta_{\text{conc}}) \quad (53.57)$$

The irreversible energy loss as heat (or waste heat generation) per mole fuel consumed can be easily obtained, because the entropy generation is, according to Equations 53.24 and 53.57,

$$\phi_s = \frac{nF(E_r - E)}{T} = \frac{nF(\eta_{\text{act}} + \eta_{\text{ohm}} + \eta_{\text{conc}})}{T} \quad (53.58)$$

Then, Equation 53.13 becomes for the total heat loss from the fuel cell

$$q = T\Delta s - T\phi_s = \underbrace{T\Delta s}_{\text{Reversible loss}} - \underbrace{nF(\eta_{\text{act}} + \eta_{\text{ohm}} + \eta_{\text{conc}})}_{\text{Irreversible losses}} \quad (53.59)$$

Since the entropy change is negative ( $\Delta s < 0$ ) for most fuel cell reactions, the heat transfer is negative as well, implying that energy as heat is lost from the fuel cell shown in [Figure 53.3](#) for both reversible and irreversible losses.

Because  $T\Delta s = \Delta h - \Delta g$  by the definition of the Gibbs function change for fuel cell reactions, Equation 53.59 can be written as

$$\frac{q}{nF} = \frac{T\Delta s}{nF} - (\eta_{\text{act}} + \eta_{\text{ohm}} + \eta_{\text{conc}}) = \frac{\Delta h - \Delta g}{nF} - (\eta_{\text{act}} + \eta_{\text{ohm}} + \eta_{\text{conc}}) \quad (53.60)$$

Considering the definition for the thermoneutral voltage and the reversible cell potential, the earlier expression becomes

$$\frac{q}{nF} = -E_{tm} + E_r - (\eta_{\text{act}} + \eta_{\text{ohm}} + \eta_{\text{conc}}) \quad (53.61)$$

Combining with Equation 53.57, Equation 53.61 reduces to

$$\frac{q}{nF} = -(E_{tm} - E) \quad (53.62)$$

Hence, the equivalent cell potential loss due to the energy loss in the fuel cell as heat is equal to the difference between the thermoneutral voltage and the actual cell potential.

The rate of heat loss per mole fuel consumed in the fuel cell, Equation 53.59, can be expressed as an equivalent power loss:

$$P_{\text{HeatLoss}} = I \left( \frac{q}{nF} \right) = -I(E_{tm} - E) = I \left[ \frac{T\Delta s}{nF} - (\eta_{\text{act}} + \eta_{\text{ohm}} + \eta_{\text{conc}}) \right] \quad (53.63)$$

This expression is important in determining the cooling requirements of fuel cell stacks.

#### 53.4.4.4 Various Forms of Irreversible Energy Conversion Efficiency

After the earlier description of the irreversible energy losses, we can now introduce several forms of energy efficiency that would be useful in the analysis of fuel cell performance.

#### 53.4.4.4.1 Voltage Efficiency, $\eta_E$

The voltage efficiency is defined as

$$\eta_E = \frac{E}{E_r} \quad (53.64)$$

Because the actual cell potential  $E$  is compared with the maximum possible cell potential  $E_r$  allowed by the second law, the voltage efficiency is really a specific form of the exergy efficiency, representing the degree of departure of the cell operation from the idealized thermodynamically reversible condition. As shown in Equation 53.57,  $E < E_r$ , hence  $\eta_E < 1$ .

#### 53.4.4.4.2 Current Efficiency, $\eta_I$

The current efficiency is a measure of how much current is produced from a given amount of fuel consumed in the fuel cell reaction, and it is defined as

$$\eta_I = \frac{I}{nF(dN_F/dt)} \quad (53.65)$$

where  $dN_F/dt$  represents the rate of fuel consumption in the fuel cell (mol/s). The current efficiency would be <100% if part of the reactants participate in non-current-productive side reactions, called parasitic reactions, such as reactant crossover through the electrolyte region, incomplete conversion of reactants to the desired products, reaction with the cell components, or even reactant leakage from the cell compartment due to sealing problem. For example, in DMFCs, about 20% of the liquid methanol can cross over to the cathode side through the proton-conducting polymer membrane, implying the current efficiency is only about 80% for such cells. However, for most practical fuel cells, especially at operating conditions where the current output is sufficiently larger than zero (without the effect of exchange current discussed previously), the current efficiency is about 100%. This is because for practical fuel cells, all the parasitic reactions are undesirable and would have been removed by appropriate design.

#### 53.4.4.4.3 Overall Free Energy Conversion Efficiency, $\eta_{FC}$

The overall free energy conversion efficiency is defined as the product of the reversible efficiency, voltage, and current efficiency:

$$\eta_{FC} = \eta_r \times \eta_E \times \eta_I \quad (53.66)$$

If the current efficiency is 100% as is often the case for well-designed practical fuel cells, substituting the definitions for the various efficiencies into the earlier equation lead to

$$\eta_{FC} = \frac{E}{E_m} \quad (53.67)$$

Therefore, the overall free energy conversion efficiency is really the overall efficiency for energy conversion process occurring within the fuel cell. Because the thermoneutral voltage is a fixed value for a given fuel and oxidant under a given operating condition of temperature and pressure, the overall energy conversion efficiency for fuel cells is proportional to the actual cell potential,

$$\eta_{FC} \sim E \quad (53.68)$$

This is a significantly important result. Once the actual cell potential is determined, the energy conversion efficiency of the fuel cell is known as well. This is the primary reason that in fuel cell literature, it is almost always that the cell polarization curve is given without specifically showing the cell energy efficiency as a function of the current. Further, Equation 53.68 implies that the fuel cell efficiency will depend on the current output in the same way as the cell potential, that is, decrease as the current output is increased.

#### 53.4.4.4 Fuel Cell System Efficiency, $\eta_s$

Since a fuel cell system is composed of one or multiple fuel cell stacks and auxiliary equipment, which would also have its own energy efficiency of  $\eta_{aux}$ , the total fuel cell system efficiency is

$$\eta_s = \eta_{FC} \times \eta_{aux} \quad (53.69)$$

### 53.4.5 Efficiency Loss in Operating Fuel Cells: Stoichiometry, Utilization, and Nernst Loss

In an operating fuel cell, reactant composition changes between the inlet and outlet of the fuel cell along the flow path over the electrode surface because reactants are consumed to yield current output and reaction products are formed along the way as well. The change in reactant composition results in additional loss of cell potential beyond those losses described in the preceding section. This potential loss arises from the fact that the cell potential  $E$  adjusts to the lowest electrode potential given by the Nernst equation, Equation 53.29, for the various reactant compositions at the exit of the anode and cathode chambers. This is because electrodes are usually made of good electronic conductors, and consequently, they are isopotential surfaces. The cell potential  $E$  may not exceed the minimum local value set by the Nernst equation. This additional cell potential loss is often also called the Nernst loss, which is equal to the difference between the inlet and exit Nernst potentials determined based on the inlet and exit reactant compositions. According to Equation 53.29, this additional cell potential loss due to the consumption of reactants in the cell is when the reactant streams are arranged in a concurrent flow:

$$\eta_N = \frac{\mathcal{R}T}{nF} \ln K_{out} - \frac{\mathcal{R}T}{nF} \ln K_{in} = \frac{\mathcal{R}T}{nF} \ln \frac{K_{out}}{K_{in}} \quad (53.70)$$

In the case of a fuel cell where both fuel and oxidant flows are in the same direction (concurrent), the minimum Nernst potential occurs at the flow outlet. When the reactant flows are in counterflow, cross-flow, or more complex arrangements, it becomes difficult to determine the location of the minimum potential due to the reactant consumption. Appropriate flow channel design for the anode and cathode sides can minimize the Nernst loss.

Equation 53.70 also implies that the Nernst loss will be extremely large and approach infinity if all the reactants are consumed in the in-cell electrochemical reaction leading to zero reactant concentration at the cell outlet. To reduce the Nernst loss to an acceptable level for practical fuel cell operations, reactants are almost always supplied more than the stoichiometric amount required for the desired current production. The actual amount of reactants supplied to a fuel cell is often expressed in terms of a parameter called stoichiometry,  $S_i$ :

$$S_i = \frac{\text{Molar flow rate of reactants supplied to a fuel cell}}{\text{Molar flow rate of reactants consumed in the fuel cell}} = \frac{\dot{N}_{in}}{\dot{N}_{consumed}} \quad (53.71)$$

For example, for proton exchange membrane (PEM) fuel cells, typical operation uses  $S_t \approx (1.1\text{--}1.2)$  for  $\text{H}_2$  and  $S_t \approx 2$  for  $\text{O}_2$  (pure or in air). Therefore, stoichiometry really represents the actual flow rate for the reactant delivered to the fuel cell. Because there are normally at least two types of reactants for fuel cell, one as fuel and another as oxidant, stoichiometry can be defined for either reactant.

Alternatively, reactant flow rate can be expressed in terms of a parameter called utilization,  $U_t$ :

$$U_t = \frac{\text{Molar flow rate of reactants consumed in the fuel cell}}{\text{Molar flow rate of reactants supplied to the fuel cell}} = \frac{\dot{N}_{\text{consumed}}}{\dot{N}_{\text{in}}} \quad (53.72)$$

Clearly, stoichiometry and utilization are inversely proportional to each other.

For properly designed practical fuel cells, no reactant crossover or leakage out of the cell may occur in general; therefore, the rate of reactant consumed within the cell is equal to the difference between the rate of molar flow into and out of the cell. For example, the stoichiometry for the fuel may be expressed as

$$S_{t,F} = \frac{\dot{N}_{F,\text{in}}}{\dot{N}_{F,\text{consumed}}} = \frac{\dot{N}_{F,\text{in}}}{\dot{N}_{F,\text{in}} - \dot{N}_{F,\text{out}}} = \frac{1}{U_{t,F}} \quad (53.73)$$

Effect of reactant utilization on the reversible cell potential is illustrated in Figure 53.11. It is seen that the reactant composition at the cell outlet decreases; hence, the reversible cell potential decreases as well when the utilization factor is increased. The decrease is rapid when utilization goes beyond about 90%. In practical fuel cell operation, 100% utilization

**FIGURE 53.11**

Reversible cell potential as a function of reactant utilization (both fuel and oxidant utilizations are set equal) for a molten carbonate fuel cell operating at 650°C and 1 atm. Reactant compositions at the cell inlet: 80%  $\text{H}_2$ /20%  $\text{CO}_2$  mixture saturated with  $\text{H}_2\text{O}(\text{g})$  at 25°C for the fuel gas, and 60%  $\text{CO}_2$ /30%  $\text{O}_2$ /10% inert gas mixture for the oxidant gas. (From Hirschenhofer, J.H. et al., *Fuel Cells: A Handbook* (Rev. 3), U.S. Department of Energy, Washington, DC, 1994.)

**FIGURE 53.12**

Inlet and outlet Nernst potential as a function of temperature and utilization for the reaction of  $\text{H}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{g})$  at 1 atm.

(or unity stoichiometry) will result in reactant concentrations vanishing at the cell exit; then, the Nernst loss becomes dominant and the cell potential is reduced to zero—this is certainly an undesirable situation that needs to be avoided. Therefore, typical operation requires that the utilization be about 80%–90% for fuel and 50% for oxidant in order to balance the Nernst loss with the parasitic losses associated with the reactant supply.

As shown in Equation 53.70, the additional Nernst loss due to the reactant depletion in the cell is directly proportional to the cell operating temperature. Figure 53.12 shows the reversible cell potential at the cell inlet and outlet for hydrogen and oxygen reaction forming gaseous water product at 1 atm as a function of temperature. The outlet Nernst potentials (i.e., the reversible cell potential at the cell outlet) are determined for oxygen utilization of 50%, and hydrogen utilizations of 85%, 90%, and 95%, respectively, as well as for the utilization of 95% for both hydrogen and oxygen. It is clearly seen that the outlet Nernst potential decreases when either utilization or temperature is increased.

If pure hydrogen is used as fuel, the anode compartment can be designed as a dead-end chamber for hydrogen supply. Similarly, if pure oxygen is used as oxidant, a dead-end cathode compartment can be employed. However, inert impurities in the reactant gas will accumulate at the anode and cathode compartments, and they must be removed either periodically or continuously in order to maintain a good fuel cell performance. Periodic purging or continuous bleeding can be implemented for this purpose, but this results in a small loss of fuel, and hence <100% utilization.

From the earlier discussion, it is evident that 100% utilization for reactants is practically an unwise design. Since in-cell fuel utilization will never be 100% in practice, the determination of in-cell energy conversion efficiency and the cell potential must take utilization factor into consideration. If the fuel exiting the fuel cell is discarded (not recirculated back to the cell or not utilized for other useful purpose such as providing heat for fuel preprocessing), then the overall energy conversion efficiency must be equal to the overall fuel cell efficiency given in Equation 53.66 multiplied by the utilization to take into account the fact that not all the fuel is being used for electric energy production.

### 53.5 Fuel Cell Electrode Processes

The thermodynamic process described in the previous section for a fuel cell is a gross underestimate of what happens in reality. It has been identified that there are many physical (i.e., transport of mass, momentum, and energy) and chemical processes involved in the overall electrochemical reactions in the porous fuel cell electrodes that influence the performance of fuel cells. The transport processes involving the mass transfer of reactants and products play a prominent role in the performance of porous electrodes in fuel cells, and those involving heat transfer and thermal management are important in fuel cell systems. Some of the important physical and chemical processes occurring in porous fuel cell electrodes during electrochemical reactions for liquid electrolyte fuel cells are the following [4]:

1. Initially, the reactant stream consists of multicomponent gas mixture, for example, the fuel stream typically contains hydrogen and water vapor, as well as carbon dioxide and even some carbon monoxide, whereas the oxidant stream usually has oxygen, nitrogen, water vapor, carbon dioxide, etc. The molecular reactant (such as  $H_2$  or  $O_2$ ) is transferred to the porous electrode surface from the reactant stream through the mechanism of convection and then transported through the porous electrode, primarily by diffusion, to reach the gas/electrolyte interface.
2. The reactant dissolves into the liquid electrolyte at the two-phase interface.
3. The dissolved reactant then diffuses through the liquid electrolyte to arrive at the electrode surface.
4. Some pre-electrochemical homogeneous or heterogeneous chemical reactions may occur, such as electrode corrosion reaction, or impurities in the reactant stream may react with the electrolyte.
5. Electroactive species (which could be reactant itself as well as impurities in the reactant stream) are adsorbed onto the solid electrode surface.
6. The adsorbed species may migrate on the solid electrode surface, principally by the mechanism of diffusion.
7. Electrochemical reactions then occur on the electrode surface wetted by the electrolyte—the so-called three-phase boundary, giving rise to electrically charged species (or ions and electrons).
8. The electrically charged species and other neutral reaction product such as water, still adsorbed on the electrode surface, may migrate along the surface due to diffusion in what has been referred to as post-electrochemical surface migration.
9. The adsorbed reaction products become desorbed.
10. Some post-electrochemical homogeneous or heterogeneous chemical reactions may occur.
11. The electrochemical reaction products (neutral species, ions, and electrons) are not only transported away from the electrode surface, mainly by diffusion, but also influenced, for the ions, by the electric field setup between the anode and the cathode. The electron motion is dominated by the electric field effect.
12. The neutral reaction products diffuse through the electrolyte to reach the reactant gas/electrolyte interface.
13. Finally, the products will be transported out of the electrode and the cell in the gas form.

Normally, any of the 13 processes can influence the performance of a fuel cell, exhibiting the complex nature of a fuel cell operation. For well-designed practical fuel cells, the earlier electrode processes might be grouped into the following three major steps:

1. *Delivery of molecular reactant to the electrode surface:* This step involves a number of physical and chemical processes preceding the electrochemical reaction, and it generally includes the transport of molecular reactant from the gas phase supply outside the electrode structure to the liquid electrolyte surface, typically through the porous electrode structure, then the dissolution of molecular reactant into the liquid electrolyte, followed by the diffusion of the dissolved reactant through the electrolyte to the electrode surface, and finally the adsorption of the reactant on the electrode surface.  
It might be pointed out that the delivery of the electrons and ions to the electrode surface is as important as the delivery of molecular reactant since they are all needed for the electrochemical reactions to occur at the electrode surface.
2. *Reduction or oxidation of the adsorbed molecular reactant at the electrode surface in the presence of electrolyte:* This is the step for electrochemical reactions that produce electric current. The reactions occur only at the electrode surface that is covered by the electrolyte, hence, often referred to as the three-phase boundary or active reaction sites. Significant increase in the reactive sites is essential for good fuel cell performance.
3. *Removal of the reaction products from the electrode surface for the regeneration of the reaction sites and for the continuous production of electric current:* This step is especially important for low-temperature acid electrolyte fuel cells, because product water is formed at the cathode and is in the liquid form. Liquid water accumulation in the porous electrode structure may block the transport of molecular oxygen to the reaction sites, severely hindering the process described in step (1), thereby degrading the cell performance due to oxygen starvation at the reaction sites. Such a phenomenon is often referred to as the *water flooding* of electrodes, a critical issue for PEM fuel cells (PEMFCs).

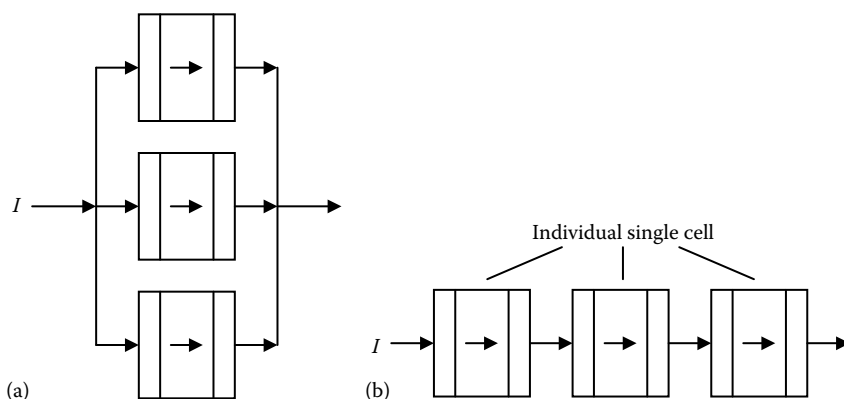

---

## 53.6 Cell Connection and Stack Design Considerations

The potential of a working cell is typically around 0.7–0.8 V, and it is normally too small for practical applications, also because of the limited power available from a single cell. Therefore, many individual cells are connected (or stacked) together to form a fuel cell stack. Although many stacking configurations are possible, the overpotential associated with the transport processes discussed in this chapter imposes limitations and technical difficulties, making cell stacking one of the significant technical challenges in the drive for the fuel cell commercialization. We will briefly discuss the stacking options later and the associated transport-related issues.

The electrical connection among the individual cells may be arranged in parallel or in series, as shown in [Figure 53.13](#). The parallel connection still provides a low voltage output from the stack, but a very high current output since the stack current is the sum of the current produced in each cell. Such an extremely large current flow will cause an

**FIGURE 53.13**

Cell connection (stacking) configurations: (a) parallel connection and (b) series connection. The arrow in the diagram represents the direction of the current flow.

excessively large ohmic voltage loss in the stack components and at the surface contacts among the components. Thus, parallel connection is typically avoided unless for small current or power applications.

Series connection can have two typical arrangements: unipolar and bipolar, as shown in Figure 53.14. Unipolar design has one fuel stream supplying fuel to two anodes for the two adjacent cells, and one oxidant stream delivering oxidant to two cathodes for the two adjacent cells. This arrangement of one reactant stream serving for two adjacent electrodes simplifies

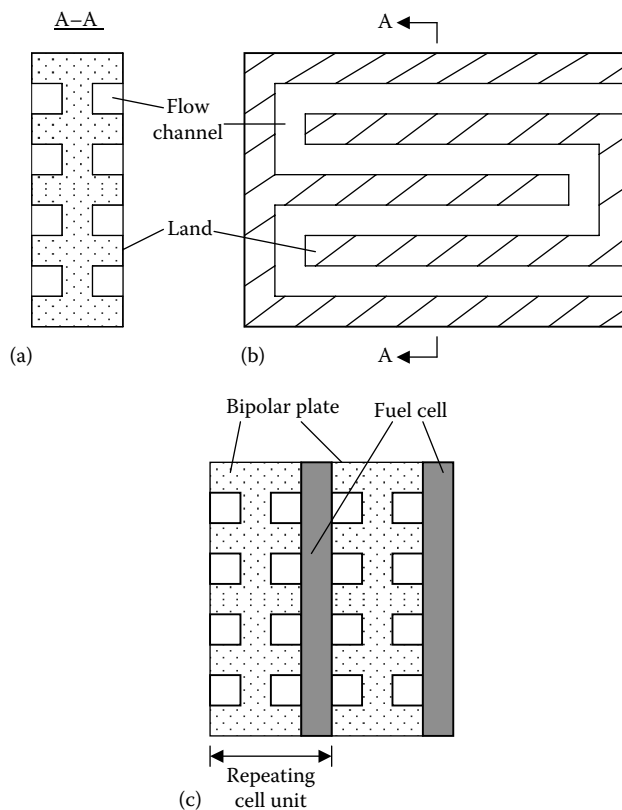

**FIGURE 53.14**

Series cell connection (stacking) configurations: (a) unipolar arrangement with the edge collection of the current generated in each cell and (b) bipolar arrangement with the end-plate collection of the current.

the reactant flow channel design. However, it forces the electrical current generated in each cell to be collected at the edge of the electrodes. Since electrode is very thin ( $<1$  mm), while the other electrode dimensions (in the direction of the current flow) are at least on the order of centimeters or larger, the ohmic resistance tends to be very large. Thus, edge collection of current, although used in early fuel cell stack designs, is generally avoided in recent fuel cell stack development, primarily due to the excessively large ohmic voltage losses.

The bipolar arrangement has the current flow normal to the electrode surface, instead of along the electrode surface as in the unipolar arrangement; thus, the current flow path is very short while the cross-sectional area available for the current flow is very large. The ohmic voltage loss for this case is very small in comparison, and bipolar design is favored in recent fuel cell stack technology. However, this end-plate collection of current results in the complex design for the reactant flow channels and complex organization for the reactant stream, and the bipolar plate has to fulfill several functions simultaneously in order to obtain a good overall stack performance. Bipolar plates serve as current collectors, for reactant delivery to the electrode surface, for cell reaction product removal (such as water), and for the integrity of the cell/stack. These functions for the bipolar plates may be contradictory to each other, and the optimal design for the bipolar plates represents one of the significant technical challenges for practical fuel cells.

A typical configuration of a bipolar plate is shown in Figure 53.15. The reactant flow follows the flow channels made on the bipolar plate, thus distributing the reactant over the

**FIGURE 53.15**

Typical configuration of a bipolar plate: (a) cross-sectional view, (b) face view, and (c) repeating cell unit in a stack.

electrode surface. On the other hand, the land between the adjacent flow channels serves as the passage for the current flow from one cell to the next. Therefore, a wide flow channel is beneficial for the reactant distribution over the electrode surface and for the reaction product removal, while a wide land is beneficial for the electron flow and for the mechanical integrity of the cells and the entire stack. Normally, the same cell unit as shown in [Figure 53.15c](#) is repeated to form a stack. The plate at the end of the stack has flow channels only on one side of its surfaces.

From the cell repeating unit in a stack, it is clear that the reactant concentration decreases along the flow direction following the flow channel design and into the electrode due to convectional and diffusional mass transfer. Thus, the concentration field is three dimensional, so is the electrical field due to the flow channels made on the bipolar plate surfaces, the nonuniform rate of electrochemical reactions in the catalyst layers, and the three-dimensional distribution of the reactant concentrations and the temperature. Therefore, an accurate prediction of the cell performance requires a three-dimensional analysis based on solving the conservation equations governing the transport phenomena of the reactant flow, species concentration, temperature, and electric fields, incorporating the in-cell electrochemical reaction processes, thus posing significant challenges to fuel cell designers.

---

### 53.7 Six Major Types of Fuel Cells

Fuel cell technology has been developed and improved dramatically in the past few years, and this has captured once again public as well as industry's attention concerning the prospect of fuel cells as practical power sources for terrestrial applications. At present, fuel cell technology is being routinely used in many specific areas, notably in space explorations, where fuel cell operates on pure hydrogen and oxygen with over 70% efficiency and drinkable water as the only by-product. There are now approximately over 200 fuel cell units for terrestrial applications operating in 15 countries; impressive technical progress has been achieved in terms of higher power density and better performance as well as reduced capital and maintenance and operation cost, and is driving the development of competitively priced fuel cell-based power generation systems with advanced features for terrestrial use, such as utility power plants and zero-emission vehicles. In light of decreasing fossil fuel reserves and increasing energy demands worldwide, fuel cell will probably become one of the major energy technologies with fiercest international competition in the twenty-first century.

The major terrestrial commercial applications of fuel cells are electric power generation in the utility industry and as a zero-emission powertrain in the transportation sector. For these practical applications, the efficiencies of fuel cells range somewhere between 40% and 65% based on the LHV of hydrogen. Typically, the cell electric potential is only about 1 V across a single cell, and it decreases due to various loss mechanisms under operational conditions. Thus, multiple cells are required to be connected together in electrical series in order to achieve a useful voltage for practical purposes, and these connected cells are often referred to as a fuel cell stack. A fuel cell system consists of one or multiple fuel cell stacks connected in series and/or parallel, and the necessary auxiliaries whose composition depends on the type of fuel cells and the kind of primary fuels used. The major accessories include thermal management (or cooling) subsystem, fuel supply, storage and processing subsystem, and oxidant (typically air) supply and conditioning subsystem.

**TABLE 53.2**

Operational Characteristics and Technological Status of Various Fuel Cells

Type of Fuel Cells	Operating Temperature (°C)	Power Density (mW/cm <sup>2</sup> ) (Present) Projected	Projected Rated Power Level (kW)	Fuel Efficiency (Chemical to Electrical)	Lifetime Projected (h)	Capital Cost Projected (U.S. \$ per kW)	Areas of Application
AFC	60–90	(100–200) >300	10–100	40–60	>10,000	>200	Space, mobile
PAFC	160–220	(200) 250	100–5,000	55	>40,000	3000	Dispersed and distributed power
PEMFC	50–80	(350) >600	0.01–1,000	45–60	>40,000	>200	Portable, mobile, space, stationary
MCFC	600–700	(100) >200	1,000–100,000	60–65	>40,000	1000	Distributed power generation
SOFC	800–1000	(240) 300	100–100,000	55–65	>40,000	1500	Baseload power generation
DMFC	90	(230) ?	0.001–100	34	>10,000	>200	Portable, mobile

*Note:* ? indicates that the projected value achievable in the near future is not available.

In this section, a summary of the state-of-the-art technology for the six major types of fuel cells is presented, including

1. Alkaline fuel cells (AFCs)
2. Polymer electrolyte membrane fuel cells (PEMFCs)
3. DMFCs
4. Phosphoric acid fuel cells (PAFCs)
5. MCFCs
6. SOFCs

Five of them are classified based on their electrolytes used, including the alkaline, phosphoric acid, PEM, molten carbonate, and solid oxide. DMFC is classified based on the fuel used for electricity generation. Table 53.2 provides a summary of the operational characteristics and application of the six major types of fuel cell.

### 53.7.1 Alkaline Fuel Cells

AFCs give the best performance among all the fuel cell types under the same or similar operating conditions when running on pure hydrogen and oxygen. Hence, they are among the first fuel cells to have been studied and taken into development for practical applications, and they are the first type of fuel cells to have reached successful routine applications, mainly in space programs such as space shuttle missions in the United States and similar space exploration endeavors in China and Europe, where pure hydrogen and

oxygen are used as reactants. Because of their success in space programs, AFCs are also the type of fuel cells on which probably the largest number of fuel cell development programs has begun in the world in an effort to bring them down to terrestrial applications, particularly in Europe. However, almost all the AFC development programs have come to an end. At present, the only few activities related to the AFC RD&D are in Europe.

The AFCs have the highest energy conversion efficiency among all types of fuel cells under the same operating conditions if pure hydrogen and pure oxygen are used as the reactants. That was one of the important reasons that AFCs were selected for the U.S. space shuttle missions. The AFCs used in the shuttle missions are operated at about 200°C for better performance (i.e., high energy conversion efficiency of over 70% and high power density that is critical for space applications), and the alkaline electrolyte is potassium hydroxide (KOH) solution immobilized in an asbestos matrix. As a result, the AFCs operate at high pressure in order to prevent the boiling and depletion of the liquid electrolyte. Consequently, these severe operating conditions of high temperature and high pressure dictate extremely strict requirement for cell component materials that must withstand the extreme corrosive oxidizing and reducing environment of the cathode and the anode. To meet these requirements, precious metals such as platinum, gold, and silver are used for the construction of the electrodes, although these precious metals are not necessary for the electrochemical reactions leading to electric power generation. Each shuttle flight contains 36 kW AFC power system. Its purchase price is about U.S. \$28.5 million, and it costs NASA additional \$12–\$19 million annually for operation and maintenance. Although the manufacturer claims about 2400 h of lifetime, NASA's experience indicates that the real lifetime is only about 1200 h. With sufficient technology development, 10,000 h are expected as the life potential (or upper limit) for the AFC system. This belief is based on the nature of the AFC systems and the data accumulated on both stacks and single cells.

The typical working temperature of AFC power systems aimed at commercial and terrestrial applications ranges from 20°C to 90°C, and the electrolyte is a KOH solution (30%–35%). There are four different cell types investigated:

1. Cell with a free liquid electrolyte between two porous electrodes
2. ELOFLUX cell with liquid KOH in the pore systems
3. Matrix cell where the electrolyte is fixed in the electrode matrix
4. The falling film cell

Many technical challenges have been encountered in the development of AFCs. The most important ones are as follows:

- *Preparation method of the electrodes:* The electrodes consist of porous material that is covered with a layer of catalyst. In general, it is very difficult to distribute the catalyst at the surface and to produce a defined pore system for the transport of the reactants.
- *Costs of the electrodes, stacks, and fuel cell systems:* The preparation of electrodes with noble metal catalysts is very expensive. In general, the electrodes are manufactured in small-scale production with high overhead costs.
- *Lifetime of the electrode/degradation:* The electrolyte is very corrosive, and the catalyst materials are sensitive to high polarization. Using nickel and silver as catalysts, in order to reduce the costs of the fuel cell, leads to a high degradation of these catalysts.

- *Diaphragm made of asbestos*: The diaphragm of low-temperature AFCs is made of asbestos. But this material is hazardous for health, and in some countries, its use is even banned. Therefore, new diaphragms should be developed, but it is difficult to find a material with a similar performance in alkaline electrolyte.
- *Carbon dioxide-contaminated fuel and oxidant streams (carbonation of electrolyte and electrodes)*: The electrolyte intolerance of carbon dioxide is the most important disadvantage of air-breathing AFCs with reformat gases from primary fossil fuels.

Other problems associated with the AFC power systems are the concerns for the safety and reliability of AFC power systems. For example, the liquid KOH electrolyte contained in an asbestos matrix can withstand only a 5 psi limit of pressure differential between the anode and cathode reactant gases. This dictates the need for sophisticated pinpoint pressure control during the operation including transient, start-up, and shutdown processes. It is also a safety issue because of its greater likelihood of the reactants mixing in the AFC system with the possibility of a serious fire breaking out. In terms of general safety considerations, the use of the corrosive potassium hydroxide electrolyte in the AFCs represents the need for hazardous material handling, and the handling of asbestos matrix poses potential hazard to one's health. With flowing reactant gases, the potential for the gradual loss of the liquid electrolyte, drying of the electrolyte matrix, reactant crossover of the matrix, and ensuing life-limiting reactant mixing (or actual AFC stack failure due to fire) is very real in the AFC system.

The major technical challenge is that alkaline electrolytes, like potassium or sodium hydroxide, do not reject carbon dioxide, even the 300–350 ppm of carbon dioxide in the atmospheric air is not tolerated (carbon dioxide concentration in both cathode and anode gases must be <10–100 ppm by volume), while terrestrial applications almost invariably require the use of atmospheric air as oxidant due to technical and economic considerations. For municipal electric applications, hydrocarbon fuels, especially natural gas, are expected to be the primary fuel, and their reformation into hydrogen-rich gases invariably contain a significant amount of carbon dioxide, for example, steam-reforming of the natural gas results in the reformat gas consisting approximately of 80% hydrogen, 20% carbon dioxide, and a trace amount of other components such as carbon monoxide. Carbonaceous products of aging and corrosion shorten AFC life; they degrade the alkaline electrolyte. Whether originating as impurities in the gaseous reactants or from some fuel cell materials, oxides of carbon will chemically react with the alkaline electrolyte and produce irreversible decay that will decrease performance and shorten life. Consequently, AFCs are currently restricted to specialized applications where pure hydrogen and oxygen are utilized. The revival of this technology will depend almost completely on the successful curing of *CO<sub>2</sub> syndrome*—the efficient and economic scrubbing of carbon dioxide, even though claims have been made of successful resolution of carbon dioxide poisoning in the AFCs. This is especially true for utility applications, although some optimistic estimate indicates that the AFC stack costs are similar to all other low-temperature fuel cell systems, and the production costs for the AFC systems seem to be the lowest. A price of about U.S. \$400–\$500 per kW has been quoted by using today's technologies and today's knowledge in large-scale production. However, small-scale commercial production cost is estimated to be 5–10 times higher.

### 53.7.2 Polymer Electrolyte Membrane Fuel Cells

#### 53.7.2.1 Introduction

The PEMFC is also called solid polymer (electrolyte) fuel cell. It is perhaps the most elegant of all fuel cell systems in terms of design and mode of operation. It was the first type of fuel

cell that was put into practical application (in Gemini space missions from 1962 to 1966). It consists of a solid polymeric membrane acting as the electrolyte. The solid membrane is an excellent proton conductor, sandwiched between two platinum-catalyzed porous carbon electrodes. It has fast start capability and yields the highest output power density among all types of the fuel cells. Because of the solid membrane as the electrolyte, there is no corrosive fluid spillage hazard, and there is lower sensitivity to orientation. It has no volatile electrolyte and has minimal corrosion concerns. It has truly zero pollutant emissions with potable liquid product water when hydrogen is used as fuel. As a result, the PEMFC is particularly suited for vehicular power application, although it is also being considered for stationary power application, albeit to a lesser degree.

The proton-conducting polymer membrane belongs to a class of materials called ionomers or polyelectrolytes, which contain functional groups that will dissociate in the presence of water. The dissociation produces ions fixed to the polymer and simple counterions that can freely exchange with ions of the same sign from the solution. The current available polyelectrolytes have cation as the counterion. In the case of hydrogen, the cation is proton. Therefore, the membrane must be fully hydrated in order to have adequate ion conductivity. As a result, the fuel cell must be operated under conditions where the product water does not evaporate faster than it is produced, and the reactant gases, both hydrogen and oxygen, need to be humidified. Therefore, water and thermal management in the membrane become critical for efficient cell performance, are fairly complex, and require dynamic control to match the varying operating conditions of the fuel cell. Because of the limitation imposed by the membrane and problems with water balance, the operating temperature of PEMFCs is usually  $<120^{\circ}\text{C}$ , typically at  $80^{\circ}\text{C}$ . This rather low operating temperature requires the use of noble metals as catalysts in both the anode and cathode side with generally higher catalyst loadings than those used in PAFCs.

Currently, the polymer electrolyte used is made of perfluorinated sulfonic acid membrane, or it is essentially acid, though in solid polymeric form. Hence, PEMFCs are essentially acid electrolyte fuel cells, with its operational principle essentially the same as PAFCs. As a result, most of PEMFC design, material selection, component fabrication, etc., are similar to those of PAFCs. The only difference is the humidification of reactant gases dictated by the membrane performance. Reactant humidification is often achieved by a number of techniques, for example, by passing gas stream through a water column, by using in-stack humidification section of cell and membrane arrangement, and by spraying water into the reactant streams. In the early stage of the PEMFC development, the membranes were based on polystyrene, but since 1968, a Teflon-based product, named Nafion by DuPont, is used. This offers high stability, high oxygen solubility, and high mechanical strength.

### 53.7.2.2 Basic Operating Principle

The PEM is essentially acid electrolyte; PEMFC requires hydrogen gas as the fuel and oxygen (typically air) as the oxidant. The half-cell reactions are

and the overall cell reaction is

The current PEMFCs use perfluorinated sulfonic acid membrane (almost exclusively Nafion from DuPont) as the proton-conducting electrolyte; carbon paper or cloth as the anode and cathode backing layers; and platinum or its alloys, either pure or supported on carbon black, as the catalyst. The bipolar plate with the reactant gas flow fields is often made of graphite plate. The stoichiometry is around 1.1–1.2 for the fuel and 2 for the oxidant (oxygen). The PEMFCs usually operate at about 80°C and 1–8 atm pressure. The pressures, in general, are maintained equal on either side of the membrane. Operation at high pressure is necessary to attain high power densities, particularly when air is chosen as the cathodic reactant.

To prevent the membrane dryout leading to local hot spot (and crack) formation, performance degradation, and lifetime reduction, both fuel and oxidant streams are fully humidified, and the operating temperature is limited by the saturation temperature of water corresponding to the operating pressure. The product liquid water formed at the cathode does not dissolve in the electrolyte membrane and is usually removed from the cell by the excessive oxidant gas stream. The accumulation of liquid water in the cathode backing layer blocks the oxygen transfer to the catalytic sites, thus resulting in the phenomenon called *water-flooding* causing performance reduction. Local hot and cold spots will cause the evaporation and condensation of water. Thus, an integrated approach to thermal and water management is critical to PEMFCs' operation and performance, and a proper design must be implemented.

#### 53.7.2.3 Acceptable Contamination Levels

As an acid electrolyte fuel cell operating at low temperature, the PEMFC is primarily vulnerable to carbon monoxide poisoning. Even a trace amount of CO drastically reduces the performance levels, although CO poisoning effect is reversible and does not cause permanent damages to the PEMFC system. Further, the performance reduction due to CO poisoning takes a long time (on the order of 2 h) to reach steady state. This transient effect may have profound implication for transportation applications. Therefore, the PEMFC requires the use of a fuel virtually free of CO (must be less than a few ppm). Also high-quality water free of metal ions should be used for the cell cooling and reactant humidification to avoid the contamination of the membrane electrolyte. This requirement has a severe implication on the materials that can be used for cell components. On the other hand, carbon dioxide does not affect PEMFC operation and performance except through the effect of reactant dilution (the Nernst loss).

#### 53.7.2.4 Major Technological Problems

For practical applications, PEMFC performance in terms of energy efficiency, power density (both size and weight), and capital cost must be further improved. This can be accomplished by systematic research in the following:

1. *New oxygen reduction electrocatalysts*: This includes the reduction of precious metal platinum and its alloys loading from 4 to 0.4 mg/cm<sup>2</sup> or lower without affecting the long-term performance and the lifetime, and the development of CO-tolerant catalysts.
2. New types of polymer electrolyte with higher oxygen solubility, thermal stability, long life, and low cost. A self-humidified membrane or a polymer without the need of humidification will be ideal for PEMFC operation and performance enhancement with significant simplification of system complexities and reduction of the cost.

3. Profound changes in oxygen (air) diffusion electrode structure to minimize all transport-related losses. The minimization of all transport losses is the most promising direction for PEMFC performance improvement.
4. Optimal thermal and water management throughout the individual cells and the whole stack to avoid local hot and dry spot formation and to avoid *water-flooding* of the electrode.

In addition to the earlier issues, the development of low-cost lightweight materials for the construction of reactant gas flow fields and bipolar plates is one of the major barriers to PEMFCs' large-scale commercialization. The successful solution of this problem will further increase the output power density. Additional issues include optimal design of flow fields with the operating conditions, and an appropriate selection of materials and fabrication techniques. It has been reported that over 20% improvement in the performance of PEMFC stacks can be obtained just by appropriate design of flow channels alone. The current leading technologies for bipolar plate design include injection-molded carbon-polymer composites, injection-molded and carbonized amorphous carbon, assembled three-piece metallic, and stamped unitized metallic.

#### 53.7.2.5 Technological Status

PEMFCs have achieved a high power density of over 1 kW/kg and 0.7 kW/L, perhaps the highest among all types of the fuel cells currently under development. It is also projected that the power density may be further improved, up to 2–3 kW/L, with unitized metallic (stainless steel) bipolar plates. The capital cost has been estimated to vary from the most optimistic of \$1,500 per kW to the most pessimistic of \$50,000 per kW at the current technology and is projected to reach approximately \$200–\$300 per kW, assuming a 10–20-fold reduction in the membrane and catalyst cost and also considering mass production. It is expected that PEMFC technology is about 5–10 years from commercialization, and pre-commercial demonstration for buses and passenger vehicles are under way with increasing intensity, and the first demonstration for residential combined heat and power application just began at the end of 1999. However, application of PEMFCs in powering portable and mobile electronics such as laptops has already been started.

#### 53.7.2.6 Applications

PEMFCs have a high power density, a variable power output, and a short start-up time due to low operating temperature; the solid polymer electrolyte is virtually corrosion free and can withstand a large pressure differential (as high as 750 psi reported by NASA) between the anode and cathode reactant gas streams. Hence, PEMFCs are suitable for use in the transportation sector. Currently, they are considered the best choice for zero-emission vehicles as far as present-day available fuel cell technologies are concerned. Their high power density and small size make them primary candidates for light-duty vehicles, though they are also used for heavy-duty vehicles. For high-profile automobile application, pure hydrogen and air are used as reactants at the present. However, conventional gasoline and diesel engines are extremely cheap, estimated to cost about \$30–\$50 per kW. Therefore, the cost of PEMFC systems must be lowered at least by two to three orders of magnitude in order to be competitive with the conventional heat engines in the transportation arena.

For electricity generation from the hydrocarbon fuels, a reformer with carbon monoxide and sulfur cleaning is necessary. It is estimated that the cost of the reforming system is about the same as the fuel cell stack itself, which is also the same as the cost of other ancillary systems. Apart from the high cost, the optimal chemical to electric conversion efficiency is around 40%–45%, and the low operating temperature makes the utilization of the waste heat difficult, if at all possible, for the reforming of hydrocarbon fuels, cogeneration of heat, and combined cycles. On the other hand, conventional thermal power plants with combined gas and steam turbines have energy efficiency approaching 60% with a very low capital cost of U.S. \$1000 per kW. Therefore, the best possible application of the PEMFC systems interesting to utility industry is the use of PEMFCs in the size of tens to hundreds of kW range for remote region and also a possibility for residential combined heat and power application.

In addition, NASA is conducting a feasibility study of using the PEMFC power systems for its space programs (mainly space shuttle missions) in place of its current three 12 kW AFC power modules. As discussed in Section 53.7.1, NASA is motivated by the extremely high cost, low lifetime, and maintenance difficulty associated with its current AFC systems. Currently, NASA's feasibility study is in its second phase by using parabolic flight tests in airplanes to simulate low-gravity environment. If all goes well, NASA will conduct real-time tests in shuttles in a couple of years.

### 53.7.3 Direct Methanol Fuel Cells

#### 53.7.3.1 Introduction

All the fuel cells reviewed earlier for commercial applications require the use of gaseous hydrogen directly or liquid/solid hydrocarbon fuels, for example, methanol, reformed to hydrogen as the fuel. Pure oxygen or oxygen in air is used as the oxidant. Hence, these fuel cells are often referred to as hydrogen–oxygen or hydrogen–air types of fuel cells. The use of gaseous hydrogen as a fuel presents a number of practical problems, such as storage system weight and volume as well as handling and safety issues especially for consumer and transportation applications. Although liquid hydrogen has the highest energy density, the liquefaction of hydrogen needs roughly one-third of the specific energy, and the thermal insulation required increases the volume of the reservoir significantly. The use of metal hydrides decreases the specific energy density, and the weight of the reservoir becomes excessive. The size and the weight of a power system are extremely important for transportation applications, as they directly affect the fuel economy and vehicle capacity, although they are less critical for stationary applications. The low volumetric energy density of hydrogen also limits the distance between vehicle refueling.

Methanol as a fuel offers ease of handling and storage, and potential infrastructure capability for distribution. Methanol also has a higher theoretical energy density than hydrogen (5 kW h/L compared with 2.6 kW h/L for liquid hydrogen). Easy refueling is another advantage for methanol. However, in the conventional hydrogen–air or hydrogen–oxygen fuel cells, a reformer is needed that adds complexity and cost as well as production of undesirable pollutants such as carbon monoxide. The addition of a reformer also increases response time.

Therefore, direct oxidation of methanol is an attractive alternative in view of its simplicity from a system point of view. The DMFCs utilizing PEM have the capability of efficient heat removal and thermal control through the circulating liquid, and elimination of humidification required to avoid membrane dryout. These two characteristics have to be accounted

for in the direct and indirect hydrogen systems, which impact their volume and weight, consequently the output power density.

### 53.7.3.2 Basic Operating Principle

The DMFC allows the direct use of an aqueous, low concentration (3%) liquid methanol solution as the fuel. Air is the oxidant. The methanol and water react directly in the anode chamber of the fuel cell to produce carbon dioxide and protons that permeate the PEM and react with the oxygen at the cathode. The half-cell reactions are as follows:

and the net cell reaction is

Because the PEM (typically Nafion 117) is used as the electrolyte, the cell operating temperature must be less than the water boiling temperature to prevent the dryout of the membrane. Typically, the operating temperature is around 90°C, and the operating pressure ranges from one to several atmospheres.

### 53.7.3.3 Acceptable Contamination Levels

The system is extremely sensitive to carbon monoxide (CO) and hydrogen sulfide (H<sub>2</sub>S). Carbon monoxide may exist as one of the reaction intermediaries and can poison the catalyst used. There are arguments whether CO is present in the anode during the reaction. Sulfur may be present if methanol is made of petroleum oils and needs to be removed.

### 53.7.3.4 Major Technological Problems

The PEM used in the DMFCs is Nafion 117, which is the same as employed in the PEMFCs. Although it works well in both types of cells, it is expensive with only one supplier. Since the electrolyte in DMFCs is essentially acid, expensive precious metals (typically platinum or its alloys) are used as the catalyst. However, the most serious problem is the so-called methanol crossover. This phenomenon is caused by the electro-osmotic effect. When the protons migrate through the electrolyte membrane, a number of water molecules are dragged along with each proton, and because methanol is dissolved in liquid water on the anode side, methanol is dragged through the membrane electrolyte to reach the cathode side together with the protons and water. Fortunately, the methanol at the cathode is oxidized into carbon dioxide and water at the cathode catalyst sites, producing no safety hazards. But the methanol oxidation in cathode does not produce useful electric energy. The development of a new membrane with low methanol crossover is a key to the success of DMFCs.

Such a low methanol crossover membrane has a number of advantages. First, it reduces the methanol crossover, enhancing fuel utilization, hence energy efficiency. Second, it reduces the amount of water produced at the cathode, leading to a lower activation and concentration

polarization, thus allowing higher cell voltage at the same operating current. Third, it allows higher methanol concentration in the fuel stream, resulting in better performance.

#### 53.7.3.5 *Technological Status*

DMFCs are the least developed among all the fuel cell technologies. Though methanol itself has simpler storage requirements than hydrogen and is simpler to make and transport, its electrochemical activity is much slower than that of hydrogen, that is, its oxidation rate is about four orders of magnitude smaller than that of hydrogen. Also, the conversion takes place at low temperature (about 80°C–90°C), and the contaminant problem is a serious issue.

The state-of-the-art performance is an energy conversion efficiency of 34% (from methanol to electricity) at 90°C using 20 psig air, at a cell voltage of 0.5 V (corresponding to a voltage efficiency of 42%) together with the methanol crossover accounting for 20% of the current produced (equivalent to a fuel efficiency of 80%). This 20% methanol crossover occurs when the fuel stream used is an aqueous solution containing only 3% methanol. It has been projected that with the better membrane under development and improvement of membrane electrode assembly, a cell voltage of 0.6 V can be achieved with only 5% methanol crossover. This is equivalent to 50% voltage efficiency and 95% fuel efficiency, resulting in an overall stack efficiency of 47% (from methanol to electricity). The DMFC system efficiency will be lower due to running the necessary auxiliary systems.

The DMFC power system is underdeveloped, and until now, nobody could demonstrate any feasibility for commercialization. It remains at a scale of small demonstration in the sub-kW range. As such, no system cost estimate is available or has ever been carried out. However, the current DMFCs basically use the same cell components, materials, construction, and fabrication techniques as the PEMFCs; therefore, it is expected that the system and component costs will be similar to that of the PEMFCs. It is said that one company in the world has recently been formed to explore the potential of the DMFC systems and to develop DMFC for transportation applications. However, the DMFC system is at least 10 years away from any realistic practical applications, judging from the progress of other types of fuel cells in the past.

#### 53.7.3.6 *Applications*

DMFCs offer a potential for high power density and cold-start capabilities, a convenience for onboard fuel storage and compatibility with existing refueling infrastructure. Therefore, DMFCs are the most attractive for applications where storage or generation of hydrogen causes significant effort and has a negative impact on the volume and weight of the system. As a result, DMFCs have a great potential for transportation applications ranging from automobiles, trains and ships, etc. For utility applications, small DMFC units have potential for use in residential and office buildings, hotels and hospitals, etc., for the combined electricity and heat supply (cogeneration). Since methanol can be made from agricultural products, the use of methanol is also compatible with renewable energy sources to allow for sustainable development.

### 53.7.4 **Phosphoric Acid Fuel Cells**

The PAFC is the most advanced type of fuel cells and is considered to be *technically mature* and ready for commercialization after nearly 30 years of RD&D and over half-a-billion-dollar expenditure. Therefore, the PAFC has been referred to as the first-generation fuel cell

technology. Unlike the AFC systems that were primarily developed for space applications, the PAFC was targeted initially for terrestrial applications with the carbon dioxide-containing air as the oxidant gas and hydrocarbon-reformed gas as the fuel for electrochemical reactions and electric power generation.

The basic components of a PAFC are the electrodes consisting of finely dispersed platinum catalyst or carbon paper, SiC matrix holding the phosphoric acid, and a bipolar graphite plate with flow channels for fuel and oxidant. The operating temperature ranges between 160°C and 220°C, and it can use either hydrogen or hydrogen produced from hydrocarbons (typically natural gas) or alcohols as the anodic reactant. In the case of hydrogen produced from a reformer with air as the anodic reactant, a temperature of 200°C and a pressure as high as 8 atm are required for better performance. PAFCs are advantageous from a thermal management point of view. The rejection of waste heat and product water is very efficient in this system, and the waste heat at about 200°C can be used efficiently for the endothermic steam-reforming reaction. The waste heat can also be used for space heating and hot water supply.

However, the PAFC cannot tolerate the presence of carbon monoxide and H<sub>2</sub>S, which are commonly present in the reformed fuels. These contaminants poison the catalyst and decrease its electrochemical catalytic activity. A major challenge for using natural gas reformed fuel, therefore, lies in the removal of carbon monoxide to a level of <200–300 ppm. Carbon monoxide tolerance is better at the operating temperature of above 180°C. However, removal of sulfur is still essential. Further, the PAFC has a lower performance, primarily due to the slow oxygen reaction rate at the cathode. Therefore, PAFC is typically operated at higher temperature (near 200°C) for better electrochemical reactivity and for smaller internal resistance, which is mainly due to the phosphoric acid electrolyte. As a result, PAFC exhibits the problems of both high- and low-temperature fuel cells, but possibly none of the advantages of either option.

The PAFC system is the most advanced fuel cell system for terrestrial applications. Its major use is in on-site integrated energy systems to provide electrical power in apartments, shopping centers, office buildings, hotels and hospitals, etc. These fuel cells are commercially available in the range from 24 V, 250 W portable units to 200 kW on-site generators. PAFC systems of 0.5–1.0 MW are being developed for use in stationary power plants of 1–11 MW capacity. The power density of PAFC system is about 200 mW/cm<sup>2</sup>, and the power density for 36 kW brassboard PAFC fuel cell stack has been reported to be 0.12 kW/kg and 0.16 kW/L. The most advanced PAFC system is the PC-25 from the International Fuel Cells in Connecticut, United States. It costs about U.S. \$3000 per kW (the best technology possible for the PAFCs), while the conventional thermal power generation system costs only about U.S. \$1000 per kW. Thus, it is believed that the PAFC is not commercially viable at present, even though U.S. DOE and DOD have been subsidizing half of the cost (\$1500 per kW) in order to gain operational and maintenance experience for practical fuel cell systems. Although Japan seems determined to push ahead for the fuel cell technology, interest in the PAFC systems is wading in the United States and Europe.

### 53.7.5 Molten Carbonate Fuel Cells

#### 53.7.5.1 Introduction

The MCFC is often referred to as the second-generation fuel cell because its commercialization is normally expected after the PAFC. It is believed that the development and technical maturity of the MCFC is about 5–7 years behind the PAFC. At present, the

MCFC has reached the early demonstration stage of pre-commercial stacks, marking the transition from fundamental and applied R&D toward product development. MCFCs are being targeted to operate on coal-derived fuel gases or natural gas. This contrasts with the PAFCs, as discussed earlier, which prefer natural gas as primary fuel.

The MCFC operates at higher temperature than all the fuel cells described so far. The operating temperature of the MCFC is generally around 600°C–700°C, typically 650°C. Such high temperature produces high-grade waste heat, which is suitable for fuel processing, cogeneration, or combined cycle operation, leading to higher electric efficiency. It also yields the possibility of utilizing carbonaceous fuels (especially natural gas) directly, through internal reforming to produce the fuel (hydrogen) ultimately used by the fuel cell electrochemical reactions. This results in simpler MCFC systems (i.e., without external reforming or fuel processing subsystem), less parasitic load, and less cooling power requirements, hence higher overall system efficiency as well. The high operating temperature reduces voltage losses due to reduced activation, ohmic, and mass transfer polarization. The activation polarization is reduced to such an extent that it does not require expensive catalysts as low-temperature fuel cells do, such as PAFCs and PEMFCs. It also offers great flexibility in the use of available fuels, say, through in situ reforming of fuels. It has been estimated that the MCFC can achieve an energy conversion efficiency of 52%–60% (from chemical energy to electrical energy) with internal reforming and natural gas as the primary fuel. Some studies have indicated that the MCFC efficiency of methane to electricity conversion is the highest attainable by any fuel cell or other single-pass/simple cycle generation scheme.

### 53.7.5.2 Basic Operating Principle

An MCFC consists of two porous gas-diffusion electrodes (anode and cathode) and a carbonate electrolyte in liquid form. The electrochemical reaction occurring at the anode and the cathode is

and the net cell reaction is

Besides the hydrogen oxidation reaction at the anode, other fuel gases such as carbon monoxide, methane, and higher hydrocarbons are also oxidized by conversion to hydrogen. Although direct electrochemical oxidation of carbon monoxide is possible, it occurs very slowly compared to that of hydrogen. Therefore, the oxidation of carbon monoxide is mainly via the water–gas shift reaction

which, at the operation temperature of the MCFC, equilibrates very rapidly at using catalysts such as nickel. Therefore, carbon monoxide becomes a fuel, instead of a contaminant

as in the previously described low-temperature fuel cells. Direct electrochemical reaction of methane appears to be negligible. Hence, methane and other hydrocarbons must be steam-reformed, which can be done either in a separate reformer (external reforming) or in the MCFC itself (the so-called internal reforming).

As a result, water and carbon dioxide are important components of the feed gases to the MCFCs. Water, produced by the main anode reaction, helps to shift the equilibrium reactions to produce more hydrogen for the anodic electrochemical reaction. Water must also be present in the feed gas, especially in low-Btu (i.e., high CO content) fuel mixtures, to avoid carbon deposition in the fuel gas flow channels supplying the cell, or even inside the cell itself. Carbon dioxide, from the fuel exhaust gas, is usually recycled to the cathode as it is required for the reduction of oxygen.

The MCFCs use a molten alkali carbonate mixture as the electrolyte, which is immobilized in a porous lithium aluminate matrix. The conducting species is carbonate ions. Lithiated nickel oxide is the material of the current choice for the cathode, and nickel, cobalt, and copper are currently used as anode materials, often in the form of powdered alloys and composites with oxides. As a porous metal structure, it is subject to sintering and creeping under the compressive force necessary for stack operation. Additives such as chromium or aluminum form dispersed oxides and thereby increase the long-term stability of the anode with respect to sintering and creeping. MCFCs normally have about 75%–80% fuel (hydrogen) utilization.

### **53.7.5.3 Acceptable Contamination Levels**

MCFCs do not suffer from carbon monoxide poisoning, and in fact, they can utilize carbon monoxide in the anode gas as the fuel. However, they are extremely sensitive to the presence of sulfur (<1 ppm) in the reformed fuel (as hydrogen sulfide,  $H_2S$ ) and oxidant gas stream ( $SO_2$  in the recycled anode exhaust). The presence of HCl, HF, HBr, etc., causes corrosion, while trace metals can spoil the electrodes. The presence of particulates of coal/fine ash in the reformed fuel can clog the gas passages.

### **53.7.5.4 Major Technological Problems**

The main research efforts for the MCFCs are focused on increasing the lifetime and endurance, and reducing the long-term performance decay. The main determining factors for the MCFC are electrolyte loss, cathode dissolution, electrode creepage and sintering, separator plate corrosion, and catalyst poisoning for internal reforming.

Electrolyte loss results in increased ohmic resistance and activation polarization, and it is the most important and continuously active factor in causing the long-term performance degradation. It is primarily a result of electrolyte consumption by the corrosion/dissolution processes of cell components, electric potential-driven electrolyte migration, and electrolyte vaporization. Electrolyte evaporation (usually  $Li_2CO_3$  and/or  $K_2CO_3$ ) occurs either directly as carbonate or indirectly as hydroxide.

The cathode consists of NiO, which slowly dissolves in the electrolyte during operation. It is then transported toward the anode and precipitates in the electrolyte matrix as Ni. These processes lead to a gradual degradation of cathode performance and the shorting of the electrolyte matrix. The time at which shorting occurs depends not only, via NiO solubility, on the  $CO_2$  partial pressure and the cell temperature, but also on the matrix structure, that is, on the porosity, pore size, and in particular, thickness of the matrix. Experience indicates that this cell-shortening mechanism tends

to limit stack life to about 25,000 h under the atmospheric reference gas conditions and much shorter for real operating conditions.

Electrode, especially anode, creepage and sintering (i.e., a coarsening and compression of electrode particles) result in increased ohmic resistance and electrode polarization. NiO cathodes have quite satisfactory sinter and creepage resistance. Creep resistance of electrodes has important effect on maintaining low contact resistance of the cells and stacks. The corrosion of the separator plate depends on many factors, such as the substrate, possible protective layers, composition of the electrolyte, local potential and gas composition, and the oxidizing and reducing atmospheres at the cathode and anode, respectively. Poisoning of the reforming catalyst occurs for direct internal reforming MCFCs. It is caused by the evaporation of electrolyte from the cell components and condensation on the catalyst, which is the coldest spot in the cell, and by liquid creep within the cell.

#### **53.7.5.5 Technological Status**

MCFC technology is in the first demonstration phase and under the product development with full-scale systems at the 250 kW to 2 MW range. The short-term goal is to reach a lifetime of 25,000 h, and the ultimate target is 40,000 h. It is estimated that the capital cost is about U.S. \$1000–\$1600 per kW for the MCFC power systems. The cost breakdown is, at full-scale production levels, about one-third for the stack and two-thirds for the balance of the plant. It is also generally accepted that the cost of raw materials will constitute about 80% of total stack costs. Although substantial development efforts supported by fundamental research are still needed, the available knowledge and number of alternatives will probably make it possible to produce pre-commercial units in the earlier part of the coming decade at a capital cost of U.S. \$2000–\$4000 per kW. Pre-competitive commercial units may be expected some years later by which time further cost reduction to full competitiveness will be guided by extensive operating experience and increased volume production.

#### **53.7.5.6 Applications**

The MCFC is being developed for their potential as baseload utility generators. However, their best application is in distributed power generation and cogeneration (i.e., for capacities <20 MW in size), and in this size range, MCFCs are 50%–100% more efficient than turbines—the conventional power generator. Other applications have been foreseen, such as pipeline compressor stations, commercial buildings, and industrial sites in the near term and repowering applications in the longer term. Due to its high operation temperature, it has only very limited potential for transportation applications. This is because of its relatively low power density and long start-up times. However, it may be suitable as a powertrain for large surface ships and trains.

### **53.7.6 Solid Oxide Fuel Cells**

#### **53.7.6.1 Introduction**

SOFCS have emerged as a serious alternative high-temperature fuel cell, and they have been often referred to as the third-generation fuel cell technology because their commercialization is expected after the PAFCs (the first generation) and MCFCs (the second generation).

SOFC is an all-solid-state power system, including the electrolyte, and it is operated at high temperature of around 1000°C for adequate ionic and electronic conductivity of

various cell components. The all solid-state cell composition makes the SOFC system simpler in concept, design, and construction; two-phase (gas–solid) contact for the reaction zone reduces corrosion and eliminates all the problems associated with the liquid electrolyte management. The high-temperature operation results in fast electrochemical kinetics (i.e., low activation polarization) and no need for noble metal catalysts. The fuel may be gaseous hydrogen,  $\text{H}_2/\text{CO}$  mixture, or hydrocarbons because the high-temperature operation makes the internal in situ reforming of hydrocarbons with water vapor possible. It is specially noticed that CO is no longer a contaminant; rather, it becomes a fuel in SOFCs. Even with external reforming, the SOFC fuel feedstock stream does not require the extensive steam reforming with shift conversion as it does for the low-temperature fuel cell systems. More important, the SOFC provides high-quality waste heat that can be utilized for cogeneration applications or combined cycle operation for additional electric power generation. The SOFC operating condition is also compatible with the coal gasification process, which makes the SOFC systems highly efficient when using coal as the primary fuel. It has been estimated that the chemical to electrical energy conversion efficiency is 50%–60%, even though some estimates go as high as 70%–80%. Also, nitrogen oxides are not produced, and the amount of carbon dioxide released per kW h is around 50% less than for power sources based on combustion because of the high efficiency.

### 53.7.6.2 Basic Operating Principle

As mentioned earlier, both hydrogen and carbon monoxide can be directly oxidized in the SOFCs. Hence, if hydrogen or hydrogen-rich gas mixture is used as fuel, and oxygen (or air) is used as oxidant, the half-cell reaction becomes

and the overall cell reaction becomes

However, if carbon monoxide is provided to the anode instead of hydrogen, the anode reaction becomes

With the cathode reaction remaining the same, the cell reaction becomes

If the fuel stream contains both hydrogen and carbon monoxide as is the case for hydrocarbon reformed gas mixture, especially from the gasification of coal, the oxidation of hydrogen and carbon monoxide occurs simultaneously at the anode, and the combined anode reaction becomes

Consequently, the corresponding cathode and overall cell reactions become

The solid electrolyte in SOFCs is usually yttria-stabilized zirconia (YSZ); thus, a high-operating temperature of around 1000°C is required to ensure adequate ionic conductivity and low ohmic resistance. This is especially important because the cell open-circuit voltage is low, compared with low-temperature fuel cells, typically around 0.9–1 V under the typical working conditions of the SOFCs. The high-temperature operation of the SOFCs makes the activation polarization very small, resulting in the design operation in the range dominated by the ohmic polarization. The conventional material for the anode is nickel–YSZ–cermet, and cathode is usually made of lanthanum–strontium–manganite. Metallic current collector plates of a high-temperature corrosion-resistant chromium-based alloy are typically used.

### 53.7.6.3 Acceptable Contamination Levels

Because of high temperature, the SOFCs can better tolerate impurities in the incoming fuel stream. They can operate equally well on dry or humidified hydrogen or carbon monoxide fuel or on mixtures of them. But hydrogen sulfide ( $\text{H}_2\text{S}$ ), hydrogen chloride ( $\text{HCl}$ ), and ammonia ( $\text{NH}_3$ ) are impurities typically found in coal-gasified products, and each of these substances is potentially harmful to the performance of SOFCs. The main poisoning factor for SOFCs is  $\text{H}_2\text{S}$ . Though the sulfur tolerance level is approximately two orders of magnitude greater than other fuel cells, the level is below 80 ppm. However, studies have shown that the effect of hydrogen sulfide ( $\text{H}_2\text{S}$ ) is reversible, meaning that the cell performance will recover if hydrogen sulfide is removed from the fuel stream or clean fuel is provided after the contaminant poison has occurred.

### 53.7.6.4 Major Technological Problems

The high-temperature operation of the SOFCs places stringent requirements on materials used for cell construction, and appropriate materials for cell components are very scarce. Therefore, the key technical challenges are the development of suitable materials and the fabrication techniques. Of the material requirements, the most important consideration is the matching of the thermal expansion coefficients of electrode materials with that of the electrolyte to prevent cracking or delamination of SOFC components either during high-temperature operation or heating/cooling cycles. One of the remedies for the thermal expansion mismatch is to increase the mechanical toughness of the cell materials by developing either new materials or doping the existing materials with  $\text{SrO}$  and  $\text{CaO}$ .

The electrode voltage losses are reduced when the electrode material possesses both ionic and electronic conductivities (the so-called mixed conduction), for which the electrochemical reactions occur throughout the entire surface of the electrode rather than only at the three-phase interface of, for example, the cathode, the air (gas phase), and the electrolyte. Therefore, it is important for performance enhancement to develop mixed-conduction materials for both the cathode and the anode that have good thermal expansion match with the electrolyte used and good electrical conductivity to reduce the ohmic polarization, which dominates the SOFC voltage losses.

Another focus of the current development is the intermediate-temperature SOFCs operating at around 800°C for better matching with the bottoming turbine cycles and lessening requirements for the cell component materials. Again, appropriate materials with adequate electrical conductivity are the key areas of the development effort, and thermal expansion matching among the cell components is still necessary.

#### **53.7.6.5 Technological Status**

There are three major configurations for SOFCs: the tubular, flat plate, and monolithic. Even though the SOFC technology is in the developmental stage, the tubular design has gone through development at Westinghouse Electric Corporation since the late 1950s and is now being demonstrated at user sites in a complete operating fuel cell power unit of nominal 25 kW (40 kW maximum) capacity. The flat plate and the monolithic designs are at a much earlier development status typified by subscale, single cell, and short stack development (up to 40 cells). The present estimated capital cost is U.S. \$1500 per kW, but is expected to be reduced with improvements in technology. Therefore, the SOFCs may become very competitive with the existing technology for electric power generation. However, it is believed that the SOFC technology is at least 5–10 years away from the commercialization.

#### **53.7.6.6 Applications**

SOFCs are very attractive in electrical utility and industrial applications. The high operating temperature allows them to use hydrogen and carbon monoxide from natural gas steam reformers and coal gasification plants, a major advantage as far as fuel selection is concerned. SOFCs are being developed for large (>10 MW, especially 100–300 MW) baseload stationary power plants with coal as the primary fuel. This is one of the most lucrative markets for this type of fuel cells.

A promising field for SOFCs is the decentralized power supply in the MW range, where the SOFC gains interest due to its capability to convert natural gas without external reforming. In the range of one to some tenths of a MW, the predicted benefits in electrical efficiency of SOFC-based power plants over conventional methods of electricity generation from natural gas can be achieved only by an internal-reforming SOFC. So internal reforming is a major target of present worldwide SOFC development.

---

### **53.8 Summary**

This chapter is focused on fuel cell, including the basic principle of operation, system composition, and balance of plants, the performance and the design considerations, as well as the state-of-the-art technology. The performance of fuel cell is analyzed in terms of the cell potential and energy conversion efficiency under the idealized reversible and practical irreversible conditions, and misconception regarding fuel cell energy efficiency is clarified. The effect of operating conditions, namely, temperature, pressure, and reactant concentration, on the reversible cell potential is also given. It is shown that both fuel cells and heat engines have the same maximum theoretical efficiency, which is equivalent to the Carnot efficiency, when operating on the same fuel and oxidant. However, fuel cells have less irreversibilities in practice, resulting in higher practical efficiencies. Further, possibilities of over 100% fuel

cell efficiency are ruled out from the fundamental principles. Both reversible and irreversible energy loss mechanisms are described for fuel cells, expression for waste heat generation in a fuel cell is derived, and various forms of fuel cell efficiency are defined. Finally, the Nernst potential loss arising from the reactant consumption in practical cells is considered, and issues related to reactant utilization are outlined. Then, important physical and chemical processes occurring in fuel cell electrodes are provided, which relate to the transport phenomena and electrochemical reactions for current generation. These processes affect how the cells are connected together to form fuel cell stack of different sizes for desired power output.

Finally, the characteristics, technological status, and preferred area of applications are summarized for each of the six major types of fuel cells. AFCs have the best performance when operating on pure hydrogen and oxygen; its intolerance of carbon dioxide hinders its role for terrestrial applications. Significant progress is being made for PEMFC, although it is still too expensive to be competitive in the marketplace today. However, PEMFC is believed to be the most promising candidate for transportation application because of its high power density, fast start-up, high efficiency, and easy and safe handling. But until its cost is lowered by at least orders of magnitude, it will not be economically acceptable. Due to the difficulty of onboard fuel (hydrogen) storage and the lack of infrastructure for fuel (hydrogen) distribution, DMFCs are believed by some to be the most appropriate technology for vehicular application. PEMFCs are expected to be 5–10 years away from commercialization, while the DMFCs are at the early stage in their technological development. DMFCs also have considerable potential for portable applications. PAFC is the most commercially developed fuel cell, operating at intermediate temperatures. PAFCs are being used for combined heat and power applications with high energy efficiency. The high-temperature fuel cells like MCFCs and SOFCs may be most appropriate for cogeneration and combined cycle systems (with gas or steam turbine as the bottoming cycle). The MCFCs have the highest energy efficiency attainable from methane to electricity conversion in the size range of 250 kW to 20 MW; whereas the SOFCs are best suited for baseload utility applications operating on coal-derived gases. It is estimated that the MCFC technology is about 5–10 years away from commercialization, and the SOFCs are probably years afterward.

# SECOND EDITION

# ENERGY EFFICIENCY AND RENEWABLE ENERGY

# HANDBOOK

## FOR THE MOVERS, SHAKERS, AND POLICY MAKERS IN ENERGY ENGINEERING AND RELATED INDUSTRIES

The latest version of a bestselling reference, *Energy Efficiency and Renewable Energy Handbook, Second Edition* covers the foremost trends and technologies in energy engineering today. This new edition contains the latest material on energy planning and policy, with a focus on renewable and sustainable energy sources. It also examines nuclear energy and its place in future energy systems, includes a chapter on natural gas, and provides extensive coverage of energy storage for numerous forms of energy generation. The text also provides energy supply, demand, and pricing factor projections for the future.

## EXPLORE THE FUTURE OF GLOBAL ENERGY

The authors address problems that industry now faces, including the limited availability of conventional energy resources such as oil, natural gas, and coal, and considers renewable energies such as wind power, solar energy, and biomass. They also illustrate the economics of energy efficiency, discuss the financial energy policies of various countries, consider the role of energy conservation in energy strategies, and examine the future of renewable energy technologies to build a sustainable energy system.

This book is divided into five sections, providing a comprehensive look at renewable energy technologies and systems:

- Global Energy Systems, Policy, and Economics
- Energy Generation through 2025
- Energy Infrastructure and Storage
- Renewable Technologies
- Biomass Energy Systems

*Energy Efficiency and Renewable Energy Handbook, Second Edition* focuses on the successful promotion of a sustainable energy supply for the future, and offers new and relevant information providing a clear reference to sustainable-development goals.
