<b>12. Economics Methods .....</b>	<b>187</b>
<i>Walter Short and Rosalie Ruegg</i>	

<b>13. Environmental Impacts and Costs of Energy .....</b>	<b>219</b>
<i>Ari Rabl and Joseph V. Spadaro</i>	

## **Section II Energy Generation through 2025**

<b>14. Distributed Generation Technologies through 2025.....</b>	<b>251</b>
<i>Aníbal T. de Almeida and Pedro Soares Moura</i>	

<b>15. Demand-Side Management.....</b>	<b>289</b>
<i>Clark W. Gellings and Kelly E. Parmenter</i>	

<b>16. Fossil Fuels.....</b>	<b>311</b>
<i>Anthony F. Armor, Rameshwar D. Srivastava, Howard G. McIlvried, Thomas D. Marshall, and Sean I. Plasynski</i>	

<b>17. Nuclear Power Technologies through Year 2035.....</b>	<b>339</b>
<i>Kenneth D. Kok and Edwin Harvego</i>	

<b>18. Outlook for U.S. Energy Consumption and Prices, 2011–2040 .....</b>	<b>375</b>
<i>Andy S. Kydes, Mark J. Eshbaugh, and John J. Conti</i>	

## **Section III Energy Infrastructure and Storage**

<b>19. Transportation.....</b>	<b>409</b>
<i>Terry Penney and Frank Kreith</i>	

<b>20. Infrastructure Risk Analysis and Security .....</b>	<b>431</b>
<i>Bilal M. Ayyub</i>	

<b>21. Electricity Infrastructure Resilience and Security .....</b>	<b>483</b>
<i>Massoud Amin</i>	

<b>22. Electrical Energy Management in Buildings.....</b>	<b>525</b>
<i>Craig B. Smith and Kelly E. Parmenter</i>	

<b>23. Heating, Ventilating, and Air Conditioning Control Systems .....</b>	<b>565</b>
<i>Bryan P. Rasmussen, Jan F. Kreider, David E. Claridge, and Charles H. Culp</i>	

<b>24. Stirling Engines .....</b>	<b>621</b>
<i>Frank Kreith</i>	

<b>25. Energy-Efficient Lighting Technologies and Their Applications in the Residential and Commercial Sectors.....</b>	<b>629</b>
<i>Karina Garbesi, Brian F. Gerke, Andrea L. Alstone, Barbara Atkinson, Alex J. Valenti, and Vagelis Vossos</i>	

<b>26. Energy-Efficient Technologies: Major Appliances and Space Conditioning Equipment.....</b>	<b>659</b>
<i>Eric Kleinert, James E. McMahon, Greg Rosenquist, James Lutz, Alex Lekov, Peter Biermayer, and Stephen Meyers</i>	
<b>27. Heat Pumps.....</b>	<b>679</b>
<i>Herbert W. Stanford, III</i>	
<b>28. Electric Motor Systems Efficiency.....</b>	<b>695</b>
<i>Aníbal T. de Almeida, Steve F. Greenberg, and Prakash Rao</i>	
<b>29. Industrial Energy Efficiency and Energy Management.....</b>	<b>723</b>
<i>Craig B. Smith, Barney L. Capehart, and Wesley M. Rohrer, Jr.</i>	
<b>30. Process Energy Efficiency: Pinch Technology.....</b>	<b>809</b>
<i>Kirtan K. Trivedi, Ed Fouche, and Kelly E. Parmenter</i>	
<b>31. Analysis Methods for Building Energy Auditing.....</b>	<b>869</b>
<i>Moncef Krarti</i>	
<b>32. Cogeneration.....</b>	<b>891</b>
<i>W. Dan Turner</i>	
<b>33. Energy Storage Technologies.....</b>	<b>939</b>
<i>Jeffrey P. Chamberlain, Roel Hammerschlag, and Christopher P. Schaber</i>	
<b>34. Advanced Concepts in Transmission and Distribution.....</b>	<b>967</b>
<i>Robert Pratt, Christopher P. Schaber, and Steve Widergren</i>	
<b>35. Smart Grid Technology.....</b>	<b>983</b>
<i>Zhixin Miao</i>	

## Section IV Renewable Technologies

<b>36. Solar Energy Resources.....</b>	<b>993</b>
<i>D. Yogi Goswami</i>	
<b>37. Wind Energy Resource.....</b>	<b>1045</b>
<i>Dale E. Berg</i>	
<b>38. Municipal Solid Waste.....</b>	<b>1085</b>
<i>Shelly H. Schneider</i>	
<b>39. Biomass Properties and Resources.....</b>	<b>1093</b>
<i>Mark M. Wright and Robert C. Brown</i>	
<b>40. Active Solar Heating Systems.....</b>	<b>1105</b>
<i>T. Agami Reddy</i>	

<b>41. Passive Solar Heating, Cooling, and Daylighting .....</b>	<b>1163</b>
<i>Jeffrey H. Morehouse</i>	
<b>42. Concentrating Solar Thermal Power .....</b>	<b>1237</b>
<i>Manuel Romero, Jose Gonzalez-Aguilar, and Eduardo Zarza</i>	
<b>43. Wind Energy Conversion .....</b>	<b>1347</b>
<i>Dale E. Berg</i>	
<b>44. Photovoltaics .....</b>	<b>1393</b>
<i>Roger Messenger and D. Yogi Goswami</i>	
<b>45. Thin-Film PV Technology .....</b>	<b>1423</b>
<i>Hari M. Upadhyaya, Senthilarasu Sundaram, Aruna Ivaturi, Stephan Buecheler, and Ayodhya N. Tiwari</i>	
<b>46. Concentrating PV Technologies .....</b>	<b>1475</b>
<i>D. Yogi Goswami</i>	
<b>47. Waste-to-Energy Combustion .....</b>	<b>1481</b>
<i>Charles O. Velzy and Leonard M. Grillo</i>	
<b>48. Energy Recovery by Anaerobic Digestion Process .....</b>	<b>1529</b>
<i>Masoud Kayhanian and George Tchobanoglous</i>	
 <b>Section V Biomass Energy Systems</b>	
<b>49. Biomass Conversion to Heat and Power .....</b>	<b>1581</b>
<i>Mark M. Wright and Robert C. Brown</i>	
<b>50. Biomass Conversion to Fuels .....</b>	<b>1597</b>
<i>Mark M. Wright and Robert C. Brown</i>	
<b>51. Geothermal Power Generation .....</b>	<b>1615</b>
<i>Kevin Kitz</i>	
<b>52. Hydrogen Energy Technologies .....</b>	<b>1669</b>

# *Preface*

---

---

## **Purpose**

The goal of this handbook is to provide information necessary for engineers, energy professionals, and policy makers to plan a secure energy future. The time horizon of the handbook is limited to approximately 20 years because environmental conditions vary, new technologies emerge, and priorities of society continuously change. It is therefore not possible to make reliable projections beyond that period. Given this time horizon, the book deals only with technologies that are currently available or that are expected to be ready for implementation in the near future.

Energy is a mainstay of an industrial society. As the population of the world increases and people strive for a higher standard of living, the amount of energy necessary to sustain our society is ever increasing. At the same time, the availability of nonrenewable sources, particularly liquid fuels, is rapidly shrinking. Therefore, there is general agreement that to avoid an energy crisis, the amount of energy needed to sustain society will have to be contained and, to the extent possible, renewable sources will have to be used. As a consequence, conservation and renewable energy (RE) technologies are going to increase in importance and reliable, up-to-date information about their availability, efficiency, and cost is necessary for planning a secure energy future.

The timing of this handbook also coincides with a new impetus for the use of RE. This impetus comes from RE policies in Europe, Japan, China, India, and Brazil and the emergence of renewable portfolio standards (RPS) in many states of the United States. Germany introduced electricity feed-in laws that value electricity produced from RE resources much higher than that from conventional resources, which have created demand for photovoltaic and wind power. Following the success of Germany, other European countries introduced feed-in laws, which accelerated the deployment of RE in Europe. Other countries, such as China and India, have adopted modified versions of feed-in laws, whereby RE power companies bid discounts to the feed-in tariffs determined by the governments. RPS policies adopted by many states in United State require that a certain percentage of energy used be derived from renewable resources. RPSs and other incentives for RE are currently in place in 34 of the 50 states of the United States and the District of Columbia (DC) and Puerto Rico. The details of the RPS for RE and conservation instituted by state governments vary, but all of them essentially offer an opportunity for the industry to compete for the new markets. Thus, to be successful, renewable technologies will have to become more efficient, reliable, and cost-effective. RPSs have already demonstrated that they can reduce market barriers and stimulate the development of RE. The use of conservation and RE can help meet critical national goals for fuel diversity, price stability, economic development, environmental protection, and energy security and thereby play a vital role in national energy policy. The expected growth rate of RE from portfolio standards and other stimulants in the United States is impressive. As a result of various policy initiatives in the world, the global growth in solar photovoltaics (PV) production has averaged over 43% per year from 2000 to 2012 and 61% from 2007 to 2012, with Europe showing the maximum growth. The average annual growth in worldwide wind energy capacity from 2001 to 2012 was over 25%. The average annual growth in the United States over the same period was

37.7%. More recently, China has increased its capacity faster than any other country. China accounted for more than a quarter of the global wind capacity in 2012. With appropriate regulations and careful planning, the technical information in this handbook will ensure an orderly and peaceful transition to a sustainable energy future.

---

## Organization and Layout

The book is essentially divided into three sections:

- General overviews, policy, and economics (Section I: Chapters 1 through 13)
- Energy efficiency, energy generation, infrastructure, and storage (Section II: Chapters 14 through 18; and Section III: Chapters 19 through 35)
- Renewable energy technologies (Section IV: Chapters 36 through 48; and Section V: Chapters 49 through 53).

The first chapter is a survey of current and future worldwide energy issues. A discussion of sound finance policies and stimulants for energy efficiency and RE is treated in Chapter 2. State and federal policies for RE in the United States are described in Chapter 3. Chapters 4 through 11 give an assessment of policies in Europe, China, India, Brazil, Israel, Australia, and Japan. Economic assessment methods for conservation and generation technologies are covered in Chapter 12, and the environmental costs of various energy generation technologies are discussed in Chapter 13. The use of renewables and conservation will initiate a paradigm shift toward distributed generation and demand-side management procedures, which are covered in Chapter 14 and 15. Although renewables, once in place, produce energy from natural resources and cause very little environmental damage, energy is required in their initial construction. One measure of the energy effectiveness of a renewable technology is the length of time required, after the system begins operation, to repay the energy used in its construction, called the energy payback period. Another measure is the energy return on energy investment ratio. The larger the amount of energy a renewable technology delivers during its lifetime compared to the amount of energy necessary for its construction, the more favorable its economic return on the investment will be and the less its adverse environmental impact. But during the transition to renewable sources, a robust energy production and transmission system from fossil and nuclear technologies is required to build the systems. Moreover, because there is a limit to how much of our total energy needs can be met economically in the near future, renewables will have to coexist with fossil and nuclear fuels for some time. Furthermore, the supply of all fossil and nuclear fuel sources is finite, and their efficient use in meeting our energy needs should be a part of an energy and CO<sub>2</sub> reduction strategy. Therefore, Chapters 16 and 17 give a perspective on the efficiencies, economics, and environmental costs of the key fossil and nuclear technologies. Finally, Chapter 18 provides projections for energy supply, demand, and prices of energy in the United States through the year 2040. Petroleum engineers predict that worldwide oil production will reach its peak within the next 10 years and then begin to decline. At the same time, demand for liquid fuel by an ever-increasing number of vehicles, particularly in China and India, is expected to increase significantly. As a result, gasoline prices will increase precipitously unless we

reduce gasoline consumption by increasing the mileage of the vehicle fleet, reducing the number of vehicles on the road by using mass transport, and producing synthetic fuels from biomass and coal. The options to prevent an energy crisis in transportation include plug-in hybrid vehicles, biofuels, diesel engines, city planning, and mass-transport systems. These are treated in Chapter 19; biofuels and fuel cells are treated in Chapters 50 and 53, respectively. It is an unfortunate fact of life that the security of the energy supply and transmission system has recently been placed in jeopardy from various sources, including natural disasters and worldwide terrorism. Consequently, energy infrastructure security and risk analysis are an important aspect of planning future energy transmission and storage systems, and these topics are covered in Chapter 20. Energy efficiency is defined as the ratio of energy required to perform a specific task or service to the amount of energy used for the process. Improving energy efficiency increases the productivity of basic energy resources by providing the needs of society with less energy. Improving the efficiency across all sectors of the economy is therefore an important objective. The least expensive and most efficient means in this endeavor is energy conservation, rather than more energy production. Moreover, energy conservation is also the best way to protect the environment and reduce global warming.

Recognizing that energy conservation in its various forms is the cornerstone of successful national energy strategy, 11 chapters (22 through 32) are devoted to conservation. The topics covered include energy management strategies for industry and buildings, HVAC controls, co-generation, and advances in specific technologies, such as motors, lighting, appliances, and heat pumps. An important aspect of energy efficiency is efficient electric grid management, which includes energy storage, advanced concepts in transmission and distribution, and smart grid technology. These topics are covered in detail in Chapters 33 through 35.

The third section of the book deals with energy storage and energy generation from renewable sources. Chapters 36 through 39 present the availability of renewable sources: solar, wind, municipal waste, and biomass. The renewable generation technologies for solar thermal, wind power, PV, biomass, and geothermal are then covered in Chapters 40 through 53.

At this time, it is not clear whether hydrogen will play a major role in the national energy structure within the next 25 years, but there is an ongoing discussion about the feasibility and cost of what is called the hydrogen economy. Energy experts recognize that the generation and use of hydrogen has a critical inefficiency problem that is rooted in basic thermodynamics. There are also ground transportation options that are less expensive than using hydrogen vehicles powered by fuel cells. But there is substantial support for continuing research to eventually develop a viable place for hydrogen in a future energy structure. Therefore, the topics of hydrogen energy and fuel cells are included in Chapters 52 and 53, respectively. This information should be useful background for comparing competing options for energy generation, storage, and distribution.

We hope that this handbook will serve as a useful reference to all engineers in the energy field and pave the way for a paradigm shift from fossil fuels to a sustainable energy systems based on conservation and renewable technologies. But we also recognize the complexity of this task, and we invite readers to comment on the scope and the topics covered. A handbook such as this needs to be updated every 5–10 years, and we will respond to readers' comments and suggestions in the next edition.

**D. Yogi Goswami**  
**Frank Kreith**  
*Editors-in-chief*

---

## *Acknowledgments*

---

At the time CRC suggested that the *Handbook of Energy Efficiency and Renewable Energy* deserved a second edition, I was approaching my 90th birthday. I was reluctant at this point in my life to undertake such a large and demanding assignment, but my long-time associate and co-editor, Yogi Goswami, and Bev Weiler, my long-term assistant, offered to help me in the endeavor. The new edition owes its existence to the invaluable contributions that these two have made in contacting previous authors and helping to find new qualified experts whenever necessary. I would also like to thank my wife Marion for having helped me in many tangible and intangible ways to continue an active professional life in my seventh decade as an engineering author.

**Frank Kreith**

---

## Editors

---

**Dr. D. Yogi Goswami** is a university distinguished professor, the John and Naida Ramil Professor, and director of the Clean Energy Research Center at the University of South Florida, Tampa, Florida.

He conducts fundamental and applied research on solar thermal energy, thermodynamics, heat transfer, HVAC, photovoltaics, hydrogen, and fuel cells.

Dr. Goswami has served as an advisor and given testimonies on energy policy and the transition to renewable energy to the U.S. Congress and the Government of India, as well as provided consultant expertise to the U.S. Department of

Energy, USAID, World Bank, and NIST, among others.

Professor Goswami is the editor-in-chief of the *Solar Energy* and *Progress in Solar Energy* journals. Within the field of RE, he has published as author/editor 16 books, 6 conference proceedings, and 393 refereed technical papers. He has delivered 52 keynote and plenary lectures at major international conferences. He holds 18 patents.

A recognized leader in professional scientific and technical societies, Professor Goswami has served as a governor of ASME-International (2003–2006), president of the International Solar Energy Society (2004–2005), senior vice president of ASME (2000–2003), vice president of ISES and president of the International Association for Solar Energy Education (IASEE, 2000–2002).

Dr. Goswami is a fellow of AAAS, ASME International, ASHRAE, the American Solar Energy Society, the National Academy of Inventors and a member of the Pan American Academy of Engineers. He is a recipient of the following awards:

- Technical Communities Globalization Medal, (ASME) 2013.
- Theodore and Venette Askounes-Ashford Distinguished Scholar Award, Univ. South Florida, 2011.
- Frank Kreith Energy Award, ASME, 2007
- Farrington Daniels Award, ISES, 2007 (highest award of ISES)
- Hoyt Clark Hottel Award, ASES, 2007
- Charles Greely Abbott Award for Outstanding Scientific, Technical and Human Contributions to the Development and Implementation of Solar Energy (highest award of the American Solar Energy Society), 1998.
- John Yellott Award for Outstanding Contributions to the Field of Solar Energy, ASME Solar Energy Division, 1995 (highest solar energy award from ASME).

He has also received more than 50 other awards and certificates from major engineering and scientific societies for his work in renewable energy.

**Professor Frank Kreith** is an internationally known energy consultant and professor emeritus of engineering at the University of Colorado, Boulder, Colorado. In 1945, after graduation from the University of California, Berkeley, he accepted a position at the Jet Propulsion Laboratory of the California Institute of Technology, where he developed a heat transfer laboratory and conducted research on building heat transfer. He received his MS in engineering in 1949 from the University of California, Los Angeles, and in 1950 was awarded a Guggenheim Fellowship to Princeton University, followed in 1951 by an appointment to the faculty of the University of California, Berkeley.

From 1953 to 1959, he was associate professor of mechanical engineering at Lehigh University, where he did research on heat transfer in rotating systems and wrote the first edition of *Principles of Heat Transfer*, now in its seventh edition. In 1958, he received the Robinson Award from Lehigh University for excellence in teaching. In 1959, he joined the University of Colorado where he held appointments as professor of mechanical and chemical engineering. In 1962, he published a text on the design of solar power plants based on his consulting for the NASA space program. During his 20 years of tenure at the University of Colorado, he did research on heat transfer in biological systems and renewable energy. In 1964, he was awarded a doctorate in engineering from the University of Paris.

Dr. Kreith served as chief scientist and ASME legislative fellow at the National Conference of State Legislatures (NCSL) from 1988 to 2001, providing professional advice and assistance to all 50 state legislatures on energy and the environment. Prior to joining NCSL, he was senior research fellow at the Solar Energy Research Institute (now the National Renewable Energy Laboratory) where he participated in the Presidential Domestic Energy Review and served as energy advisor to the governor of Colorado. From 1974–1977, he was president of Environmental Consulting Services. Dr. Kreith has been an energy consultant to NATO, the U.S. Agency of International Development, and the United Nations. He has published more than a hundred peer-reviewed technical articles and more than 15 books, many translated into foreign languages and used extensively in engineering programs around the world. His books include *Principles of Heat Transfer* (now in its seventh edition), *Principles of Solar Engineering* (with J.F. Kreider), *Nuclear Impact* (with C.B. Wrenn), the *Handbook of Solid Waste Management*, the *CRC Handbook of Mechanical Engineering*, and *Principles of Sustainable Energy*, which is now in its second edition. He is a fellow of AAAS and was promoted to honorary member of ASME in 2004. Dr. Kreith's work has received worldwide recognition, including the Washington Award, Charles Greeley Abbot Award from ASES, the Max Jacob Award from ASME-AIChE, and the Ralph Coats Roe Medal from ASME for "significant contributions...through provision of information to legislators about energy and the environment." In 2004, ASME recognized Dr. Kreith's lifelong contributions to heat transfer and renewable energy by establishing the Frank Kreith Energy Award. He has recently completed an autobiography, *Sunrise Delayed: A Personal History of Solar Energy*, which is available on Amazon.com.

A thing that will assume enormous importance quite soon is the exhaustion of our fuel resources. Coal and oil have been accumulating in the earth over five hundred million years, and at the present rates of demand for mechanical power, the estimates are that oil will be all gone in about a century, and coal probably in a good deal less than five hundred years. For the present purpose, it does not matter if these are under-estimates; they could be doubled or trebled and still not affect the argument. Mechanical power comes from our reserves of energy, and we are squandering our energy capital quite recklessly. It will very soon be all gone, and in the long run we shall have to live from year to year on our earnings.\*

\* Quote from *The Next Millenium*, 1953, by Charles Galton Darwin, the grandson of Charles Darwin, author of *On the Origin of Species*.

## 1.1 Global Energy Needs and Resources

Global energy consumption in the last half century has rapidly increased and is expected to continue to grow over the next 50 years, however, with significant differences. The past increase was stimulated by relatively “cheap” fossil fuels and increased rates of industrialization in North America, Europe, and Japan; yet while energy consumption in these countries continues to increase, additional factors make the picture for the next 50 years more complex. These additional factors include China’s and India’s rapid increase in energy use as they represent about a third of the world’s population; the expected depletion of oil resources in the near future; and, the effect of human activities on global climate change. On the positive side, the renewable energy (RE) technologies of wind, biofuels, solar thermal, and photovoltaics (PV) are finally showing maturity and the ultimate promise of cost competitiveness.

Statistics from the International Energy Agency (IEA) World Energy Outlook 2004 and 2010 show that the total primary energy demand in the world increased from 5,536 MTOE in 1971 to 10,345 MTOE in 2002, representing an average annual increase of 2% (see Figure 1.1 and Table 1.1).\*

By 2008, the world energy demand had increased to 12,271 MTOE representing an average annual increase of about 3%. The main reason for a 50% increase in the annual rate is the fast growing energy demand in Asia Pacific, more specifically China. Since the per capita energy used in the most populous countries, China and India is still very small,

**FIGURE 1.1**

World primary energy demand (MTOE). (Data from IEA, *World Energy Outlook*, 2004; IEA, *World Energy Outlook 2010*, International Energy Agency, Paris, France, 2010; IEA, *World Energy Outlook 2013*, International Energy Agency, Paris, France, 2013.)

\* The energy data for this chapter came from many sources, which use different units of energy, making it difficult to compare the numbers. The conversion factors are given here for a quick reference.

MTOE = Mega tons of oil equivalent; 1 MTOE =  $4.1868 \times 10^4$  TJ (Terra Joules) =  $3.968 \times 10^{13}$  Btu.

GTOE = Giga tons of oil equivalent; 1 GTOW = 1000 MTOE.

Quadrillion Btu, also known as Quad:  $10^{15}$  British Thermal Units or Btu; 1 Btu = 1055 J.

1 TWh =  $10^9$  kilowatt hours (kWh), 1 kWh =  $3.6 \times 10^6$  J.

**TABLE 1.1**

Sources: Data from IEA, *World Energy Outlook*, 2004; IEA, *World Energy Outlook 2010*, International Energy Agency, Paris, France, 2010; IEA, *World Energy Outlook 2013*, International Energy Agency, Paris, France, 2013.

their energy use may continue to increase at a high rate. From 2008 to 2011, the annual increase in energy use dropped back to 2.1% mainly because of a deep recession in United States and Europe where the energy use actually declined.

The last 10 years data for energy consumption from BP Corp. shows that during the most recent 10-year period even though the total primary energy use in North America and Europe has gone down, the global average increase has gone up to 2.8% (see Table 1.2). The rate of growth has risen mainly due to very rapid growth in Asia Pacific, which recorded an average annual increase of 6.1%. More specifically, China increased its primary energy consumption by approximately 10%/year from 2002 to 2012. Based on the current plans of China this trend will continue for at least another decade (IEA, 2013).

*Even at a 2% increase per year, the primary energy demand of 12,271 MTOE in 2008 would double by 2043 and triple by 2063.* Of course the global energy use cannot continue to increase at the same rate forever. IEA (2013) estimates that the global energy use will increase at an average annual rate of 1.2 up to 2035. Even at that optimistic slow growth rate of 1.2%, the global energy use will increase by 38% by 2035 reaching a value of 16,934 MTOE/year.

**TABLE 1.2**Primary Energy Consumption (MTOE)<sup>a</sup>

Source: Data from BP Corp., London, U.K.

<sup>a</sup> This data does not include traditional biomass which was approximately 835 MTOE in 2011 according to IEA data.

Of the total world primary energy demand in 2002, fossil fuels accounted for about 80% with oil, coal, and natural gas being 36%, 23%, and 21%, respectively. Biomass accounted for 11% of all the primary energy in the world, with almost all of it being traditional biomass for cooking and heating in the developing countries, which is used very inefficiently. By 2011, fossil fuels contribution increased to approximately 82% of the global primary demand with oil, coal, and natural gas accounting for 31%, 29%, and 21%, respectively. Even though the oil use has continued to increase year after year, its overall share in the primary energy went down from 35% in 2002 to 31% in 2011. On the other hand, the share of coal in the primary energy increased from 23% in 2002 to 29% in 2011. The predominant reason for this shift is the rapid increase in power production in China where coal provides more than 75% of the electrical power (Table 1.3). The power capacity of China has been increasing at an annual rate of 12% since 2000 (Table 1.4) (Zhou, 2012) and has already overtaken the power capacity of United States.

With such high energy demand expected in the future, it is important to look at the available resources to fulfill the future demand 50 years from now, especially for electricity and transportation.

Although not a technical issue in the conventional sense, no matter what types of engineering scenarios are proposed to meet the rising demands of a growing world population, as long as that exponential growth continues, the attendant problems of energy and food consumption, as well as environmental degradation may have no long term solution (Bartlett, 2002). Under current demographic trends, the United Nations forecasts a rise in the global population to around 9 billion in the year 2050. This increase in 2.5 billion people will occur mostly in developing countries with aspirations for a higher standard of living. Thus, population growth should be considered as a part of the overall supply and demand picture to assure the success of future global energy and pollution strategy.

## 1.2 Major Sectors of Primary Energy Use

The major sectors using primary energy sources include electrical power, transportation, heating and cooling, industrial and others, such as cooking. The IEA data shows that the electricity demand almost tripled from 1971 to 2002 and quadrupled by 2011. This is not unexpected as electricity is a very convenient form of energy to transport and use. Although primary energy use in all sectors has increased, their relative shares except for transportation and electricity have decreased (Figure 1.2). Figure 1.2 shows that the relative share of primary energy for electricity production in the world increased from about 20% in 1971 to about 40% in 2011. This is because electricity is becoming the preferred form of energy for all applications.

Figure 1.3 shows that coal is presently the largest source of electricity in the world. Consequently, the power sector accounted for almost 42% of all CO<sub>2</sub> emissions in 2011. Emissions could be reduced by increased use of RE sources. All RE sources combined accounted for about 20% share of electricity production in the world. Wind and solar power technologies have vastly improved in the last two decades and are becoming more cost effective. Therefore, their share of electricity production has been increasing at a very fast pace. Over the last decade wind power capacity has been increasing at an annual rate of close to 30% and solar photovoltaic power capacity has been increasing at an annual rate of close to 50%, which has resulted in wind and solar providing a combined 2% of all the electricity generation in the world in 2011, almost all of it coming online in less than two decades. Since solar and wind technologies are now mature, substituting fossil fuels with RE for electricity generation must be an important part of any strategy of reducing CO<sub>2</sub> emissions into the atmosphere and combating global climate change.

**FIGURE 1.2**

Sectoral shares in world primary energy demand. (Data from IEA, *World Energy Outlook*, 2004; IEA, *World Energy Outlook 2013*, International Energy Agency, Paris, France, 2013.)

**FIGURE 1.3**

World electricity production by fuel in 2011. (Data from IEA, *World Energy Outlook 2013*, International Energy Agency, Paris, France, 2013.)

### 1.3 Electricity-Generating Capacity Additions to 2040

Figure 1.4 shows the global electricity-generating capacity in 2010 and additional electricity-generating capacity forecast by Energy Information Agency (EIA) of the U.S. Department of Energy for different regions in the world. The overall global annual increase of 1.6% in the electricity-generating capacity is in general agreement with the estimates from IEA (2013), which projects an average annual growth of 1.6% up to 2035. It is clear that of all countries, China will add the largest capacity with its projected electrical needs accounting for about 27.5% of the total world electricity-generating capacity. Non-OECD Asian countries (including China, India, Thailand, and Indonesia) combined will add about 60% of all the new capacity of the world. Therefore, what happens in these countries will have important consequences on the worldwide energy and environmental situation. If coal provides as much as 70% of China's electricity in 2030, as forecasted by IEA (2013), it will certainly increase worldwide CO<sub>2</sub> emissions which will further increase global warming.

### 1.4 Transportation

Transportation is a major sector with a 20% relative share of primary energy. This sector has serious concerns as it is a significant source of CO<sub>2</sub> emissions and other airborne pollutants—and it is almost totally based on oil as its energy source (Figure 1.5). In 2010, the transportation sector accounted for about 20% of all CO<sub>2</sub> emissions worldwide. An important aspect of future changes in transportation depends on what happens to the available

**FIGURE 1.4**

Electricity-generating capacity and projected additions to 2040 by region. (From EIA, *Annual Energy Outlook 2013*, U.S. Department of Energy, Washington, DC, 2013, [www.eia.gov/ies](http://www.eia.gov/ies).)

**FIGURE 1.5**

Share of transport in global oil demand and share of oil in transport energy demand. (Data and Forecast from EIA, *Annual Energy Outlook 2013*, U.S. Department of Energy, Washington, DC, 2013, [www.eia.gov/aero](http://www.eia.gov/aero).)

oil resources, production, and prices. At present 95% of all energy for transportation comes from oil, and according to Figure 1.5, the EIA projects that petroleum will still provide 95% of all energy for transportation in 2040. However, with policy changes happening in the world due to serious concerns about global climate change and expected future technology developments, projections simply based on the past use will probably prove to be wrong.

As explained later in this chapter, irrespective of the actual amount of oil remaining in the ground, oil production will peak in the foreseeable future. Therefore, the need for

careful planning for an orderly transition away from oil as the primary transportation fuel is urgent. An obvious replacement for oil would be biofuels such as ethanol, methanol, biodiesel, and biogases. Some believe that hydrogen is another alternative, because if it could be produced economically from renewable energy sources or nuclear energy, it could provide a clean transportation alternative for the future. Some have claimed hydrogen to be a “wonder fuel” and proposed a “hydrogen-based economy” to replace the present carbon-based economy (Veziroglu and Barbir, 1992). However, others (Shinnar, 2003; Kreith and West, 2004; Hammerschlag and Mazza, 2005) dispute this claim based on the lack of infrastructure, problems with storage and safety, and the lower efficiency of hydrogen vehicles as compared to hybrid or fully electric vehicles. Electric transportation presents a promising viable alternative to the oil-based transportation system (West and Kreith, 2006). Already plug-in hybrid-electric automobiles are becoming popular around the world as petroleum becomes more expensive.

The environmental benefits of renewable biofuels could be increased by using plug-in hybrid electric vehicles (PHEVs). These cars and trucks combine internal combustion engines with electric motors to maximize fuel efficiency. But PHEVs have more battery capacity that can be recharged by plugging it into a regular electric outlet. Then these vehicles can run on electricity alone for relatively short trips. The electric-only trip length is denoted by a number, for example, PHEV 20 can run on battery charge for 20 miles. When the battery charge is used up, the engine begins to power the vehicle. The hybrid combination reduces gasoline consumption appreciably. Whereas the conventional vehicle fleet has a fuel economy of about 22 mpg, hybrids can attain about 50 mpg. PHEV 20s have been shown to attain as much as 100 mpg. Gasoline use can be decreased even further if the combustion engine runs on biofuel blends, such as E85, a mixture of 15% gasoline and 85% ethanol (Kreith, 2006; West and Kreith, 2006).

Plug-in hybrid electric technology is already available and could be realized immediately without further R&D. Furthermore, a large portion of the electric generation infrastructure, particularly in developed countries, is needed only at the time of peak demand (60% in the United States), and the rest is available at other times. Hence, if batteries of PHEVs were charged during off-peak hours, no new generation capacity would be required. Moreover, this approach would levelize the electric load and reduce the average cost of electricity, according to a study by the Electric Power Research Institute (EPRI) (Sanna, 2005).

Given the potential of PHEVs, EPRI (2004) conducted a large-scale analysis of the cost, battery requirements, and economic competitiveness of plug-in vehicles today and in the future. As shown by West and Kreith, the net present value of lifecycle costs over 10 years for PHEVs with a 20 mile electric-only range (PHEV 20) is less than that of a similar conventional vehicle (West and Kreith, 2006). Furthermore, currently available nickel metal-hydride (NiMH) batteries are already able to meet required cost and performance specifications. More advanced batteries, such as lithium-ion (Li-ion) batteries, may improve the economics of PHEVs even further in the future.

---

## 1.5 World Energy Resources

With a view to meet the future demand of primary energy in 2050 and beyond, it is important to understand the available reserves of conventional energy resources including fossil fuels and uranium, and the limitations posed on them due to environmental considerations.

### 1.5.1 Conventional Oil

There is a considerable debate and disagreement on the estimates of “ultimate recoverable oil reserves,” however, there seems to be a good agreement on the amount of “proven oil reserves” in the world. According to BP (2013), total identified or proven world oil reserves at the end of 2012 were 1668.9 billion barrels (bbl). This estimate is close to the reserves of 1700 billion bbl from other sources listed by IEA (2013). The differences among them are in the way they account for the unconventional oil sources. Considering the production rate of about 86.5 million bbl/day at the end of 2012, these reserves will last for about 53 years if there is no increase in production. Of course there may be additional reserves that may be discovered in the future. An analysis by the U.S. Energy Information Agency (2006) estimates the ultimately recoverable world oil reserves (including resources not yet discovered) at between  $2.2 \times 10^{12}$  and  $3.9 \times 10^{12}$  bbl. More recently, IEA has estimated that the ultimate remaining recoverable oil resources are as much as 2670 billion bbl of conventional oil (including Natural Gas Liquids), 345 billion bbl of light oil, 1880 billion of extra heavy oil and bitumen, and 1070 billion bbl kerogen oil. It is important to note that for this high estimate the IEA puts in a disclaimer, “However, resource estimates are inevitably subject to a considerable degree of uncertainty; this is particularly true for unconventional resources that are very large, but still relatively poorly known, both in terms of the extent of the resource in place and judgments about how much might be technically recoverable.”

Ever since petroleum geologist M. King Hubbert correctly predicted in 1956 that U.S. oil production would reach a peak in 1973 and then decline (Hubbert, 1974), scientists and engineers have known that worldwide oil production would follow a similar trend. Today, the only question is when the world peak will occur. Bartlett (2002) has developed a predictive model based on a Gaussian curve similar in shape to the data used by Hubbert as shown in Figure 1.6. The predictive peak in world oil production depends on the assumed total amount of recoverable reserves.

If the BP estimated oil reserves are correct, we are close to the peak in the world oil production. If, however, estimates of the ultimate reserves (discovered and undiscovered)

**FIGURE 1.6**

World oil production vs. time for various amounts of ultimate recoverable resource. (From Bartlett, A.A., *Math. Geol.*, 32, 1, 2002.)

are used, we may expect the oil production to increase a little longer before it peaks. But changing the total available reserves from  $3 \times 10^{12}$  to  $4 \times 10^{12}$  bbl increases the predicted time of peak production by merely 11 years, from 2019 to 2030. IEA World Energy Outlook 2013 estimates that under one policy scenario the oil production will peak at about 91 million bbl/day in 2020 while another policy scenario puts the peak at 101 million bbl/day in 2035. It is clear that no matter which scenario turns out to be true, the global oil production will peak sometime between 2019 and 2035. There is no question that once the world peak is reached and oil production begins to drop, either alternative fuel will have to make up the difference between demand and supply, or the cost of fuel will increase precipitously and create an unprecedented social and economic crisis for our entire transportation system.

The present trend of yearly increases in oil consumption, especially in China and India, shortens the window of opportunity for a managed transition to alternative fuels even further. Hence, irrespective of the actual amount of oil remaining in the ground, peak production will occur soon. Therefore, the need for starting to supplement oil as the primary transportation fuel is urgent because an orderly transition to develop petroleum substitutes will take time and careful planning.

### **1.5.2 Natural Gas**

According to BP (2013) the total proven world natural gas reserves at the end of 2012 were 187.3 trillion m<sup>3</sup>. Considering the production rate of gas in 2012, with no increase in production thereafter, these reserves would last for 55.7 years. However, production of natural gas has been rising at an average rate of 2.7% over the past 5 years. If production continues to rise because of additional use of CNG for transportation and increased power production from natural gas, the reserves would last for fewer years. Of course, there could be additional new discoveries. However, even with additional discoveries, it is reasonable to expect that all the available natural gas resources may last from about 50 to 80 years, with a peak in production occurring much earlier.

### **1.5.3 Coal**

Coal is the largest fossil resource available to us and the most problematic from environmental concerns. From all indications, coal use will continue to grow for power production around the world because of expected increases in China, India, Australia, and other countries. From an environmental point of view this would be unsustainable unless advanced “clean coal technology” (CCT) with carbon sequestration is deployed.

CCT is based on an integrated gasification combined-cycle (IGCC) that converts coal to gas that is used in a turbine to provide electricity with CO<sub>2</sub> and pollutant removal before the fuel is burned (Hawkins et al., 2006). According to an Australian study (Sadler, 2004), no carbon capture and storage system is yet operating on a commercial scale, but may become an attractive technology to achieve atmospheric CO<sub>2</sub> stabilization.

According to BP, the proven recoverable world coal resources were estimated to be 861 billion tons at the end of 2012 with a reserve to production ratio (R/P) of 107 years. The BP data also shows that coal use increased at an average rate of 3.7% from 2007 to 2012, the largest increase of all fossil resources. Since more than 75% of China’s electricity-generating capacity is based on coal and both China and India are continuing to build

new coal power plants, it is reasonable to assume that coal use will continue to increase for at least some years in future. Therefore, the R/P ratio will decrease further from the present value of 107 years. The R/P ratio will decrease even more rapidly when clean coal technologies such as coal gasification and liquefaction are utilized instead of direct combustion.

#### 1.5.4 Summary of Fossil Fuel Reserves

Even though there are widely differing views and estimates of the ultimately recoverable resources of fossil fuels, it is fair to say that they may last for around 50–100 years with a peak in production occurring much earlier. However, a big concern is the climatic threat of additional carbon that will be released into the atmosphere. According to the estimates from the IEA, if the present shares of fossil fuels are maintained up to 2040 without any carbon sequestration, a cumulative amount of approximately 1000 gigatons of carbon will be released into the atmosphere (based on Figure 1.7). This is especially troublesome in view of the fact that the present total cumulative emissions of about 500 gigatons of carbon have already raised serious concerns about global climate change.

#### 1.5.5 Nuclear Resources

Increased use of nuclear power presents the possibility of additional carbon-free energy use and its consequent benefit for the environment. However, there are significant concerns about nuclear waste and other environmental impacts, the security of the fuel and the waste, and the possibility of their diversion for weapon production.

**FIGURE 1.7**

World energy-related CO<sub>2</sub> emissions by fuel (billion metric tons). (Data and forecast from IEA, *World Energy Outlook 2013*, International Energy Agency, Paris, France, 2013.)

Nuclear fission provided 14% of the electricity in the world in 2011 (IEA, 2013) and the worldwide nuclear capacity in 2011 was 375 GW (IAEA, 2011). Although a number of countries have decided to not build additional nuclear power plants after the Fukushima accident, nuclear power capacity is expected to continue to grow mainly because of the ongoing and planned construction in China and some other countries. IAEA estimates that the worldwide nuclear power capacity will increase at an average rate of 1.5%–2.7% until 2035 (IAEA, 2011). At present, uranium is used as the fissile material for nuclear power production. Thorium could also be used for nuclear fission; however, to date nobody has developed a commercial nuclear power plant based on thorium. Terrestrial deposits of both uranium and thorium are limited and concentrated in a few countries of the world. The International Atomic Energy Agency (IAEA) estimates the total identified recoverable uranium reserves in the world to be about 5 million tons which increase to about 7 million tons if the price of uranium goes up to \$264/kg U (Figure 1.8). Additionally, there are nonconventional uranium resources, such as sea water which contains about 3 parts per billion uranium and some phosphate deposits (more than half of them in Morocco) which contain about 100 parts per million uranium. These resources are potentially huge; however, their cost effective recovery is not certain (Figure 1.9).

For generating 1 TWh of electricity from nuclear fission, approximately 22 tons of uranium are required (UNDP, 2004). Based on the 2011 world capacity of 375 GW, the identified reserves will last about 97 years if there is no change in the generation capacity. At an average annual growth rate of 2%, the uranium reserves of 7 million tons will last for about 60 years. This estimate does not consider regeneration of spent fuel. At present, nuclear fuel regeneration is not allowed in the United States. However, that law could be changed in future. Development of breeder reactors could increase the time period much further. The major impediment may be economic viability. Nuclear fusion could potentially provide a virtually inexhaustible energy supply; however, it is not expected to be commercially available in the foreseeable future.

**FIGURE 1.8**

## 1.6 Present Status and Potential of Renewable Energy

According to the data in Table 1.5, 13.2% of the world's total primary energy supply (TPES) came from RE in 2011. However, approximately 75% of the RE supply was from biomass, and in developing countries it is mostly converted by traditional open combustion, which is very inefficient. Because of its inefficient use, biomass resources presently supply only about 20% of what they could if converted by modern, more efficient, available technologies. As it stands, biomass provides only about 10% of the world total primary energy

**TABLE 1.5**

2011 Fuel Shares in World Total Primary Energy Supply

Source	Share (%)
Oil	31.4
Natural gas	21.3
Coal	28.9
Nuclear	5.2
Renewables	13.2

Source: IEA, *World Energy Outlook 2013*, International Energy Agency, Paris, France, 2013.

which is much less than its real potential. The total technologically sustainable biomass energy potential for the world is 3–4 TW<sub>e</sub> (UNDP, 2004), which is about 80% the entire present global electricity-generating capacity of about 5 TW<sub>e</sub>.

In 2011, shares of biomass and hydropower in the total primary energy mix of the world were about 10% and 2.3%, respectively. All of the other renewables, including solar thermal, solar PV, wind, geothermal and ocean combined, provided only about 1% of the total primary energy. During the same year, biomass combined with hydroelectric resources provided almost 50% of all the primary energy in Africa. However, biomass is used very inefficiently for cooking in these countries. Such use has also resulted in significant health problems, especially for women. As of 2012, renewable energy contributes more than 40% of their total energy needs in 4 countries (Nigeria, Norway, Brazil, and Sweden) and more than 20% in 10 countries listed in Table 1.6 (Finland, Indonesia, India, Colombia, Chile, and Portugal). Other countries that provide significant shares of their energy from RE but <20% include, New Zealand (19.9%), Canada (18.4), Thailand (18.3%), Romania (15.2%), and Germany (14.2%).

Table 1.7 shows the share of renewable energy in 2011 and projections to 2020 and 2035. Keeping in mind that the future projections are only as good as the assumptions they are based on, and the energy situation is in a flux because of the impact on environment which is a major reason for the global climate change, IEA developed three scenarios for the future projections: (1) Current Energy Policies, (2) New Energy Policies (policies that have already been developed by major countries as of 2012), and (3) 450 Scenario, which assumes that policies around the world will be strengthened to limit the global temperature rise to 2°C or global atmospheric CO<sub>2</sub> concentrations to 450 ppm. Although there is considerable uncertainty about future policies, it is very likely that the future energy developments will lie somewhere in between the last two scenarios. According to these projections, the share of renewable energy will rise to as much as 18%–26% of the global primary energy and 31%–48% of the electricity-generating capacity by 2035. Based on the trends in the development and deployment of wind power and solar power in the last decade, there is reason to believe that values close to 450 scenario are achievable.

**TABLE 1.6**

### 1.6.1 Wind Power

Wind energy technology has progressed significantly over the last two decades. The technology has been vastly improved and capital costs have come down to as low as \$1000/kW. At this level of capital costs, wind power is already economical at locations with fairly good wind resources. Therefore, the average annual growth in worldwide wind energy capacity from 2001 to 2012 was over 25% (Figure 1.10). The average growth in the United States over the same period was 37.7%. The total worldwide installed wind power capacity which was 24 GW in 2001 (Figure 1.10), reached a level of 282 GW in 2012 (WWEA, 2013). The countries with the largest wind capacity in 2012 include China (75 GW), United States (60 GW), Germany (31 GW), Spain (23 GW), and India (18 GW) (Figure 1.11). The total theoretical potential for onshore wind power for the world is around 55 TW with a practical potential of at least 2 TW (UNDP, 2004), which is about 40% of the entire present worldwide generating capacity. The offshore wind energy potential is even larger.

**FIGURE 1.10**

World wind energy installed capacity and growth rates. (Data from WWEA, World Wind Energy Association, 2012, [http://www.windea.org/webimages/WorldWindEnergyReport2012\\_final.pdf](http://www.windea.org/webimages/WorldWindEnergyReport2012_final.pdf).)

**FIGURE 1.11**

### 1.6.2 Solar Energy

The amount of sunlight striking the earth's atmosphere continuously is  $1.75 \times 10^5$  TW. Considering a 60% transmittance through the atmospheric cloud cover,  $1.05 \times 10^5$  TW reaches the earth's surface continuously. If the irradiance on only 1% of the earth's surface could be converted into electric energy with a 10% efficiency, it would provide a resource base of 105 TW, while the total global energy needs for 2040 are projected to be about 8–9 TW. The present state of solar energy technologies is such that solar cell efficiencies have reached over 40% and solar thermal systems provide efficiencies of 40%–80%. With the present rate of technological development these solar technologies will continue to improve, thus bringing the costs down, especially with the economies of scale.

**FIGURE 1.12**

World solar PV production, 2000–2012 (GWp). (From EPIA, European Photovoltaic Industries Association, 2012, [www.epia.org](http://www.epia.org).)

Solar PV panels have come down in cost from about \$30/W to about \$0.50/W in the last three decades. At \$0.50/W panel cost, the overall system cost is around \$2/W, which is already lower than grid electricity in the Caribbean island communities. Of course, there are many off-grid applications where solar PV is already cost-effective. With net metering and governmental incentives, such as feed-in laws and other policies, grid-connected applications such as building integrated PV (BIPV) have become cost-effective even where grid electricity is cheaper. As a result, the worldwide growth in PV production has averaged over 43%/year from 2000 to 2012 and 61% from 2007 to 2012 (Figure 1.12) with Europe showing the maximum growth.

Solar thermal power using concentrating solar collectors was the first solar technology which demonstrated its grid power potential. A 354 MW<sub>e</sub> concentrating solar thermal power (CSP) plant has been operating continuously in California since 1988. Progress in solar thermal power stalled after that time because of poor policy and lack of R&D. However, the last 10 years have seen a resurgence of interest in this area and a number of solar thermal power plants around the world are under construction. The largest CSP plant with a capacity of 400 MW came on line in Nevada in February 2014. The cost of power from these plants (which is so far in the range of 12–16 U.S. cents/kWh<sub>e</sub>) has the potential to go down to 5 U.S. cents/kWh<sub>e</sub> with scale-up and creation of a mass market. An advantage of solar thermal power is that thermal energy can be stored efficiently and fuels, such as, natural gas or biogas may be used as back up to ensure continuous operation. If this technology is combined with power plants operating on fossil fuels, it has the potential to extend the time frame of the existing fossil fuels.

Low temperature solar thermal systems and applications have been well developed for quite some time. They are being actively installed wherever the policies favor their deployment. Figure 1.13 gives an idea of the rate of growth of solar thermal systems in the world. In 2011, approximately 234 GW<sub>th</sub> solar collectors were deployed around the world, a vast majority (65%) of those being in China (IEA, 2013) (Figure 1.14).

**FIGURE 1.13**

Deployment of solar heat (glazed) collectors,  $\text{MW}_{\text{th}}$ . (From ESIF, IEA SHC.)

**FIGURE 1.14**

Worldwide distribution of solar thermal collector markets (a) glazed collectors and (b) total glazed and unglazed in 2012. (From Mauthner, F. and Weiss, W., Solar heat worldwide—Markets and contribution to energy supply 2011, IEA Solar Heating and Cooling Program, Paris, France, May 2013.)

### 1.6.3 Biomass

Although theoretically harvestable biomass energy potential is of the order of 90 TW, the technical potential on a sustainable basis is of the order of 8–13 TW or 270–450 EJ/year (UNDP, 2005). This potential is 1.6–2.6 times the present electricity-generating capacity of the world. It is estimated that by 2025, even the municipal solid waste (MSW) could generate up to 6 EJ/year.

The biggest advantage of biomass as an energy resource is its relatively straightforward transformation into transportation fuels. Biofuels have the potential to replace as much as 75% of the petroleum fuels in use for transportation in the United States (Worldwatch, 2006). This is especially important in view of the declining oil supplies worldwide. Biofuels will not require additional infrastructure development. Therefore, development of biofuels is being viewed very favorably by governments around the world. Biofuels, along with other transportation options such as electric vehicles and hydrogen, will help diversify the fuel base for future transportation. Table 1.8 and Figure 1.15 show the global production of biofuels from 2001 to 2011. United States, Brazil, and Europe are the top producing countries and region of the world. Biofuel production grew more than five times in 10 years, although it started from a much

**TABLE 1.8**

Total Biofuels Production (1000 bbl/day)

	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011

World	342.9	403.5	499.4	554.8	656.3	840.6	1,103.3	1,477.3	1,635.4	1,865.4	1,897.2

Sources: Enerdata, *Enerdata Energy Statistical Yearbook 2013*, 2013; IEA, *World Energy Outlook 2013*, International Energy Agency, Paris, France, 2013.

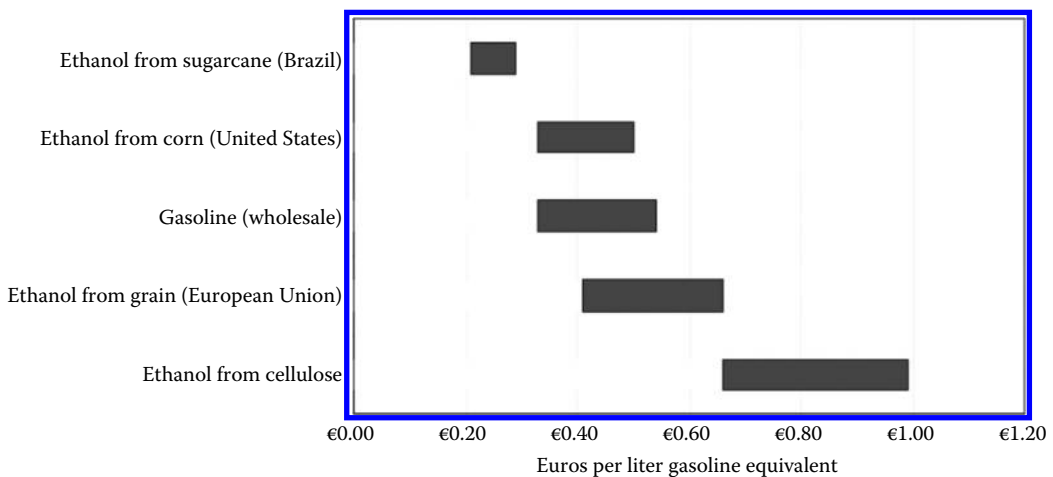

**FIGURE 1.15**

World biofuel production, 2001–2011. (From IEA, *World Energy Outlook 2013*, International Energy Agency, Paris, France, 2013.)

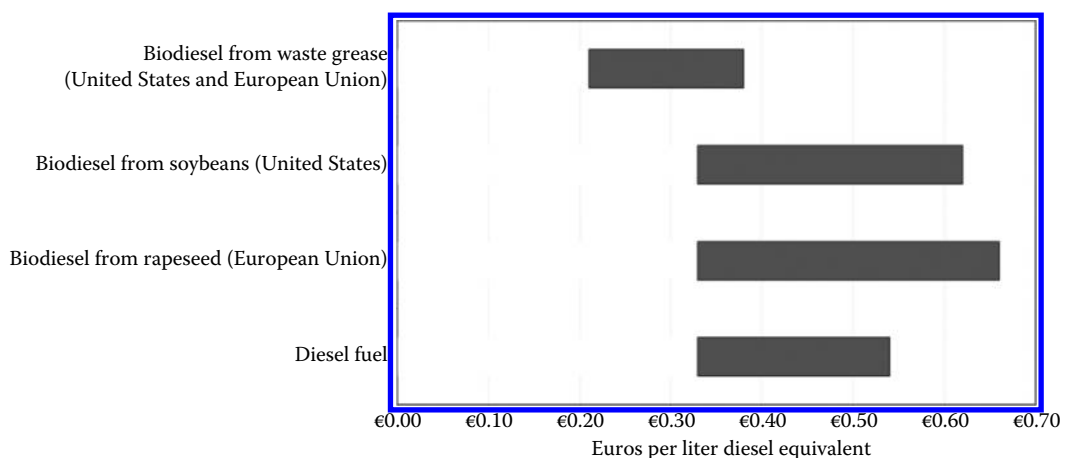

smaller base. In 2005, the world ethanol production had reached about 36 billion L/year while biodiesel production topped 3.5 billion L during the same year.

The present cost of ethanol production ranges from about €0.25 to about €1/gasoline equivalent L, as compared to the wholesale price of gasoline which is between €0.40 and €0.60/L (Figure 1.16). Biodiesel costs, on the other hand, range between €0.20 and €0.65/L of diesel equivalent (Figure 1.17). Figure 1.18 shows the feedstock used for these biofuels. An important consideration for biofuels is that the fuel not be produced at the expense of food while there are people going hungry in the world. This would not be of concern if biofuels were produced from MSW or nonfood forest resources.

**FIGURE 1.16**

Cost ranges for ethanol and gasoline production, 2006. (From IEA, Reuters, DOE.)

**FIGURE 1.17**

Cost ranges for biodiesel and diesel production, 2006. (From IEA, Reuters, DOE.)

**FIGURE 1.18**

Biofuel yields of selected ethanol and biodiesel feedstocks. (From Hunt, S. and Forster, E. 2006. *Biofuels for Transportation: Global Potential and Implications for Sustainable Agriculture and Energy in the 21st Century*. Worldwatch Institute, Washington, DC.)

According to the Worldwatch report, a city of one million people produces about 1,800 tons of MSW and 1,300 tons of organic waste every day, which using the present-day technology could produce enough fuel to meet the needs of 58,000 persons in the United States, 360,000 in France, and nearly 2.6 million in China at current rates of per capita fuel use (Worldwatch, 2006).

#### 1.6.4 Summary of Renewable Energy Resources

By definition, the term “reserves” does not apply to renewable resources. So we need to look at the annual potential of each resource. Table 1.9 summarizes the resource potential and the present costs and the potential future costs for each renewable resource.

As in the case of other new technologies, it is expected that cost competitiveness of the renewable energy technologies will be achieved with R&D, scale-up, commercial experience, and mass production. The experience curves in Figure 1.19 show industry-wide cost reductions in the range of 10%–20% for each cumulative doubling of production for wind power, photovoltaics, ethanol, and gas turbines (UNDP, 2004). Similar declines can be expected in solar thermal power and other renewable technologies. As seen from Figure 1.19, wind energy technologies have already achieved market maturity, and PV technologies are well on their way. Even though concentrating solar thermal power (CSP) is not shown in this figure, a GEF report estimates that CSP will achieve the cost target of about \$0.05/kWh by the time it has an installed capacity of about 40 GW (GEF, 2005). As a reference point, wind power achieved that capacity milestone in 2003.

**TABLE 1.9**

Potential and Status of Renewable Energy Technologies

Technology	Annual Potential	Operating Capacity 2005	Investment Costs U.S. \$/kW	Current Energy Cost	Potential Future Energy Cost
<i>Biomass energy</i>	276–446 EJ Total or 8–13 TW MSW ~ 6 EJ

*Note:* ge, gasoline equivalent liter; de, diesel equivalent liter; kW<sub>e</sub>, kilowatt electrical power; kW<sub>th</sub>, kilowatt thermal power.

## 1.7 Role of Energy Conservation

Energy conservation can and must play an important role in future energy strategy, because it can ameliorate adverse impacts on the environment rapidly and economically. [Figures 1.20](#) and [1.21](#) give an idea of the potential of energy efficient improvements. Figure 1.20 shows that per capita energy consumption varies by as much as a factor of 3

**FIGURE 1.19**

Experience curves for wind, PV, ethanol and gas turbines. (Adapted from UNDP, *World Energy Assessment: Energy and the Challenge of Sustainability*, 2004. For wind turbines: Neij, L. et al., *Experience curves: A tool for Energy Policy Assessment*, March 2003; For gas turbines: Claeson Colpier, U. and Cornland, D., *Energy Policy*, 30, 209, 2002; For photovoltaics: Parente, V. et al., *Prog. Photovolt. Res. Appl.*, 10(8), 571, 2002; For ethanol: Goldemberg, J. et al., *Biomass Energy*, in press.)

between the United States and some European countries with almost the same level of Human Development Index (HDI). Even taking just the OECD European countries combined, the per capita energy consumption in the United States is twice as much. It is fair to assume that the per capita energy of the United States could be reduced to the level of OECD Europe of 4.2 kW by a combination of energy efficiency improvements and changes in the transportation infrastructure. This is significant because the United States uses about 25% of the energy of the whole world. The present per capita energy consumption in the United States is 284 GJ, which is equivalent to about 9 kW/person, while the average for the whole world is 2 kW. Board of Swiss Federal Institutes of Technology has developed a vision of a 2 kW per capita society by the middle of the century (UNDP, 2004). The vision is technically feasible. However, to achieve this vision will require a combination of increased R&D on energy efficiency and policies that encourage conservation and use of high efficiency systems. It will also require some structural changes in the transportation systems. According to the 2004 World Energy Assessment by UNDP, a 25%–35% reduction in primary energy in the industrialized countries is achievable cost effectively in the next 20 years, without sacrificing the level of energy services. The report also concluded that similar reductions of up to 40% are cost effectively achievable in the transitional economies and more than 45% in developing economies. As a combined result of efficiency improvements and structural changes such as increased recycling, substitution of energy intensive materials, etc., energy intensity could decline at a rate of 2.5%/year over the next 20 years (UNDP, 2004).

McKinsey and Company conducted a comprehensive study of the energy conservation potential in United States in 2020. Figure 1.22 shows the potential in various sectors including the average cost of savings. According to this figure, the total U.S. economical potential of energy conservation to 2020 is 9500 trillion Btu or 25 GTOE.

**FIGURE 1.20**

Relationship between Human Development Index (HDI) and per capita energy use, 1999–2000. (From UNDP, World Energy Assessment: Energy and the Challenge of Sustainability, 2004.)

**FIGURE 1.21**

Per capita energy use by region (commercial and noncommercial) 2000. (From UNDP, World Energy Assessment: Energy and the Challenge of Sustainability, 2004.) *Note:* Asia excludes Middle East, China, and OECD countries; Middle East and North Africa comprises Algeria, Bahrain, Egypt, Iran, Iraq, Israel, Jordan, Kuwait, Lebanon, Libya, Morocco, Oman, Qatar, Saudi Arabia, Syria, Tunisia, United Arab Emirates, and Yemen; Latin America and Caribbean excludes Mexico; OECD Pacific comprises Australia, Japan, Korea, and New Zealand; Former USSR comprises Armenia, Azerbaijan, Belarus, Estonia, Georgia, Kazakhstan, Kyrgyzstan, Latvia, Lithuania, Moldova, Russia, Tajikistan, Turkmenistan, Ukraine, and Uzbekistan; Non-OECD Europe comprises Albania, Bosnia and Herzegovina, Bulgaria, Croatia, Cyprus, Gibraltar, Macedonia, Malta, Romania, and Slovenia; OECD North America includes Mexico.

**FIGURE 1.22**

Energy saving potential of various sectors and cost of savings as compared to the price of electricity. (From Granade, H. et al., *Unlocking energy efficiency in the U.S. economy*, 2010 EIA Energy Conference, Washington, DC, April 2010, [www.eia.gov/conference/2010/session9/granade.pdf](http://www.eia.gov/conference/2010/session9/granade.pdf).)

Rocky Mountain Institute in Colorado, estimates that the total potential of energy savings due to efficiency improvements in the industry sector in United States by 2050 could be as much as 30% of energy use under the business as usual scenario (see Figure 1.23).

Improving energy efficiency across all sectors of the economy should become a worldwide objective (Energy Commission, 2004). It should be noted, however, that free market price signals may not always be sufficient to effect energy efficiency. Hence, legislation on the state and/or national level for energy efficiency standards for equipment in the residential and commercial sector may be necessary. There is considerable debate whether incentives or mandates are the preferred way to improve energy efficiency. Such measures may be necessary because surveys indicate that consumers consistently rank energy use and operating costs quite low on the lists of attributes they consider when purchasing an appliance or construct a building. Incentives may be the preferred option provided they induce decision makers to take appropriate action.

Figure 1.24 shows the projected energy savings from upgraded standards for products installed in the years 2010–2020. Outside the United States, over 30 countries have also adopted minimum energy performance standards. These measures have been shown to be economically attractive and can provide an appreciable reduction in adverse environmental impacts.

This handbook describes energy efficient improvements achievable with available technologies. The challenge is to adopt policies that accelerate the adoption of these technologies all over the world.

FIGURE 1.23

U.S. industry energy savings potential (2010–2050) as a percentage of the total industrial energy use in business as usual scenario. ## 1.8 Forecast of Future Energy Mix

As explained in this chapter, it is clear that oil production will peak in the near future and will start declining thereafter. Since oil comprises the largest share of world energy consumption, a reduction in availability of oil will cause a major disruption unless other resources can fill the gap. Natural gas and coal production may be increased to fill the gap, with the natural gas supply increasing more rapidly than coal. However, that will hasten the time when natural gas production also peaks. Additionally, any increase in coal consumption will worsen the global climate change situation. Although CO<sub>2</sub> sequestration is feasible, it is doubtful that there will be any large-scale application of this technology for existing plants. However, all possible measures should be taken to sequester CO<sub>2</sub> from new coal-fired power plants. Nuclear power does not produce CO<sub>2</sub>, however, it is doubtful that nuclear power alone will be able to fill the gap. Forecasts from IAEA show that nuclear power around the world will grow at a rate of 1.2%–2.7% over the next 25 years (IAEA, 2013). This estimate is in the same range as that of IEA.

Based on this information it seems logical that the RE technologies of solar, wind, and biomass will not only be essential but will hopefully be able to fill the gap and provide a clean and sustainable energy future. Although wind and photovoltaic power have grown at rates of over 30%–35%/year over the last few years, this growth rate is based on very small existing capacities for these sources. There are many differing views on the future energy mix. The IEA gives forecasts based on different policy scenarios. Figure 1.25 shows the growth in primary energy demand and the corresponding CO<sub>2</sub> emissions for the

**FIGURE 1.25**

World primary energy demand by fuel types. (According to IEA, *World Energy Outlook 2013*, International Energy Agency, Paris, France, 2013.)

**FIGURE 1.26**

World primary energy demand by fuel in new policy scenario. (From IEA, *World Energy Outlook 2013*, International Energy Agency, Paris, France, 2013.)

three scenarios. Figure 1.26 shows the demand by fuel type in the “New Policy Scenario,” in which renewable energy will provide 18% of the primary energy demand by 2035. However, in the “450 Scenario,” renewable energy share goes up to 26% by 2035. This estimate is close to the estimate by the German Advisory Council on Global Change (WBGU), which performed a detailed analysis on combating global climate change with an orderly transition to increased energy efficiencies and increased use of renewable energy. WBGU estimates that as much as 50% of the world’s primary energy in 2050 will come from renewable energy, increasing to 80% by 2100 (Figure 1.27). However, to achieve that level of RE use by 2050 and beyond will require a global effort on the scale of Apollo Project.

**FIGURE 1.27**

The global energy mix for year 2050 and 2100. (According to WBGU, *World in transition—Towards sustainable energy systems*, German Advisory Council on Global Change, Berlin, Germany, 2003, Report available at <http://www.wbgu.de>.)

This chapter presents examples that illustrate the economics of energy efficiency and renewable energy systems. Further sections of this chapter delve more deeply into United States and international financial energy policies.

Financial policy for energy efficiency and renewable energy technology is simply based on comparing the cost of the device with the monetary savings resulting from its deployment. In the present setting, the cost of power from the renewable energy system must be less than the cost of power from fossil fuels in order to be economically competitive.

The problem, of course, is that, at this stage in the development of civilization, these events seldom occur naturally. In most cases, the cost of energy efficiency devices exceeds the savings. Likewise with renewable energy: it usually costs more than fossil energy.

If you want people to buy energy efficient “on-demand” (tankless) water heaters, for example, which cost, let’s say, \$800 more than the conventional system, then the energy savings must be more than \$800 over a reasonable period of time.

Same sort of thing is true about renewable energy. There is a gentleman who owns property on Lake Chautauqua in New York. He recently installed a geothermal heating system that cost him \$60,000. The man wrote a check for \$60,000! The savings on his electricity bill is \$1000/month. He is very proud of the fact that—using straight accounting numbers—he will get his money back in 60 months, or 5 years.

Not many of us can write a check for \$60,000. So, let us drop our example down an order of magnitude to \$6000. Say we are offered a geothermal system for that sum that will save

us \$100 a month on our energy bill. Would you write a check for \$6000? Would you be willing to wait 5 years to get your money back? Most people would not. Furthermore, if you put the \$6000 into a CD at 3% for 5 years you would have \$6955.64. So it's not really just \$6000 that you're out; it's \$6955.64. It will take you more than 5 years to break even. Closer to six.

Instead, you could get a \$6000 second mortgage for 5 years at 7%. If so, you would be paying the bank \$118.81 a month while you are saving only \$100. In other words you'd be losing \$18.81 a month for 5 years. So at the end of the 5 years, you'd still be out \$1216.\* You'd still have to wait another 13 months to break even.

The point here is that very, very few people will wait 60 or 73 months to get their renewable energy investment back. Likewise, people who buy energy efficiency devices don't want to wait several years to get their money back. So, if people want to get serious about energy efficiency and renewable energy they must—if a government or financial institution—create finance programs that deliver the goods at prices below the expected savings. If they are businesses or NGOs, they must seek out these programs and lobby their state, federal, and local legislators to create such programs.

When the wealthy gentleman in Chautauqua signed his \$60,000 check and started saving his \$1,000 a month, he was probably unaware that in several states other than New York there were government programs that would have financed his geothermal project for about \$375 a month with \$0 down. This means that in month one he would have spent \$375, but saved \$1,000.

In our lesser example, the county would have financed our \$6,000 project and charged us \$37.50 a month, meanwhile we would be saving \$100 a month. Don't you think that many, many more people are likely to take on renewable energy projects when the savings kick-in on day one? So, now we just have to figure out how to design finance programs that do just that.

---

## 2.1 Some Sound Finance Principles for Creating Effective Finance Programs

Here are seven sound principles of finance for energy efficiency and renewable energy. First, we will list them and then discuss them individually.

1. *Leverage*: Leverage money. The most important word in improving environmental quality is "leverage."
2. *Guaranties*: Never make loans; guaranty them.
3. *Term*: Finance assets over the full term of their service lives.
4. *Subsidies*: Stop general subsidies, which waste billions of dollars. Target subsidies only to those who need them.
5. *Grants*: Never give grants unless absolutely necessary.

---

\* Discounting at 3%.

6. *Cost/benefit analyses*: Make financial decisions based on strict cost/benefit analyses. Get politics and chance out of the decision making matrix.
7. *Full-cost pricing*: Insist on full-cost pricing of environmental services. Full cost pricing will drive technological innovation. In turn, new technologies will drive down costs.

### 2.1.1 Leverage

Many people think that leverage is some black art practiced by the charlatans on Wall Street. It's not. It's something we all use every day. We just don't call it that. For example, if you buy a \$250,000 home with a \$50,000 down payment and a \$200,000 mortgage, you will have achieved a 5:1 leverage on your home purchase. If you can get away with putting only \$25,000 down and get a \$225,000 mortgage, then you'll have achieved a 10:1 leverage ratio. Sounds sinister to you? Of course not.

Same is true if you buy a \$20,000 car with a \$2,000 down payment and finance the balance. You will have achieved a 10:1 leverage again on this transaction. When car dealers get desperate, they often offer cars with no money down. In that case you can achieve infinite leverage. Black magic? No. Not even life in the fast lane. As a matter of fact, leverage is pretty common.

In these examples, the institution that provided the leverage was a bank. Think instead of the U.S. bond market, which was estimated to be \$35.2 trillion in the second quarter of 2011 by the Securities Industry and Financial Markets Association, or the international bond market, which is close to \$90 trillion. As far as energy efficiency and renewable energy projects are concerned, these international capital markets can provide almost a limitless source of funds.

Now, what's the impact on the projects—or in our examples, the homebuyer or the car buyer? Ask yourself this: if two car dealers offered you the same vehicle with financing for the same term at the same rate of interest but one wanted \$4000, or 20%, down and the other wanted \$0 down, which would you choose? Exactly! The one with the greatest leverage. And that is precisely why it is so important to design renewable energy and energy efficiency programs with the greatest possible leverage.

### 2.1.2 Guaranties

The best way to achieve truly extraordinary leverage is to use financial guaranties instead of making direct loans. Let us illustrate this by comparing four most common types of government finance programs: grants, subsidized loans, market-rate loans, and guaranties. To do this, we will set up a little game.

#### 2.1.2.1 Rules of the Game

1. Government contributes \$100,000,000 to the New Energy Fund (NEF)
2. Project size: \$5,000,000
3. Term: 5 years
4. Payment terms: Level Principal Method
5. Interest rate on subsidized loans = 0%

6. Interest rate on market-rate loans = 10%
7. Interest rate on guaranty fund = 5%
8. Leverage ratio\* paradigm†:

Number of Loans	Coverage (%)
0–20	100
20–30	90
30–40	80
40–50	70
50–60	60
60–70	50
70–80	40
80–90	30
90–100	20
100+	10

In our game, the legislature gives your finance agency \$100 million and tells you to use it to finance as many energy efficiency and renewable energy projects as possible. So, you look at a grant program, a subsidized loan program, a market-rate loan program and a loan guaranty program.

The following table compares the effectiveness of these four financing techniques.

Year	0	1	2	3	4	5	6	7	8	9	10
<i>Comparison of NEF financing schemes</i>											
Total grants made	20	0	0	0	0	0	0	0	0	0	0
Total subsidized loans made	20	24	28	34	41	49	55	61	68	74	81
Total market rate loans made	20	26	33	42	53	66	79	93	109	126	145
Total guaranties issued	20	27	34	45	60	80	94	119	180	435	543

Let's turn these project numbers into project costs by multiplying the number of projects by \$5 million:

Grants	20	\$100,000,000
Subsidized loans	81	\$405,000,000
Market-rate loans	145	\$725,000,000
Loan guaranties	543	\$2,715,000,000

Just look at that! \$2,715,000,000 worth of energy projects! 543 projects financed! All for the same \$100,000,000 that bought you 20 grant projects!

\* In this example, the leverage is the ratio of guaranteed loans outstanding to money in the bank pledged to cover them.

† Estimating coverage between the minimum (>20) and the maximum (<100) loans is a totally inexact science; but what is presented certainly suffices for our illustrative purposes.

Loan guaranty programs are so efficient because they incorporate leverage. Leverage, as you already know, is the ability to increase the effect of the use of money. The same sum of money (\$100,000,000) was used in each financing scheme. Under the subsidized loan program, there was modest leverage because the funds were paid and could be re-loaned for another project. Thus, the same amount of money could be used twice. This is leverage.

In market rate loan program, there was additional leverage because not only was the \$100,000,000 of principal repaid, but 10% interest was also paid each year. So, this increased the leverage.

With loan guaranties, even greater leverage occurs because of the principle of insurance. A guaranty is the same as an insurance policy.

A loan guaranty program insures “prompt and full payment” of debt. It works just like an insurance policy. With \$100,000,000, a fund such as the NEF should easily be able to guaranty over \$1,000,000,000 of projects at any one time, because of the extreme unlikelihood that more than 10% of its projects would ever go into default at any one time. Thus, if the NEF were to guaranty commercial bank loans for \$1,000,000,000 of projects, and 10% or \$100,000,000 of them were to default, the NEF could still make good on its guaranties by paying the banks holding the defaulted \$100,000,000 held in their reserve account.

Thus, from the point of view of a government wishing to finance energy efficiency or renewable energy projects, the creation of a loan guaranty program would be—by far—the most effective use of its funds.

### 2.1.3 Term

When most people talk about “low-cost” government finance programs they are almost always referring to a low interest rate. The world’s most successful environmental finance program, the Clean Water State Revolving Fund (SRF) at EPA, routinely offers low-cost financing, which—to them and their borrowers—means loans with low interest rates. In SRF’s case they offer loans at about 50% of market rates. So, if the market rate on a 20-year, AAA/Aaa tax-exempt municipal bond is 4%, an SRF will offer loans at 2%. If the market rate is 6%, SRFs will finance at 3%, and so on.

Now, to be able to offer sub-market rate loans requires the SRFs to subsidize such loans. This is an egregious waste of money. Here’s why.

The reason for the low rates/subsidies is so that sewer-user fees can be minimized. Right? Now watch this.

The annual payment on a 20-year loan of \$1 million at 2% is \$61,157.

The annual payment on a 30-year loan of \$1 million at 4% is \$57,830.

Even if the 30-year market rate is a bit higher, say 4.5%, the annual payment is \$61,392, which is only \$235 higher. That’s \$235 a year—not a month—on a \$1,000,000 loan. Peanuts!

The point here is that you can have a much more effective program if you lengthen the term rather than subsidizing an interest rate. Furthermore, you save all of the money wasted on the needless subsidies.

Now we will compare annual payments on identical loans with different terms. We will do so with both types of loans: level principal payment loans and level payment loans.

The following table sets forth the first years' annual payments on a \$100 loan at several different interest rates over several different terms. The first table deals with level principal payment loans. The second deals with level payment loans.

Interest Rates	0%	5%	10%	15%	20%
<i>Term</i>					
1 year	\$100	\$105	\$110	\$115	\$120
2 years	\$50	\$55	\$60	\$65	\$70
3 years	\$33	\$38	\$43	\$48	\$53
4 years	\$25	\$30	\$35	\$40	\$45
5 years	\$20	\$25	\$30	\$35	\$40
10 years	\$10	\$15	\$20	\$25	\$30
20 years	\$5	\$10	\$15	\$20	\$25
30 years	\$3	\$8	\$13	\$18	\$23
40 years	\$2.50	\$7.50	\$12.50	\$17.50	\$22.50

Please note the hugely significant impact that term has on the annual debt service payments for these loans.

And, now we turn to the level payment method.

The impact of term on annual debt service payments is as significant when the level payment method is used as when the level principal payment method is used.

Interest Rates	0%	5%	10%	15%	20%
<i>Term</i>					
1 year	\$100	\$105	\$110	\$115	\$120
2 years	\$50	\$54	\$58	\$62	\$65
3 years	\$33	\$37	\$40	\$44	\$47
4 years	\$25	\$28	\$32	\$35	\$39
5 years	\$20	\$23	\$26	\$30	\$33
10 years	\$10	\$13	\$16	\$20	\$24
20 years	\$5	\$8	\$12	\$16	\$21
30 years	\$3	\$7	\$11	\$15	\$20
40 years	\$2.50	\$6	\$10	\$15	\$20

A final word about lengthening term. How long is too long? The answer—which is an axiom of public finance—is that assets should be financed over terms commensurate with their service lives. Home insulation, for example, lasts as long as the home it insulates: so 30 years. I understand solar panels last 20 years. So, finance them over 20 years. Geothermal projects last forever, almost. So, again, 30 years should be no problem.\*

## 2.1.4 Subsidies

When a normal person thinks of subsidies, one usually thinks of helping the poor pay for things they can't afford. Right? Well, in the energy infrastructure game, being poor has

\* Although many assets have service lives longer than 30 years, the municipal bond market thins out considerably beyond that period. So, better to sell into a 30-year market with lots of buyers than a 30-plus-year market with relatively few.

nothing to do with subsidies...most of the time. Take the case of Loudoun County, Virginia, which has the highest Median Household Income (MHI) in the country. Their MHI was about \$119,000 in 2011. That was the *median*. That means that 50% of the households earned *more than \$119,000*. Let us now imagine the household with the absolute highest income in Loudoun County. Would it surprise you to learn that the families receive subsidies from the Commonwealth of Virginia? Well, they do.

A very wise mentor of mine breaks down subsidies into two main categories. The first is “general, supply-based subsidies.” That’s what you see in Loudoun County. The second category is “targeted, demand-based subsidies.”

Think of a young family out west who lives in a double-wide, have household income of about \$22,000 a year, has two young children, one with asthma, and lives in a valley that in terms of air quality is classified as a nonattainment area because of the wood smoke that hangs constantly over their valley like the sword of Damocles. The only heat the young couple has in their home is an old wood stove. When it gets cold, they have to light it. But when they light it, they are slowly killing their little girl with asthma. A few years ago, there was a \$1500 tax credit program for—among other things—replacing old wood stoves. Now, our young couple can’t use a tax credit. They don’t pay taxes. Their income is too low. The tax credit is useless to them. On the other hand, their wealthy neighbors with weekend cabins on the tops of the mountains can use it. But not people, like our young couple, who really need help. So, instead of this wasteful general subsidy, how about a 100% cash rebate (subsidy) for people: (1) living in nonattainment areas, (2) below the poverty line, (3) with no other source of home heat, and (4) with a resident with a pulmonary ailment. Now, these exceedingly narrow criteria may be a bit over the top; but you see what we mean by a “targeted, demand-based” subsidy.

Now let us show you how truly wasteful general, supply-based subsidies are, by illustrating the point with the most infamous example of all: the tax-exempt municipal bond.

In 1895, the U.S. Supreme Court ruled that the Congress had no power under the Constitution to tax the interest on state or local debt.\* In 1913, this position became statutory.

In the municipal bond market, the rule of thumb is that the best (AAA/Aaa) municipal bonds should have interest rates of about 75% of United States.<sup>†</sup> Treasury bonds of the same term. So let us envision an interest rate environment where, say, 20-year treasuries carried an 8% interest rate. Under these circumstances, you would expect AAA/Aaa tax-exempt municipal bonds to carry a rate of about 6%. Now, let us say that the 8% Treasury was bought by the richest householder in Loudoun County. We’ll call her Ms Loudoun. If she bought \$10,000 of these bonds, she would receive \$800 a year in interest. Being in the 35% tax bracket, Ms Loudoun would pay \$280 in federal income taxes, and so have net earnings of \$520.

Now, let us say, instead, that Ms Loudoun bought \$10,000 of tax-exempt bonds at a 6% interest rate issued by the Commonwealth of Virginia. In this latter case, Ms Loudoun would receive \$600/year in interest. Because this interest is exempt from federal income taxation, Ms Loudoun gets to keep the whole \$600. She doesn’t pay a penny of that \$600 in taxes.

So, we now know that if Ms Loudoun bought the 6% tax-exempt bond, she would be \$80 better off than if she had bought the 8% Treasury and paid taxes on it.<sup>‡</sup>

\* This case, *Pollock vs. Farmers’ Loan & Trust Co.*, was effectively overruled by the Supreme Court in 1988 in *South Carolina vs. Baker*. But the statutory prohibition remains intact.

<sup>†</sup> As of this writing, as the damage from the sub-prime mortgage crisis is still being felt in the financial markets, this 75% ratio isn’t true. Today it’s about 120%. But the 75% number is a decent historical ratio.

<sup>‡</sup> Some Ms Loudouns might choose to forego the extra \$80 because treasuries are a safer investment than munis. Or at least, that’s how the story goes on Wall Street.

But what about the \$280 that the U.S. Treasury *didn't get, that they missed out on*. Let's look at it this way. There are 535 members of Congress. Each one receives a salary of \$174,000/year. That means there should be \$93,090,000 in the Congressional payroll account at the beginning of the fiscal year. Let us say that this account is \$280 short because Ms Loudon opted not to buy the treasury bond. If this were really the case, panic would sweep Capitol Hill! Congress would undoubtedly immediately pass a bill to raise some tax by \$280 to make up the shortfall. Who would pay that tax? You and I would—as would the poorest tax-paying family in Buffalo County, South Dakota, the poorest county (by MHI)\* in the country.

Targeted subsidies for our poor young couple with the sick little girl? Yes.

General subsidies for Loudon County and our wealthy cabin owners? No.†

### 2.1.5 Grants

Grants are subsidies. So they should only be used in relatively rare circumstances. And, as we learned earlier, they should be tightly targeted.

The four legitimate uses of grants are as follows:

1. *Paying for environmental services that are not affordable, either to individuals or communities:* Remember our young couple with the sick little girl. They desperately needed to buy a new wood stove to keep their home warm and their baby daughter healthy. What form of government assistance was available to them? A tax credit, which they were too poor to use. What did they need? A grant. Either a 100% grant, or something very close to 100%. That is an example of a good use of grants for individuals.

A good example of a sound community grant is in the case of the USDA water and wastewater program. Here, when the USDA sees that a project costs a significant share of MHI and will make rates higher than in surrounding districts, then the USDA uses grant money to buy down the cost of the project to levels where it will be affordable to the average ratepayer. Targeted grants for communities. Good finance policy.

2. *Inducing people or businesses to make environmental improvements that they are not legally required to do:* When the American Reinvestment and Recovery Act (ARRA) was passed in 2009 to help us get out of the sub-prime mortgage disaster, renewables were just beginning to be a major buzzword. ARRA included substantial grant funds for those who would reduce their carbon footprint by installing solar panels. No one was required to install any kind of renewable or energy saving devices. So, the government paid them to do so. Good idea.

Cover crops are another good example. After crops are harvested, a large amount of nitrogen remains in the soil. Over the Winter, with snows and rain on the now-bare soil, much of this nitrogen migrates to the nearest water body where it pollutes it. Cover crops are planted after the main crop is harvested. Their sole purpose is to sop up nitrogen left over in the soil to prevent it from polluting any streams or ponds. In the United States, we pay (i.e., give grants to) farmers who will plant cover crops. These grants come out of the “farm bills” that the Congress passes to maintain its elaborate scheme of subsidies for agriculture. In Germany,

\* The MHI in Buffalo County, South Dakota is \$12,692.

† Although the probability of ending tax-exempt bonds is close to zero.

they have a cover crop program too. It is also a grant program, but in Germany the grants come from a special tax that is collected each year. The point here is that planting cover crops is a good thing. But doing so is entirely voluntary. There is no law—anywhere—requiring farmers to plant cover crops. So, we should use grants to persuade them to do so.

3. *Creating or commercializing new environmental technologies.* Until most recently, it was not cost-effective to install solar panels. Even with generous government financing programs, the monthly cost of the panels exceeded the savings in electricity from the panels. In order to jump-start the solar industry, the U.S. Department of Energy started a grant (i.e., a subsidy program) for solar panel manufacturers. China did the same. However, the Chinese subsidies were so large that the Chinese manufacturers were able to sell their solar panels below the cost of production. The Chinese government created subsidies so that their manufacturers could export all over the world, creating thousands of good manufacturing jobs in China in the process. The United States, European Union, and China are now embroiled in a trade fight over this issue. Regardless of the trade issue, using grants to jump-start new, needed, environmental technologies is a very good idea.
4. *Environmental/Energy Education:* Giving out smallish grants is a good way to get community groups to take an avid interest in energy efficiency and the environmental issues such as climate change. This is especially so for poorer groups that can't readily raise funds for projects themselves. Maryland has a grant fund called the Chesapeake and Atlantic Coastal Bays Trust Fund, which most natives call the "green fund." This fund is relatively small but it gives out grants to community groups for such activities as streambed restoration, tree plantings and the like. Educating people about the value of the environment and the steps necessary to protect it is certainly a valid expenditure of public funds. And, in this case, it really needs to be grant funds.

### 2.1.6 Cost/Benefit Analyses

Cost/benefit analyses are extremely important for two allied reasons. First, to make sure money for projects or energy efficiency devices is wisely spent, and second, to convince the public of the same, so that they will support these types of programs.

In the field of financing water and wastewater facilities, these analyses can get complicated. They involve the collection of empirical data from the general public, which, in some less-developed countries, is not easy to come by. But for energy efficiency devices and renewable energy, they are quite simple—at least in theory.

In the case of energy efficiency devices, the benefit is the number of kilowatt hours saved. In the case of renewables, it is the number of kilowatt hours generated.

The cost, for energy efficiency devices, is the price of the device paid over the service life of the device at the lowest possible rate of interest.

This is easy for such devices as light bulbs. You know the four critical pieces of information to complete the cost/benefit analysis. You know the lumens the bulb will put out. You know the watts the bulb uses per hour. You know the service life of the bulb in hours (at least as estimated by the manufacturer). And you know the cost of the bulb. With these four pieces of information you can conduct a cost/benefit analysis on these bulbs and thus compare them to get the best value.

The cost for renewables is the installed cost of generating a kilowatt *hour* of electricity. This is a little different. Most people rate installed power by the kilowatt, not the kilowatt hour. But many renewables, such as wind or solar, don't generate power on a constant basis. They generate intermittently. Here is a very simplified example, omitting, among other things, the cost of maintenance.

Let us say two homeowners, one in Buffalo, New York, the other in Las Vegas, Nevada, each purchase a 4 kW solar array at an installed cost of \$5/W, or \$20,000/W. Let us say they each finance them for a 20-year term at an interest rate of 5% for an annual payment of \$1605. Las Vegas has an average of 3825 h/year of sunlight. So, our homeowner in Las Vegas is paying \$0.42/kW h.

On the other hand, Buffalo gets 2207 h of sunlight a year. So, our Buffalo homeowner pays \$0.73/kW h.

So, you see why we need to use kilowatt HOURS, not just kilowatts to rate renewable energy projects.

### 2.1.7 Full Cost Pricing

As you already know, environmental utility costs are heavily subsidized. This does no one any good. If there are poor people who cannot afford their water or sewer bill, there are several strategies to effectively and compassionately deal with that.

Now the rest of the ratepayers who *can* afford the full cost of their service should definitely pay for it. No one likes to pay more. No board member or politician likes to raise rates. But rates can be raised gradually. (And when raising rates over, say, 5 years, the authorizing resolution should be passed today for all forthcoming increases. This will save the board and/or politicians the anguish of having to go back to the people every year for more money.)

Raising rates, whether to full-cost pricing levels, or not, will promote conservation. The higher the rate increase the more people will conserve. Think of raising our gasoline rates to the \$7+ a gallon rates they charge in Europe. People would definitely find ways to drive less. Car manufacturers would smarten up too. Ditto when you raise power rates. People find ways to use less.

Finally, higher rates will also drive innovation, which will have the eventual effect of lowering costs. Take the example of installing a technology that costs \$10 million at a system with full-cost pricing, that is, no subsidies. Engineers and scientists will know that if they can create a technology that does the same or better job at the same or lower cost, they can get into the game without being trumped by some hidden subsidy.

So, these seven principles should be used to guide the creation of any finance programs for renewable energy or energy efficiency.

Now that you know how to spend money most efficiently, please consider a few more principles—these to raise the money that you will spend most efficiently.

1. Raise money from many small charges, fees or taxes—not one big one. Many small sources of money are more stable than one large one. A small tax or surcharge on vehicle registration based on its fuel consumption. A carbon tax loaded into electricity bills.
2. Once collected, put all the environmental money in one basket. Do not fragment or piddle it away.

3. Change behavior while raising money. Do not tax all equally; tax the polluters more while rewarding energy efficiency and green practices. The vehicle/fuel consumption surcharge discussed earlier and the carbon tax will send effective messages to consumers, car manufacturers, and power companies.
4. Use “dedicated revenue streams” (such as annual taxes or fees) to finance capital, not operational, expenses. Such revenue streams that derive from charges like the vehicle/fuel consumption and carbon tax are highly regular and predictable. As such, they constitute an excellent, high quality source of repayment for bonds issued to finance energy efficiency and renewable energy projects. With proper structuring, they can be used to achieve the highest, AAA, ratings on bonds, which result in the lowest possible interest rates. Furthermore, these solid revenue streams don’t actually even need to be used to repay bonds to achieve AAA ratings! They can just be pledged to repayment! In other words, let us take the example of a small business energy efficiency/renewable energy program. Small businesses are not known for stellar credit ratings. Moreover, since many small businesses rent their premises, there is no real property that can be used as collateral. In this case, a bond containing a portfolio of uncollateralized loans to small businesses would get either no rating or a triple zilch rating. In this case, the bonds could be structured with the loan receivables as the primary source of repayment and the revenue stream as a secondary source of repayment, that is, the revenue stream would be called upon if, and only if, a small business defaulted on its loan.
5. Make it as painless as possible. At the federal level, raising the rates on a general tax—like the income tax—will set up howls of protest across the country. It will mobilize armies of lobbyists in Washington who will roam the halls of Congress wheedling and bullying the members to oppose it. At the state level, the same phenomenon will occur if there is an income tax increase proposal or a real property tax increase proposal. Virtually, every newspaper in the state will editorialize against it. And the lobbyists will mob the state legislature. The more opposition, the less likely that an effective environmental finance program will be adopted.

The title of this chapter is “Sound Finance Policies for Energy Efficiency and Renewable Energy.” These seven principles should be used not only to design programs that spend money on energy efficiency and renewable energy projects in a highly efficient manner, but also on how to raise money for such programs in a highly efficient manner as well.

### 3.1 Tax Incentives

Tax incentives have provided a key form of direct subsidy to renewable energy and energy efficiency in the United States at both the state and federal levels. These incentives can take several forms, including deductions from taxable income or a credit against tax liability. In addition, tax credits can be applied to the initial purchase or investment in a particular technology, or to the ongoing utilization of a technology or production of a covered commodity. In some cases, lower efficiency investments can be subject to additional taxes.

#### 3.1.1 Investment

Renewable energy and energy efficient technologies are typically characterized by higher upfront costs resulting in significantly reduced fuel and/or operating costs (although not all technologies fit this characterization, e.g., biomass energy can involve substantial ongoing costs for fuel and operations). Many early policy incentives at both the Federal and state levels were intended to reduce the acquisition cost of these technologies, frequently through the use of tax credits proportional to capital investment costs. In some cases, such as some of the early deployment of wind generating technology in California during 1980s, it was believed that investment incentives provided insufficient incentive for high-quality technology or projects that would continue to operate once the initial incentive had been fully realized by the project owner. Such failures, however, may also be attributed to insufficient technology qualification measures, such as technology criteria or screening.<sup>1</sup>

Despite the apparent shortcomings of investment incentives in the early U.S. wind industry, these continue to see widespread use in both federal and state policies for other renewable energy and energy efficiency technologies.

Federal tax incentives proportional to the investment in renewable energy technologies played a significant role in the early adoption of these technologies during the 1980s. Originally adopted as part of the Energy Tax Act of 1978, permanently set at 10% for solar and geothermal facilities by the Energy Policy Act of 1992 (EPACT 92), and currently 30% for solar facilities through 2016, the investment tax credit directly offsets federal corporate income tax liability in proportion to the initial investment cost of the covered technology.<sup>2</sup> Current federal law also allows technologies eligible to receive the production tax credit (PTC) (see the following section) to instead receive a 30% investment tax credit. In addition, most renewable electricity generating technologies are also able to benefit from preferential federal tax depreciation allowance schedules. The Modified Accelerated Cost Recovery Schedule allows much faster depreciation of renewable generation investment costs than is allowed for other generation technologies, using a 5-year schedule rather than a 15- or 20-year schedule for combustion turbines or other thermal plants.<sup>3</sup>

Some states also have or have had tax incentives on the investment in renewable energy or energy efficiency. Additional investment tax credits in California during the 1980s, along with other policies such as the Public Utilities Regulatory Policy Act discussed in Section 3.2.2, helped spur the early adoption of wind and solar thermal generating capacity in that state.<sup>4</sup> Several states currently offer substantial investment tax credits to preferred renewable energy technologies, such as photovoltaic (PV) systems.<sup>5</sup> These credits, however, are not uniformly offered, vary significantly among states that do offer them, and may apply to electric generating technologies or to facilities that produce renewable fuels, such as ethanol. Rebates or exemptions from state-imposed sales taxes on both renewable technologies and energy-efficient appliances and equipment also offer a mechanism to reduce the first-cost of adopting these technologies by the end-user. Availability of such programs varies significantly among states, as do the sales-tax rates and the value and timing of a rebate or exemption where offered.<sup>5</sup> Sales-tax rebates may also, or instead, apply to a renewable fuel, such as biofuel. In this context, such a program may have an effect closer to that of a production incentive rather than an investment incentive. Certain vehicles with low gas mileage will incur a “gas guzzler” tax, which acts as a disincentive for low-efficiency technology investment.

### **3.1.2 Production/Utilization**

Production-based tax incentives provide a tax credit proportional to the quantity of commodity, such as electric generation, produced or sold in a given year. Since production-based incentives reward project performance, they should tend to transfer project performance risk to the project owner, rather than the taxing authority, and without the need for extensive qualification criteria or screening of each project or technology. However, technologies that do not produce easily marketable (and hence taxable) output, such as most energy efficiency technologies, or where the output is generally consumed on-site (without a third-party transaction), such as on-site PV, may be not be amenable to a production-based incentive. In these cases, there may not be a sufficiently auditable record of production or the establishment of such an auditable record (such as internal metering of PV output) may add unwanted cost to a project.

The PTC for renewable electricity, Section 45 of the U.S. Internal Revenue Code, established by EPACT 92 and subsequently modified, provides an inflation-adjusted payment, 2.3¢/kW h in 2013, for the third-party electricity sales from the plant during the first 10-years of operation. The range of technologies eligible for the tax credit has been expanded since its inception, and now includes wind, several types of biomass resources, geothermal, and landfill-gas. However, some technologies do not receive the full credit amount or the same 10-year claim period.<sup>6</sup> The PTC has generally been credited with contributing to the significant growth in U.S. wind power since 1998. Having been allowed to expire and subsequently extended several times, the credit expired for projects starting development after December 31, 2013.<sup>7</sup> A number of states also offer tax credits on the production of preferred renewable energy sources.<sup>5</sup>

A tax credit of \$1.00/gal for biodiesel and \$0.50/gal for other qualified alternative fuels, including certain biomass-derived fuels, expired at the end of 2013.<sup>8</sup> A number of states also have tax credits for the production of ethanol or other renewable fuels. These credits may reduce income tax liability or, like the federal credit, be applied to a motor fuels tax (in effect, a sales-tax rebate). State programs vary by credit amount as well as by restrictions on local origin of the fuel.<sup>5</sup>

---

## 3.2 Regulatory

Regulatory mechanisms generally establish restrictions on market activity that are intended to result in increased adoption of policy-preferred technologies or limitation on policy-undesired technologies. Costs are typically borne directly by market participants, or by either energy producers, consumers, or both. Although regulatory policy may affect markets in many ways, this section will examine three major types of regulatory intervention: target-based standards, market facilitation or limitation policies, and technology specification standards.

### 3.2.1 Target-Based Standards

Target-based standards establish a target metric of renewable energy or energy efficiency achievement and require regulated industry to achieve the goal. The most important types of goal-based standards in U.S. energy policy are renewable electricity targets established by the various states, the Renewable Fuels Standard (RFS) for transportation fuels, and automotive fuel efficiency standards established by the federal government.

Renewable electricity targets can take the form of absolute levels of capacity (or generation) or of a specified fraction of some future level of total generation (or capacity). Generally called renewable portfolio standards (RPS), these targets can be targeted for a single future year or can be based on a gradually increasing compliance schedule. Renewable energy goals—found in a few states—can mimic RPS programs, but generally lack enforceability provisions, and thus cannot be considered as regulatory policy.<sup>9</sup> RPS policies can require absolute compliance by affected utilities, or, as frequently occurs, can allow the accumulation of “renewable energy credits” (RECs) that can facilitate either inter-temporal compliance “banking” (i.e., using RECs earned in 1 year to meet compliance targets in another year) and/or inter-utility or inter-state credit trading (whereby a utility that over-complies may

sell RECs to a utility that cannot meet targets with native resources). Most states with RPS policies limit the geographic source of compliance to in-state resources, resources within the electric power pool(s) that service the state, or resources that can be “delivered” to the state or state power pool. The prevailing selling price of RECs may also be used to calibrate a penalty or alternative compliance payment, typically in the form of a price ceiling at which the state will provide RECs (without actual renewable capacity or generation) or otherwise waive actual compliance. Such “safety-valve” prices are generally intended to provide a clear maximum impact on general electricity prices. Other states may have a “safety valve” that explicitly limits compliance based on realized electricity rate impacts, and in some states compliance may also be waived or delayed for other, statutorily sanctioned reasons, such as protecting the financial solvency of affected utilities. Policies among states also show significant variation in resource eligibility, “grandfathering” of existing capacity, and mechanisms to show preferences among eligible technologies, such as awarding “bonus” credits or having differentiated targets for preferred technologies.<sup>5,12</sup>

The federal RFS was established by the Energy Policy Act of 2005 and the Energy Independence and Security Act of 2007. It establishes volume-based targets for ethanol and advanced biofuels, increasing each year through 2022. By this year, the RFS will require the use of 36 billion gal of renewable fuel. The law ensures the use of a variety of fuel types by limiting the amount of conventional ethanol (ethanol derived from corn) to be used for compliance and setting volumetric targets for various advanced biofuels. Advanced biofuels include fuels derived from “cellulosic” feedstocks and can include ethanol, biodiesel, “drop-in” fuels, and other qualifying formulations. Compliance is tracked through the use of Renewable Identification Numbers (RINs) assigned to each batch of qualifying fuel entering the market. RINs can be banked or traded to facilitate compliance.<sup>10</sup>

In 1975, the federal government established a target of doubling the fuel efficiency of the automobile fleet within 10 years. To implement this target, the aggregate sales of each manufacturer selling cars in the U.S. market had to achieve a set schedule for Corporate Average Fuel Economy (CAFE). In 2007, the law was updated, and, in 2012, regulations were issued to establish a target of over 40 miles/gal for passenger cars and light duty trucks by 2021 on a gasoline energy equivalent basis, potentially increasing to over 49 miles/gal by 2025.<sup>11</sup> With the current regulation, compliance for any given manufacturer is facilitated through credit banking and trading provisions. That is, excess credits earned in 1 year may be used to cover a shortfall in another year, or may be traded to another manufacturer to help cover their shortfall. Provisions to support the adoption of electric drive train vehicles may be adopted outside of the construct of the CAFÉ program.

### **3.2.2 Market Facilitation or Restriction**

Regulatory policy can also be used to facilitate or hinder a preferred or undesirable renewable energy or energy efficiency technology from participating in the market. Facilitation can take many forms, including the target-based and technology-specification approaches discussed in Sections 3.2.1 and 3.2.3. Other types of market facilitation can require non-discriminatory or even preferential market treatment of preferred technologies. Such policies operating at the federal or state level can include “feed-in tariff” (FIT) laws, net metering requirements, and interconnection standards.

In 1978, the Congress passed the Public Utilities Regulatory Policy Act (PURPA), which established the requirement that electric utilities must interconnect (i.e., accept generation feed from) small qualifying facilities that either co-generate process heat and electricity (combined heat and power or CHP) or utilize certain renewable resources.<sup>12</sup>

Furthermore, PURPA established a price floor for the power, known as “avoided cost,” subsequently defined to mean the cost of electricity that the utility otherwise would have purchased. PURPA, in theory, established a non-discriminatory framework for adoption of efficient industrial CHP and renewable electricity, established by the federal government, but largely implemented by state regulatory authorities. Some of the non-discriminatory market features that PURPA specifically applied to renewable and CHP facilities were subsequently applied to the broad class of all power generation technologies as federal electricity policy moved toward deregulation of the wholesale power market.<sup>13</sup>

Many states have adopted regulations at the retail/distribution level to require the acceptance of some renewable electricity feeds at an established price floor.<sup>5</sup> Such net-metering laws typically require load serving utilities to facilitate end-user connection of renewable distributed generation technologies (especially solar, but sometimes wind or other renewable or non-renewable technologies) on the customer side of the meter. When instantaneous generation from the local resource exceeds instantaneous customer demand, the meter is allowed to “run backward,” effectively causing the utility to purchase the excess generation at the prevailing retail rate. Most states limit the size of the distributed resource, sometimes by customer class, and may also provide limits on the total generation off-set allowed (e.g., the monthly or net annual bill may not be less than zero). Some states have also established limits on the number of customers or level of installed distributed capacity that may participate in net-metering.

More recently, a number of states, localities, and utilities have adopted FITs more similar to those found in Europe.<sup>5</sup> In the FIT model, the utility accepts the renewable feed, as with net metering, but also offers a premium payment over the consumer’s retail value of the generation. In some cases, these FIT programs are established by a state or local government, but in other cases, the programs are voluntarily established by the utility itself, and thus may not be, strictly speaking, regulatory policy.

### 3.2.3 Technology Specification Standards

Another common form of regulatory intervention for renewable and energy efficient technologies is the establishment of minimum product specifications, either as voluntary targets or mandatory limits on product performance. Such standards are seen as an effective approach to improving energy efficiency among individual consumers. Commercial and industrial consumers presumably have significant incentive to optimize energy efficiency for their operations to maintain or improve profitability. However, individuals, while still sensitive to energy prices, may have less motivation to seek out products with higher upfront costs to achieve lower ongoing energy costs. In some cases, market structures may affect consumer decision-making with respect to energy efficiency.

The federal Energy Star program allows qualifying products—ranging from computer equipment to household appliances, to commercial building equipment—to display the “Energy Star” logo on product advertising and packaging.<sup>14</sup> This serves as a proxy for disclosure, in that the consumer is thus aware that the product is “best-in-class” for energy efficiency (although for products not displaying the logo, the consumer cannot tell if this is because the product did not meet the specification or because the manufacturer did not participate in the program). Through the Energy Policy and Conservation Act and its various amendments, the federal government also establishes mandatory energy efficiency specifications, such as minimum levels of energy efficiency, for a wide array of consumer appliances, such as furnaces, air conditioners, light bulbs and fixtures, and kitchen

appliances.<sup>15</sup> At the state and local levels, energy efficiency standards may also be incorporated into building codes.

There are both federal and state regulations regarding transportation fuel composition that either directly or indirectly provide incentive for renewable fuels. In addition, the Clean Air Act Amendments of 1990 established a number of fuel specifications, including oxygenation, that vary by region and/or season.<sup>16</sup> Ethanol has emerged as a preferred oxygenate, especially in states with additional ethanol incentives or that have restricted the use of alternatives such as MTBE, but is also incentivized by the RFS. Restrictions on the sulfur content in diesel fuels may also encourage the use of “biodiesel” fuels derived from plant oils, if such fuels can be economically produced.

---

### **3.3 Research and Development**

Government research and development (R&D) funding for renewable and energy efficiency technologies can support the adoption of these technologies by facilitating cost reductions, higher efficiency, and improved utilization. R&D funding may occur at all stages of the technology development cycle, including basic science, bench-scale technology development, proof-of-concept demonstration, and pilot applications.<sup>17</sup> Government funds may be directed toward government-owned research laboratories, academic institutions, or industry participants. For many projects, especially those developing technologies closer to commercialization, the government will leverage its contributions by requiring substantial cost-sharing (either financial or in-kind) with industry participants.

---

### **3.4 Financing**

Government-assisted financing has also been used to support renewable energy and energy efficiency, both at the project level and at the manufacturing level. In particular, Section 1703 of the Energy Policy Act of 2005 and Section 1705 of the American Recovery and Reinvestment Act of 2009 established loan guarantee programs,<sup>18</sup> whereby the federal government would act as a third-party guarantor for qualified borrowers using the proceeds for allowed purposes, such as new project development or development of technology manufacturing capability. While no new loans may be authorized under Section 1705 authority, loans for advanced energy technologies (which may include some renewable technologies) may still be authorized under older Section 1703 authority.

The federal government has also provided financial assistance to publicly owned utilities and other governmental entities in the form of a tax-advantage bonding authority.<sup>5</sup> With such bonds, the government may borrow money, repaying only the principal to the bond holders. The bond holder receives interest payments in the form of income tax credits. Programs have been offered for Clean and Renewable Energy Bonds (CREBs) and Qualified Energy Conservation Bonds (QECBs). The CREB program had limited funding and is no longer accepting new project applications.

Several states also offer assistance with project or technology loans. A number of states and localities have also started financing distributed renewable energy projects (such as roof-top PV) using “Property Assessed Clean Energy” (PACE) financing. In PACE financing, the local government (typically) acts as the lender, allowing the project owner to repay the loan through an assessment attached to a property tax bill.

---

### 3.5 Other Direct Policy

Other common programs at the state and federal levels include direct payments (such as through grants or awards) and government purchase of these technologies. These mechanisms generally require continuing budgetary support, which may be provided from a dedicated revenue source, or may require periodic affirmation in appropriations process.

A number of states have established system benefit funds dedicated to supporting renewable energy and energy efficiency projects and technologies. Although varying greatly by state, these programs are typically structured to collect revenue based on an additional fee on retail generation or billing, commonly referred to as a systems benefit charge or public benefit fund.<sup>5</sup> As a result of EPACT and subsequent presidential orders, the various agencies of the federal government are required to obtain a share of their energy from renewable sources and reduce their consumption of energy per square foot of facility.<sup>19</sup> Finally, the federal-owned fleet of cars and other vehicles is required to meet requirements for both fuel economy and use of alternative fuels. Several local state governments have also established similar purchase or efficiency requirements for electricity or motor fuels.<sup>5</sup>

---

### 3.6 Indirect Policy

Numerous other policies at the state and federal levels, while not designed specifically to address renewable energy and energy efficiency markets, may have a significant or notable impact on these markets. Perhaps most significant among this broad category are efforts to regulate energy or other markets, manage government—or privately—owned lands, and protect the environment.

Efforts at the federal level to introduce competition in wholesale electricity generation markets, as well as in a number of states to introduce competitive retail electricity supply, have created the opportunity for electricity suppliers to sell “green” power—typically electricity produced from renewable, low-emission, or high efficiency technologies.<sup>20</sup> Such programs include competitive supply of clean or renewable power, special pricing for green power by regulated utilities, or the sale of the environmental attributes of renewable power apart from sale of electricity. In addition, the specific design of competitive wholesale markets for generation and transmission can impact the competitiveness of some renewable, especially intermittent resources such as wind.

Environmental regulation at the federal or state level, for air quality, water quality, solid waste disposal, land use, greenhouse gas emissions, and other pollution problems, can have substantial impact on both the cost and value of renewable energy and energy efficiency. The Clean Air Act Amendments of 1990 (CAA) provides the foundation for

cap-and-trade regulation of sulfur dioxide, and for emission limits on other pollutants.<sup>21</sup> While these programs do not always directly address the use of renewables or efficiency as a pollution avoidance mechanism, they do not necessarily preclude their use to reduce overall emissions. Other CAA impacts on renewable energy and energy efficiency include reformulated gasoline requirements discussed earlier, which have interacted with state-level groundwater protection efforts to provide a preference (in some states) for ethanol as a preferred fuel additive for CAA compliance. More recently, EPA has begun to use authorities in the CAA to regulate greenhouse gas emissions, which may have a more pronounced, if still indirect, impact on renewable generation resources. As a result of the Resource Conservation and Recovery Act, some landfill operations have been required to install collection and flaring systems to prevent the dangerous build-up of methane-rich gas that results from the decomposition of organic matter in the landfills.<sup>22</sup> These systems have significantly reduced the cost of deploying small generators fueled by this off-gas. Impacts of land management policy at both the Federal and state levels can be significant factors in renewable energy policy, either to encourage or preclude its development on government owned land.

At the state level, a number of states, either working alone or in cooperation with other states, have established policies to control the emissions of greenhouse gases. For example, the California law known as AB32 (for Assembly Bill number 32, its ascension number in the legislative session) implements a number of policies to control or limit carbon emissions.<sup>23</sup> Some of these policies, such as a modification of the state's RPS or the low carbon fuel standard, directly address renewable energy or energy efficiency, while other policies, such as the cap on greenhouse gas emissions, may serve to encourage additional adoption of renewable energy resources and increased energy efficiency. The Regional Greenhouse Gas Initiative is a cooperative agreement among several states in the Northeast to limit greenhouse gas emissions, which may also incentivize renewable generation resources.

### **4.1 Framework for a Sustainable Development of Energy Supply Systems**

#### **4.1.1 Political Drivers toward the Transformation of Energy Supply**

AGENDA 21, which was adopted at the United Nations Conference on Environment and Development in 1992 in Rio de Janeiro, sets out the requirements for sustainable development. Critical issues for sustainable development in energy supply are the continuous growth in human needs for energy in the face of limited fossil and nuclear resources, and their serious impacts on the environment and the climate.

Per capita consumption of energy varies widely between countries across the world. Cost-effective energy supplies are key to overcoming poverty. About 1.3 billion people have no

access to electricity, and 2.6 billion are without clean cooking facilities [1]. At the same time, the economic development in countries like China and India increases the global demand for energy, especially for fossil sources. The resources are unequally distributed; much of fossil and nuclear energy resources are in the hands of a few countries. This can present a considerable barrier to the economic development of resource-poor countries.

Costs are a key driver for the choice of energy source. The costs of fossil and nuclear energy supplies cannot be realistically evaluated unless the considerable environmental damage, climate change, and the risk posed by nuclear energy are taken into account. Insufficient attention continues to be paid to the external costs linked with fossil energy. Furthermore, the World Energy Outlook (WEO) reports energy production using fossil and nuclear sources as being supported by subsidies amounting to U.S. \$544 billion in 2012 [2]. These must be systematically reduced.

On the other hand, nuclear energy can be seen to be subject to growing constraints to ensure operational safety, which leads to rising costs and therefore calls its economic viability into question. The costs for the use of renewable energy (RE) are falling, due to technological development. In addition to mitigating climate change, dynamic development of RE use offers access to comparably reliable, environmentally sound, and low-risk energy supplies as well as the opportunity for poor countries to develop socially and economically. Furthermore, significant cost-effective potential to save energy through efficient conversion and use exists worldwide and is only partly utilized today.

#### 4.1.2 Successful Promotion of a Sustainable Energy Supply

The transformation of energy supply system requires a number of *framework conditions, instruments, and measures* which are capable of breaking down the decades-old structures of the existing energy supply system and promoting system changes which in part are fundamental. Important, if not an essential prerequisite for such a development in a country or an association of countries, is a basic commitment of government, administration, business, and the population. Generally, there must be a transparent strategy with legally binding development paths. The latter must refer to transparent and soundly calculated indicators with a clear reference to the short- and long-term goals. The development should be monitored continuously to make sure the trajectory is being complied with. The International Energy Agency has proposed general approaches to promoting efficient energy conversion and energy use [3]. In principle they can also be applied to the promotion of RE.

Generally, a set of instruments which specifically address the various market segments is needed. A strategy geared to a single goal, for example, climate protection, will not be sufficient to achieve the manifold sustainable-development goals. The instruments must be continuously adjusted as required for the long-term transformation of the energy system and must be coordinated in order to avoid contradictions between them. They should promote the development and application of the technical basis, encourage the integration of new products into the market, and activate cost reduction potential. One priority, alongside installations for the utilization of RE, should be the development and use of integrative elements such as energy grids, load management, and storage facilities in order to adapt fluctuating wind and solar energy to the given load profiles.

This is being discussed today mainly in the context of electricity supply, but in order to optimize the energy system as a whole, provision of electricity, heating and cooling as well as the energy needs for transport must be considered as a connected system. The implementation of cost-effective efficiency measures should be made mandatory through suitable legal norms, and longer amortization periods should be compensated

through suitable support. The transformation of energy supply must be coordinated with the declining energy demand brought on by energy efficiency (EE) measures in order to ensure that the expansion of RE utilization does not thwart subsequent efficiency measures in, for example, the buildings sector.

Making the energy supply system sustainable involves far-reaching changes. Policy-makers, administrations, companies, and citizens must not only accept this transformation, they must also actively support it. International organizations and states committed to this task must therefore establish target-group-specific public relations activities in order to communicate the opportunities and challenges it involves. They must also devise new training and further-training contents to prepare the people and professions charged with this task for tackling it.

#### 4.1.3 International Agreements on the Use of Renewable Energy

The debate about global sustainable development has also had an impact on organizations in the energy sector. Over the last 10 years, various global initiatives and organizations have been established in this context. They include, but are not limited to, those briefly described in the following section.

In 2011, United Nations Secretary-General Ban Ki-moon launched the *Sustainable Energy for All initiative* (SE4ALL). It has three objectives which are to be achieved by 2030: to ensure universal access to modern energy service, to double the global rate of improvement in EE, and to double the share of RE in the global energy mix. The initiative has developed a Global Action Agenda with 11 Action Areas: 7 “sectoral” areas (e.g., modern cooking appliances and fuels, large-scale renewable power, and buildings and appliances), and 4 “enabling” areas (energy planning and policies, business model and technology innovation, finance and risk management, capacity building and knowledge sharing). The initiative seeks to encourage governments and actors to initiate their own specific actions in these areas. Suitable metrics will be established to measure progress toward achievement of the objectives [4].

The proposal to set up an international organization for RE dates back to the United Nations Conference on New and Renewable Sources of Energy held in 1981 in Nairobi. It took three decades of manifold international efforts until on April 4, 2011, the International Renewable Energy Agency (IRENA) was established in Abu Dhabi, United Arab Emirates. By June 2013, 160 participants were registered, including 114 states and the EU as members and 45 states as signatories or in accession. Mandated by its Member States (MS), IRENA serves as a network hub of country, regional and global programs and activities, an advisory resource on planning, policy development and deployment, and as an authoritative, unified global voice for RE [5].

Numerous conferences paved the way for the activities and organizations addressed earlier. The World Summit for Sustainable Development in 2002 in Johannesburg stressed the importance of RE, and the foundation of IRENA was mentioned for the first time in the final declaration of the International Renewable Energy Conference in 2004 in Bonn. This was followed by a series of International Renewable Energy Conferences (IREC) in Beijing, Washington, Delhi, and Abu Dhabi. The 2013 IREC took place in conjunction with the third session of the IRENA Assembly and the Annual World Future Energy Summit during Sustainable Energy Week [6].

Last but not the least, the Renewable Energy Network (REN21) was established as a result of the Renewables 2004 Conference. It is a global network connecting actors from governments, international organizations, industry associations, science and civil society to support exchange of knowledge and data as well as global activities in the field of RE. REN21 annually publishes the Global Status Report, the Global Future Report as well as

reports on regional activities and RE policies, and runs several websites [7]. The international activities outlined earlier cooperate closely and assist one another. UN Secretary-General Ban Ki-moon has welcomed IRENA as RE hub within the SE4ALL initiative [8], and the conferences served to discuss and prepare the global activities and were actively supported by REN21. Despite the growing intensity of this exchange, governments must take action themselves to promote RE within their own remit.

---

## **4.2 Strategies and Instruments in Europe**

The global debate on climate change (e.g., reports by the Intergovernmental Panel on Climate Change [IPCC], Kyoto Protocol) and the dependency of the European Union (EU) on energy imports led to the adoption of the EU Climate and Energy Package in April 2009. It consists of several instruments designed to prevent or reduce greenhouse gas (GHG) emissions and sets three targets for the year 2020: a reduction of GHG emissions by 20% compared to 1990 levels (30% if other industrialized countries set own targets), an energy efficiency (EE) improvement of 20% compared to 2005, and an increase in the use of Renewable Energy (RE) to a share of 20% of gross final energy consumption. In addition, RE's share in the transport sector is to be increased to 10% [9].

### **4.2.1 European Energy Supply and Dependency on Energy Imports**

In 2011, gross primary energy consumption in the 27 EU MS amounted to about 1,698 million tons of oil equivalent (toe), which corresponds to 71,092 terajoules (TJ) and is 6% less than in 2008. Gross final energy consumption saw a decrease of similar magnitude, to about 1103 toe. The energy dependency rate is about 54% of primary energy consumption, that is, more than half of energy consumption comes from imported sources. Consumption and dependency on imports vary greatly between MS. The largest energy consumers are—in line with economic performance—Germany, France, the United Kingdom, Spain, and Italy. As regards dependency on imports, small countries (many of them islands) like Malta, Zyperus, or Luxembourg head the list, but also Ireland, Italy, and Portugal have to import much of their energy requirement. On the other hand, Denmark is a net energy exporter [10].

### **4.2.2 Renewable Energy Directive (2009/28/EC) of April 23, 2009**

Directive 2009/28/EC on the promotion of the use of energy from renewable sources (RE Directive, RED) is one of the instruments of the Climate and Energy Package and entered into force in June 2009 [11]. It establishes a framework for the further development of RE use in the electricity, heating, and transport sectors in the MS of the EU and provides recommendations for the design of the environment for RE promotion and expansion. The RED allocates the overall EU RE development target among the MS by setting MS-specific targets. Its main contents are

- A national action plan and progress reports serve for precise communication between MS, European Commission and European Parliament on progress made to achieve the Directive's goals. The MS submitted their national action plans by June 31, 2010. They contain the energy data structure needed to calculate GHG reduction effects (taking into account savings in consumption due

to energy efficiency) and the expected expansion of RE until 2020 with 2-year intermediate values (trajectory). The report also describes the measures and instruments established to comply with the RED. From 2011 to 2019, the MS draw up a progress report every 2 years presenting an interim assessment of the development described in the action plan. The European Commission evaluates these reports and summarizes them in a progress report to the European Parliament and the Council. In the first progress report of March 27, 2013, the European Commission calls for improvements in MS, for example, better framework conditions for expansion of RE, and finds compliance with the trajectory unsatisfactory in some cases. It has even launched infringement proceedings against some MS. However, it also sees a need for further action in its own domain.

- The base data and methods needed to calculate GHG reduction effects.
- For cooperation between MS, the RED defines mechanisms for the statistical transfer of used amount of RE joint support schemes, and joint projects for production of electricity, heating, or cooling. Electricity production projects may also be carried out with non-EU countries. The produced amounts of energy are divided up between the countries involved for the purpose of counting them toward national targets.
- To reduce barriers to RE expansion, the RED addresses in detail the favorable framework conditions for project planning and implementation, access to and operation of grids as well as information and training, and recommends appropriate adjustment of relevant regulations.
- The system for guarantees of origin of renewable electricity defined by Directive 2001/77/EC was further developed and may now be extended to include heating and cooling. The system serves to ensure that the share of RE in electricity, heating or cooling product can be proven to final customers in a transparent and objective manner.
- The RED places great emphasis on sustainable provision of biofuels, addressing the global dimension of relevant markets. As a key requirement, biofuels are only accepted within the scope of the RED, for example, for fulfillment of the RE shares, if their use leads to a 35% GHG emission saving compared to the fossil-fuel reference. From 2017 the saving must be 50%. This aspect is discussed further in the following paragraphs.

The EU-wide *target for the share of RE in transport* applies equally to each MS. In addition to biofuels, fuels, or electricity from other RES may be counted toward this target. Since highly efficient technologies such as batteries and new conversion processes (e.g., power to gas) are still not available at feasible costs, this target has generated considerable pressure toward the production of biodiesel in particular.

The provision and use of biomass for energy production usually has adverse environmental impacts. In addition to other environmental impacts, intensified land use or the use of land previously used otherwise, referred to as land use change (LUC), for example, plowing up of meadows, can increase the eutrophication and acidification of soil and water bodies and lead to correspondingly higher emissions of highly potent GHG. GHG emissions from fossil-fuelled machinery or artificial fertilizers are hardly evitable. Competition with food and feed production is another relevant problem. In tropical countries, and especially in poor countries, the effects from this may be much

more pronounced, for example, when food production is displaced to previously virgin rainforest areas (indirect land use change—ILUC). Competition with food production can have serious social consequences in these countries, for example, due to rising food prices [12].

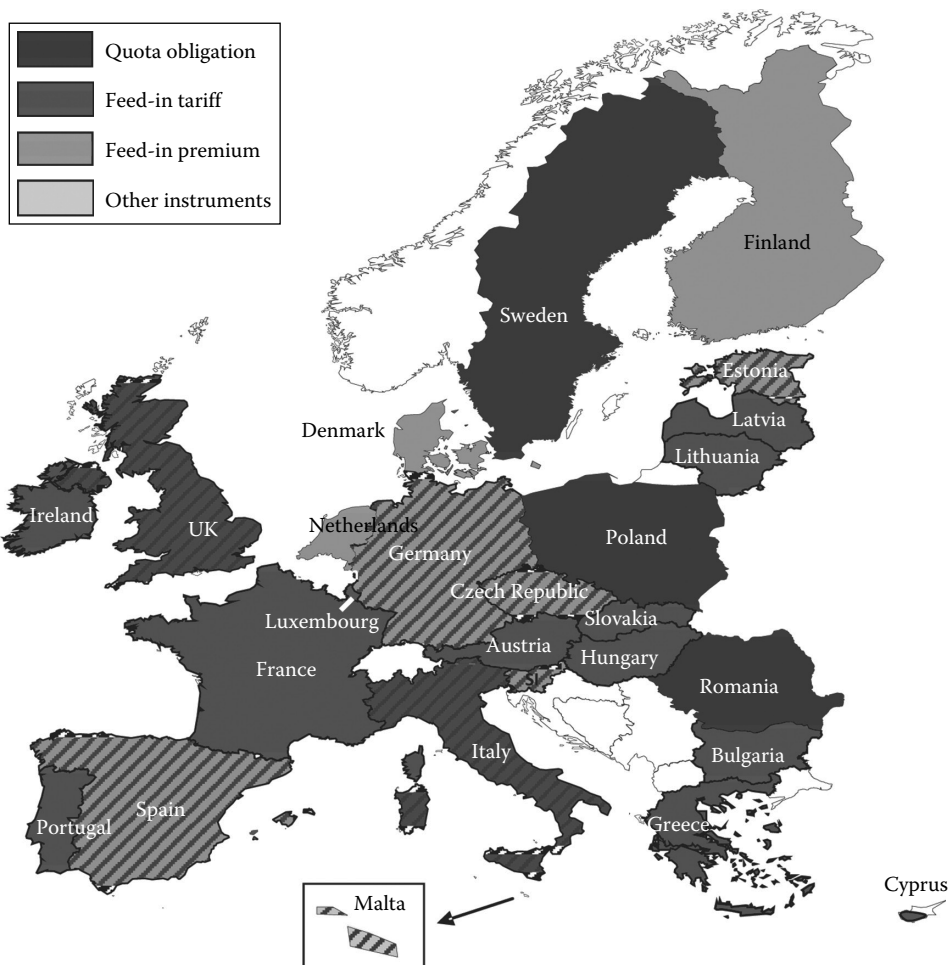

These insights raise serious doubts as to the sustainability of biofuels (especially of biodiesel) or even their positive effects for the climate. Calculated GHG emissions do not yet include the effects of ILUC, as a commonly accepted calculation method does not yet exist. Therefore, the European Commission presented in autumn of 2012 a controversial initial proposal, on the basis of several experts' reports, on how ILUC could be accounted for in reporting under the RED on the promotion of RES [13]. The implementation of the proposal would lead to the situation that a reduction of GHG emissions could no longer be demonstrated for biofuels with a high oil-crop share [14]. This has led to an intense debate about the contribution of food-crop-based biofuels to the target for RE in the transport sector by 2020 under the RED, and for this option, a limitation to the current level is under discussion.

#### 4.2.3 Instruments in EU Member States to Promote Renewable Energy for Electricity Generation

EU MS essentially use two instruments as main support instruments: feed-in payments with fixed tariffs or variable premiums, and quota models with tradable certificates in different variations. In addition, tendering, tax incentives, and mixed schemes are used. The support instruments are constantly changing, and their design and respective frameworks differ markedly between MS. Therefore, a comprehensive description would only have transitory relevance and would go beyond the scope of this contribution. [Figure 4.1](#) shows the main support instruments applied by MS at the end of 2012 [15]. In the subsequent section, the basic schemes are briefly described and evaluated in terms of their economic efficiency.

With the *fixed feed-in tariff*, operators of RE installations receive fixed payments per kW h for the amount of electricity they produce. This makes electricity revenues readily calculable and provides high investment security. However, it eliminates the electricity price signal from being the decisive criterion for the RE installation operator; neither investment nor operating decision will be determined by the real-world shortage situation in the electricity market. With fixed feed-in payments, the speed of expansion can be controlled only indirectly and roughly via the funding rates. Adjusting the payments to the price development is difficult, especially when it is dynamic. Differentiating the payments according to technology may be appropriate, especially in the case of large cost differences, and may reduce or prevent the problem of windfall profits in RE promotion. When long term, the support can be adjusted to reflect the learning curves of RE technologies and windfall profits can be prevented.

With the *premium model*, the installation operator or a trader markets the renewable electricity via a power exchange. In addition to the market prices, RE installation operators are paid a premium per kW h for the amount of electricity produced. The premium is geared to the exchange price (e.g., the average monthly price) and therefore provides an incentive for market-adapted production. The behavior of a market premium model in terms of windfall profits and controllability of the speed of expansion is similar to that of the fixed feed-in payment. The uncertain electricity price reduces certainty for investors, but linkage with a fixed payment as in the case of the market premium provided for in Germany by the EEG limits this effect.

**FIGURE 4.1**

Overview of RE support instruments primarily applied in EU Member States. *Notes:* (1) The patterned colors represent a combination of instruments; (2) investment grants, tax exemptions, and fiscal incentives are not included in this picture unless they serve as the main support instrument. (From Ragwitz, M. et al., Review report on support schemes for renewable electricity and heating in Europe, report D8 compiled within the E European research project RE-Shaping [work package 3], January 2011, p. 21ff, [www.resaping-res-policy.eu](http://www.resaping-res-policy.eu), as of March 6, 2015.)

The *quota system with trading of certificates* requires market actors to provide a certain share of renewable electricity within their portfolio. Alternatively, they can buy certificates for renewable electricity generated by other market actors at variable market prices and might thus fulfill their quota in a more cost-effective way than in the case of own production. The quota system affords good controllability of the development path, provided that nonfulfillment of the required quota is sufficiently sanctioned. Since the revenues from renewable electricity in this scheme are directly dependent upon the electricity prices on the energy exchange, market integration is given. There is little certainty for investors, as not only the electricity prices on the energy exchange but also the prices for the certificates are volatile. RE investors must take high risk premiums into account, which reduces the efficiency of a quota system. On the other hand, the competition orientation has—in the short term—a beneficial effect on efficiency, since RE expansion is channeled to the most

cost-effective RE technologies. Quotas could also be set for specific technologies, but this increases the complexity and uncertainty. As can be expected, windfall profits are high, especially if a technology-neutral design is applied.

*Tendering* alone is not a functional RE support instrument. Tendering can be used for production capacity or produced amount of electricity. In the bidding process, the most competitive bidders are identified and receive investment grants or a payment, for example, spread over the plant depreciation period. This means that support rates are determined by competition, and not set administratively as in the case of fixed feed-in payments and premium model. Tendering offers large scope in designing the instrument while at the same time substantial trade-offs have to be considered in its optimization. Transaction costs tend to be high.

#### 4.2.4 Energy Efficiency

An efficient and economical use of energy can partially offset the rise in energy prices. It can reduce the provision of energy, installations for energy production and conversion, and the necessary infrastructure, for example, energy grids and storage facilities. In addition, energy saving makes the economy more competitive. EE improvement measures for end-users concern local energy provision, conversion, and use in all sectors. The many and varied ways in which energy losses can occur through inefficient use requires correspondingly diverse and small-scale measures. The most important are described in the following paragraphs.

The aim of Directive 2012/27/EU on *energy efficiency* (EE Directive, EED) [16] is to help ensure achievement of the Union's target of improving EE by 20% by 2020 compared to business as usual. The EED contains a multitude of requirements for MS to increase EE. A key element is Article 7, which requires MS to achieve an annual savings quota of 1.5% by 2020. Renovation of public buildings owned by central governments is to be stepped up and energy audits carried out in all larger enterprises. A flexibility clause allows MS to apply derogations, which may be counted toward the saving target in Article 7 at a rate of up to 25% (i.e., application of the derogations may not lead to a reduction of more than 25% of the energy savings resulting from the 1.5% target).

Directive 2009/125/EC, also known as *Energy-related Products Directive*, establishes a framework for the ecodesign of energy-related products [17]. It requires all manufacturers placing products on the market in EU MS to present a declaration of conformity indicating that the product's design complies with the provisions of the Directive and of regulations issued under it for homogenous groups of products. The regulations limit, for example, stand-by and off-mode power consumption of specific groups of devices like household and office equipment. Regulation 1275/2008/EC on electrical office and household equipment [18] alone will reduce unnecessary power losses in the EU by 35 billion kW h/year by 2020. This translates to a saving of 14 million tons of carbon dioxide emissions and nine 800 MW power plants [19]. Another regulation, 2013/801/EU, for data network equipment has entered into force recently. There are also regulations on the EE of televisions, lamps, electric motors, and other groups. Due to the factual ban on basic incandescent lamps, compact fluorescent lamps, also known as energy saving lamps, are being launched on the market in a large variety of forms and designs.

Many of appliances discussed earlier, as well as dishwashers, washing machines, refrigerators and freezers are labeled for their annual energy consumption under Directive 2010/30/EC [20]. Originally, starting in the 1990s, EE was divided into classes A to G for *labeling* purposes. This system had to be changed in response to the EE improvements

which labeling brought about for these product groups. Appliances in classes C to G have largely disappeared from the market, and three further classes with one to three plus signs above class A (A+ to A+++ ) were introduced. The EE of labeled appliances improved 7% in the EU between 2005 and 2010 (ranging from 0% in the United Kingdom and 18% in Spain) [21].

Buildings account for a large proportion of final energy consumption. The European Commission has estimated a share of 40% and addresses existing saving potential in Directive 2010/31/EU on the *energy performance of buildings* [22]. The Directive requires EU MS *inter alia* to set minimum energy performance requirements for new buildings and existing buildings subject to major renovation with a view to achieving cost-optimal levels. By the end of 2020, all new buildings must be nearly zero-energy buildings. Buyers and tenants must be given information on the EE of the building; for example, it is now obligatory for EE parameters to be indicated in housing advertisements.

---

### 4.3 Strategies and Instruments in Germany

In Germany, the energy debate started in the 1970s, with the anti-nuclear movement as a part of the New Social Movement and received impetus from the oil-price crises in the 1970s and 1980s, forest dieback in Germany, and the Chernobyl nuclear disaster in 1986. After the UN-Conference in Rio 1992, increasing attention was given to the issues of sustainable development of the energy supply system as an overarching concept as well as climate protection. These discussions promoted various approaches to EE in the buildings sector and to the use of renewable energy (RE) in Germany. By the turn of the millennium, transforming the energy supply system had become an issue acknowledged by the German public as one of the most important tasks of the twenty-first century and which it now broadly supports.

#### 4.3.1 Use of Renewable Energy in Germany

Primary energy consumption in Germany in 2011 amounted to 13,522 PJ. It has remained at similar levels since 1990, between 13,000 and 15,000 PJ. The share of fossil energy sources in primary energy consumption in 2011 was almost 79% (mineral oil 33.5%, natural gas 20.8%, hard coal 12.8%, and lignite 11.6%) and that of nuclear energy was <9%. The contribution of RES, in contrast, rose to a total of 11% [23]. In 2011, Germany had to import over 60% of primary energy consumption placing it in the upper mid-range of EU MS [10].

Provision of electricity, heat, and fuels from RES has almost quadrupled, from about 83 terawatt hours (TW h) in 1998 to around 318 TW h, or 12.3% of total final energy consumption, in 2012. Seventy seven terawatt hours of electricity from RE were provided in 2012. Their proportion in electricity production increased from 4.7% (1998) to 23.5%. Heat supply from RE in 2012 totaled approximately 140 TW h or 10.2% of total final energy consumption for heating (space heating, hot water, and industrial process heat). In the transport sector the contribution of RE was roughly 35 TW h in 2012, or about 5.7% of total fuel consumption by road transport [24] (Figure 4.2).

At the end of 2012, wind turbines with a capacity of about 31,300 megawatts (MW) were installed in Germany, which produced almost 50.7 TW h of electricity in that year.

**FIGURE 4.2**

Contribution of RE to final energy consumption. \*Biomass: solid and liquid biomass, biogas, landfill and sewage gas, biogenic share of waste. \*\*Geothermal energy in the heat sector: deep geothermal energy, near-surface geothermal energy, ambient heat. \*\*\*Biofuels: biodiesel, bioethanol, vegetable oil, from 2008: biomethane; values rounded; as at August 2013. (From Federal Ministry for the Environment, Nature Conservation and Nuclear Safety (publisher), Renewable Energy Sources in Figures, July 2013; as at March 6, 2015 only the 2014 German update "Erneuerbare Energien in Zahlen", now published by Federal Ministry for Economic Affairs and Industry, is available on <http://www.erneuerbare-energien.de/EE/Redaktion/DE/Downloads/erneuerbare-energien-in-zahlen.html>; numbers might differ slightly due to statistical adjustments.)

In addition, photovoltaic systems with a capacity of over 32,600 MW were installed yielding almost 26.4 TW h. Bioenergy outdoes photovoltaics, with over 43.5 TW h from an installed capacity of almost 7600 MW, but is increasingly viewed critically due to harmful environmental and climate effects. Besides these sources, only hydropower plays an appreciable role, with 21.8 TW h from an installed capacity of 5600 MW. Old hydropower facilities in particular can have high impact on the environment; moreover hydropower's potential is largely exhausted in Germany. Electricity production from geothermal systems exhibits large technical potential, but the extent to which it is used is still small due to high costs and other hurdles.

In heat supply from RE, the use of bioenergy dominates, mainly from traditional log burning. This source is viewed critically from the viewpoint of sustainable resource use and because of its environmental impacts, for example, emissions of fine particulate matter. Heat provision from solar thermal and geothermal systems in 2012 only amounted to 6.7 and 7 TW h, respectively despite their large overall potential [24].

#### 4.3.2 Renewable Energy Sources Act—Promotion in the Electricity Market

The Renewable Energy Sources Act (EEG) was enacted in 2000, the last overall amendment became effective in 2014. The purpose of the Act is to facilitate a sustainable development of energy supply by promoting the use of RES in the electricity sector. The objective is the

TABLE 4.1

Current Status and Targets under the *Energiewende* in Germany

	Basis	2011	2020	2030	2040	2050
<i>Greenhouse gas emissions (reduction)</i>						
Greenhouse gas emissions	1990	–26.4%	–40%	–55%	–70%	–80% to –95%
<i>Efficiency (reduction/share of electricity generation)</i>						
Primary energy consumption	2008	–6%	–20%		–50%	
Final energy consumption	2008	–2% per annum		–2.1% per annum (2008–2050)		
Gross electricity consumption	2008	–2.1%	–10%	—	—	–25%
Combined heat and power plants		15.4% (2010)	25%	—	—	—
<i>Building stock (reduction/share in building stock)</i>						
Heat requirement		—	–20%	—	—	—
Primary energy requirement		—	—	—	—	Appr. –80%
Building refurbishment		1% per annum		Increase to 2% per annum		
<i>Transport (reduction/number of vehicles)</i>						
Final energy consumption	2005	Appr. –0.5%	–10%	—	—	–40%
Electric vehicles		Appr. 6600	1 million	6 million	—	—
<i>Renewable energies (share in consumption)</i>						
Gross electricity consumption		20.3%	35% min	50% min	65% min	80% min
Final energy consumption		12.1%	18%	30%	45%	60%

See full report (in German) for detailed data, p. 21ff., p. 3, download from [www.bundesnetzagentur.de/monitoringenergyofthefuture](http://www.bundesnetzagentur.de/monitoringenergyofthefuture) (as at March 6, 2015).

continuous expansion of RE to at least 80% of total electricity supply by 2050 at the latest, with corresponding intermediate targets (see Table 4.1). Due to the investment security for plant operators established by the EEG, the targets so far have always been exceeded. Many countries around the world are therefore adopting feed-in tariffs to promote RES in the electricity sector.

*Basic elements in the EEG* are the obligation to connect the facilities to the electricity grid and the obligation of grid operators to purchase and convey the electricity. The fixed feed-in tariffs per kilowatt hour paid by the grid operator for 20 years are based on the electricity production costs of the respective type of installation. They are continuously adjusted in line with cost developments.

Due to the growing market shares, *integration of electricity from RES in the energy market and system* is gaining in importance and gradually the EEG is being changed to this end. The amended EEG of 2012 introduces the possibility of direct marketing by the plant operator or a respective service provider on the spot market in conjunction with a market premium, which turned mandatory for plants over 500 kW installed capacity in the 2014 amendment. The plant operator receives a comparable total remuneration as in the fixed feed-in system, which now arises as the sum of revenues in the electricity market and the market premium. Yet facility operation considering the electricity price allows (slightly) higher profits and thus encourages the integration of RE. Corresponding potentials are primarily available in adjustable systems such as biogas facilities.

In addition, the 2014 amendment introduced controversially discussed auction procedures to determine the necessary funding of RE plants. There is great concern regarding the expectations of reduced costs of RE development. Private citizens and cooperatives, who have covered the main part of RE investments so far, might not be able to manage auctioning procedures and economic risks. RE development might be taken over by a few large companies and the current satisfaction with the *Energiewende* amongst German citizens could suffer.

The electricity that is not direct marketed is sold on the electricity exchange by transmission system operators. The remuneration paid to plant operators is reduced by the sales proceeds. The remaining sum and the paid premiums are allocated to the quantity of electricity sold in Germany and is thus paid by the consumers. This means, the financing of this instrument is independent of annual public budgets, which is a major reason for the stable development of the expansion of RE in the electricity sector [25].

The EEG must be linked with other climate protection instruments. For example, when setting emission caps the European emissions trading system takes into account the GHG emission reduction expected to arise from the EEG development targets and corresponding policies in other EU MS.

#### 4.3.3 Renewable Energies Heat Act and Market Incentive Program

The Renewable Energies Heat Act (EEWärmeG) sets a target of 14% to increase the proportion of RE in final energy consumption for heating and cooling in Germany by 2020 [26]. This percentage is to be achieved by the expansion of RE for heat supply in buildings. For new buildings partial mandatory use applies: a portion of the building supply with heat and cooling must be covered by RES such as geothermal, solar thermal, or biomass. Alternatively, compensating measures for the efficient use of energy may be applied.

For existing buildings in general no mandatory use of RE applies. They are instead incentivized by financial support from the Market Incentive Program (MAP) [27]. Merely public buildings which are thoroughly renovated are for role model reasons obliged to use RE. The restriction of mandatory use to new buildings reduces the scope of the law considerably. Experts therefore advocate obligatory use of RE in the course of extensive refurbishment of all existing buildings. This is rejected by relevant stakeholders such as housing associations citing lack of economic viability. Regardless of this, however, use of RES in combination with EE measures in buildings must be strongly supported.

Additionally to the measures under the EEWärmeG, the MAP fosters the installation of RE facilities for heat supply in general by grants paid by the Federal Office of Economics and Export Control (BAFA). Moreover, the “Premium” Reconstruction Credit Institute (KfW) Renewable Energies Programme finances large commercial RE installations through inexpensive loans. In 2011, a total amount of €350 million were available. To achieve the *Energiewende* target of 14% by 2020, the MAP must be continuously developed.

#### 4.3.4 Energy Efficiency Measures for Buildings

To achieve German and European targets, the entire building stock must undergo energy-saving renovation in the framework of regulatory elements and a long-term support strategy.

In Germany, the legal basis for this is the *Energy Saving Ordinance* (EnEV). It was formed in 2002 through merging of the Thermal Insulation Ordinance and the Heating Systems Ordinance to facilitate a coordination of technical and heat insulation requirements (i.e., a lower level of thermal insulation can be compensated for by better plant technology,

and vice versa). Its central requirement for new buildings and extensively refurbished buildings is the limitation of the specific annual primary energy demand for space heating, ventilation, cooling, and water heating. This facilitates an adequate evaluation of the use of RE, among others. In addition, for new buildings the Ordinance requires compliance with a minimum level of thermal insulation by limiting transmission heat loss of the building shell. For major refurbishment of existing buildings (e.g., rendering refurbishment of external walls), it sets requirements for the heat transmission coefficient of the building components concerned. The energy quality of a building is described in an energy certificate, which must be issued and presented when a building is constructed, sold, or rented out.

The requirements of the EnEV were gradually further increased in 2007 and 2009. Another step will apply from 2016 to achieve the EU target for a nearly zero-energy standard for new buildings by the end of 2020. Refurbishments should be made using passive house components no later than 2018. For the funding of building refurbishment the KfW programme “Energy Efficient Refurbishment” was set up. It should continue to be equipped with a budget of at least €2 billion/year beyond 2020 in order to promote this important task.

#### 4.3.5 Germany's *Energiewende*

In 2010 and 2011, the German government adopted a number of instruments, measures, and long-term goals for a permanent transformation of the energy supply system, subsuming them under the term *Energiewende*. The aim is for Germany to become one of the world's most energy-efficient and environmentally friendly economies which achieves a secure supply of energy with competitive prices and a high level of prosperity [28]. Instruments already in place prior to this, such as the EEG and its goals, were integrated into this concept. The *Energiewende* envisages a significant long-term reduction of energy consumption through much more efficient conversion and use of energy and the extensive replacement of fossil energy sources with RE (see Table 4.1). The complete phase-out of nuclear energy by 2022, which had already been adopted in 2004, was confirmed in the wake of the accident at the Fukushima nuclear power plant.

The implementation of the *Energiewende* is monitored through annual *monitoring reports* and a 3-year *progress report*, which is evaluated by independent experts. The public is closely involved in various developments in order to win the necessary acceptance. Barriers to the planning, funding, realization, and marketing of projects are addressed. On the technical side,

- Fossil-fuel power plants and RE installations are further developed with a view to improving their EE
- Grid expansion—regional, national and offshore—is systematically planned and promoted within the scope of annually revised grid concepts
- Concepts for the integration of heat and electricity use are developed
- Market integration is improved through development and promotion of load management and storage

German government supports, through research programs and other instruments for market development, investigations into cost reduction in the use of RE and EE, and also promotes marketing and the development of new market models to improve supply security.

The *economic effects* of the development that has been set in motion are, in principle, viewed positively. However, their assessment involves methodological problems. For instance, the

current development as guided by Germany's energy policy must be compared with the unknown development that would have taken place without this guiding influence. The rise in energy prices brought on by the support must be contrasted with avoided energy imports, avoided external costs such as damage to the environment and climate, or industrial innovations from research and development. For example, in 2011 energy imports valued at €25 billion were avoided due to efficiency measures and RE expansion (energy imports in that year came to €89 billion). The investments triggered by the support, as well as employment and growth effects, also figure on the positive side of the balance sheet, but must be checked against the dampening impact of higher energy prices [30].

*Criticism by independent experts and relevant institutions* is based on various aspects of the development of individual key indicators. In the area of EE improvement in both the heat and transport sectors, a key prerequisite for GHG reduction, the limited progress is being criticized. In order for the *Energiewende* to succeed, it is essential that EE renovation of the building stock be speeded up. Development and system integration of RE does not happen automatically, not even in the electricity sector, but is progressing only slowly, especially in the heat and transport sectors. The implementation of integrated mobility concepts for passenger and freight transport, which help reduce dependency on fossil energy resources through more efficient traffic management, is essential to achieve this. Environmental protection, as a key requirement for sustainable development, continues to be relevant even when the use of RE (not just of biofuels) is substantially increased. Criticism is also leveled at the economic evaluation of energy supply, which is geared primarily to energy prices rather than macroeconomic indicators including external costs where appropriate. There are also reminders not to forget coordination with European climate policy and to ensure the functioning of the European emissions trading scheme. The drop in allowance prices has largely eliminated incentive for GHG reduction. The experts lament the lack of suitable indicators in several areas (e.g., EE, environmental protection, economic effects), which confounds proper assessment of the development [31].

Energy policy in Germany has embarked on a difficult, highly ambitious course, which is why it is followed closely worldwide. Despite all criticisms, the experts emphasize in their opinion that the process has only just begun and that this prohibits rash or overcritical judgment. It is important, however, that the advancement of the many and varied tasks remains sufficiently dynamic to prevent the possible loss of positive economic and technical development perspectives.

## 5.1 Energy Conservation

As the world's second largest economy, China has remained at an average annual growth rate of about 10% for the last 30 years. With rapid growth of its economy, China's energy sector has also made remarkable progress. China is now the world's largest energy producer and consumer. It has built up a comprehensive energy supply system comprising coal, electricity, petroleum, natural gas, and new and renewable energy resources.<sup>1</sup> However, China has also paid a costly price and faced stiff challenges in the process of transformation from a backward developing country to one of the top economies in the world. During the 11th Five Year Plan period (FYP, 2006–2010), China consumed 40% of the coal, 50% of the cement, 60% of the iron and steel, and 9% of the oil produced in the world, but it only created 5% of the world GDP during the same period.<sup>2</sup> China's energy consumption per unit of GDP is five times the world average.<sup>2</sup> The rapid economic development also brought up serious consequences for the country's air, land, and water.

With limited fossil energy resources at home and huge emission control pressure from the international world, energy conservation and renewable energy have increasingly been a priority of the Chinese government. In 2009, China made a commitment that it would reduce the carbon emission per unit of GDP (carbon intensity) by 40%–45% by 2020, relative to 2005 intensity levels. In 2014, China announced that it will reach carbon emission peak in 2030. To achieve these goals and other related energy efficiency and renewable energy targets, the Chinese government has enacted various laws, rules, and regulations; implemented numerous energy efficiency and renewable energy programs; and also reconstructed its energy-governing agencies to make them function more efficiently.

China's energy sector has been mostly regulated and controlled by government agencies and state-owned enterprises (SOEs). China's National Development and Reform Commission (NDRC) is in charge of coordination of energy planning with the country's overall economic and social development. The National Energy Administration (NEA), which was established in 2008 and restructured in 2013, is under the NDRC and responsible for formulating and implementing energy development strategy, planning, and policies; advising energy system reform; and regulating the overall energy sector in China. Specifically, renewable energy development in China is mainly under the jurisdiction of NEA's New Energy and Renewable Energy Department. In addition to the NDRC, industry energy efficiency is also under the jurisdiction of Ministry of Industry and Information Technology (MIIT), whereas Ministry of Housing and Urban-Rural Development (MOHURD) also covers building energy efficiency. All these government agencies work with each other and other related government agencies such as the Ministry of Finance (MOF), the Ministry of Science and Technology (MOST), and the Standardization Administration in terms of fiscal, tax, and financial incentives; energy-related science and technology; and technical standards and codes for energy conservation and renewable energy development.

### 5.1.1 General Policy

In 2010, China reduced 19.1% of energy consumption per unit of GDP compared with the level of 2005, close to the 20% reduction target that the Chinese government set for the 11th FYP period that ended 2010. This is largely owing to the robust energy conservation policies and programs that the Chinese government implemented. In 1997, China introduced the country's first energy conservation law, which stipulated general regulations and guidelines for energy conservation in China. The law not only identified four focus

areas of energy conservation—industry, building, transportation, and public institutions, but also defined main subjects of energy conservation—enterprises with annual energy consumption more than 10,000 tce (ton coal equivalence).

The law was amended in 2007 and one of the major revisions was the introduction of target responsibility system (TRS) concept. TRS uses a top-down approach to mandate the energy conservation target for the central, provincial, municipal, and county level governments. Local governments are accountable for energy conservation by signing an agreement with higher-level government. The outcomes of local energy conservation activities are directly linked to the performance evaluation of government officials.

The 12th FYP (2006–2010) for National Economy Development and Social Development, passed by the country's legislators in 2011, first proposed that China's energy intensity (energy consumption per unit of GDP) will be reduced by 16% and carbon intensity (carbon emissions per unit of GDP) will be reduced by 17% below 2010 levels by the end of 2015. The 16% reduction will bring the total reduction for the total 10-year period (2006–2015) to 32% below 2005 levels.<sup>3</sup>

Also in 2011, the State Council, China's cabinet, released the Comprehensive Work Plan on Energy Efficiency and Emissions Reduction for the 12th FYP (2011–2015), which details 50 specific measures to be carried out in support of the energy intensity target (as well as absolute reduction targets for criteria pollutants such as chemical oxygen demand, ammonia, sulfur dioxide, and nitric oxides).<sup>4</sup> In the following year, the State Council further issued the 12th FYP for Energy Conservation and Emission Control, which proposed major targets, and prioritized tasks and key projects of energy conservation. According to the plan, priorities will be given to restricting energy-intensive and high emission sectors, retiring outdated production capacity, upgrading traditional sectors, adjustment of energy consumption structure, and promotion of service and other newly emerging industries. Specifically, the plan listed prioritized tasks for energy conservation of industry, building, transportation, and public institutions.

## 5.1.2 Sector-Specific Energy Conservation Policies

### 5.1.2.1 Industry

With its energy consumption taking up about 70% of the national total, industry is the largest energy consumer in China. According to the 12th FYP Plan for Industry Energy Conservation issued by MIIT in 2012, China aims to reduce energy consumption per unit of industrial value-added output by 21% from 2011 to 2015 and achieve energy conservation of 670 million tce. The plan also sets specific energy consumption reduction targets for 9 energy-intensive sectors (including steel, nonferrous metals, petrochemical, chemical, building materials, mechanical, light industry, textile, and electronics) and 20 types of products.

To help achieve these targets, the same plan also identified key technologies and approaches to improve energy efficiency for each one of these 9 sectors and 10 types of prioritized energy efficiency projects including energy efficiency of industrial boilers and burners, internal combustion engines, generators, recovery and utilization of waste heat and pressure, combined heat and power, industrial by-product gas, enterprise energy management and control centers, and the combination of industry and information technology in energy conservation. In 2014, MIIT published the National Industry Energy Efficiency Guide (2014), which gives a comprehensive overview of the industry energy efficiency progress made since 2000. Interested readers can refer to the detailed effort China made in industry energy efficiency effort in the past decade.<sup>5</sup>

As a major initiative to help meet the energy conservation target of 670 million tce, the NDRC launched the Top 10,000 Energy-Consuming Enterprises Program, targeting enterprises that use more than 10,000 tce/year. The program, which is an expansion of the

Top 1000 Program that China implemented during the 11th FYP period, aims to achieve an absolute energy saving of 250 million tce. This is almost one-third of the country's total energy saving target in the 12th FYP.<sup>6</sup>

### **5.1.2.2 Building**

Building accounts for nearly one-third of China's total primary energy consumption and carbon emissions. China has 40 billion m<sup>2</sup> of existing buildings, but only 1% is energy efficient. Between 2010 and 2020, China is expected to add 10–15 billion m<sup>2</sup> of residential buildings in urban areas. To improve building energy efficiency of the existing buildings and new buildings, the Chinese government has been actively engaged in the formulation and deployment of a series of legal and policy instruments.

The Renewable Energy Law, the Energy Conservation Law, and the Civil Building Energy Efficiency Code are three major laws and regulations covering building energy efficiency. In addition, more than a dozen of provinces and municipalities have also passed their own general energy efficiency codes and specific regulations. These laws and regulations, together with the 12th FYP on Building Energy Efficiency issued by MOHURD in May 2012 and the Green Building Work Plan issued by the general office of China's State Council released in January 2013, constitute the policy framework of building energy efficiency in China.

According to the 12th FYP on Building Energy Efficiency, China aims to reduce 116 million tce and plans to achieve the target through four prioritized areas: new buildings (45 million), heating supply reform and retrofitting in China's northern areas (27 million tce), government office and public buildings (14 million tce), and renewable energy adoption in buildings (30 million tce).<sup>7</sup>

As early as the 1990s, the Chinese government began to launch a series of policies to promote heat reform and retrofitting in existing buildings, especially in the northern areas where centralized heating is provided in most buildings. The aim of the heat reform is to reduce the amount of energy used through the reform of the heating pricing system and to establish a market mechanism to encourage heat suppliers' effort to improve the energy efficiency of their heat supply networks.<sup>8</sup> Given that the building in China's northern regions accounts for more than 40% of the country's total urban building energy consumption, the residential retrofitting in northern regions also plays a significant role in China's building energy efficiency efforts. From 2006 to 2010, China retrofitted 182 million m<sup>2</sup> of residential space in northern China.<sup>8</sup> It is predicted in the 12th FYP on Building Energy Efficiency that by 2015, China will complete heat supply measurement and retrofitting of 400 m<sup>2</sup> of existing buildings in the northern area.<sup>9</sup>

In addition, the Chinese government takes the initiative to implement various energy efficiency policies and measures for government office buildings, large-scale public buildings, and college and university buildings.<sup>7</sup> This effort is mainly focused on energy consumption monitoring and retrofit of public buildings. By 2015, China aims to retrofit 120 million m<sup>2</sup> of government office buildings and public buildings.<sup>9</sup>

Application of renewable energy resources in buildings is also one of the government's priorities in building energy efficiency. During the 11th FYP, major initiatives included renewable energy building demo projects and demo cities, and renewable energy application in buildings of rural areas. At provincial and local levels, many supportive policies were introduced and implemented to promote the application of renewable energy technologies in building such as photovoltaic power generation, building integrated photovoltaic (BIPV), solar water heating, and geothermal heat pumps. According to the government's plan, by 2015, the newly added renewable energy building will amount to

**FIGURE 5.1**

China's building energy efficiency target by 2015: 116 million tce. (From Ministry of Housing and Rural Urban Development, 12th FYP for Building Energy Efficiency, May 9, 2012.)

2.5 billion m<sup>2</sup>, and renewable energy will account for 10% of the total energy consumption of buildings in renewable energy building demo cities (Figure 5.1).<sup>9</sup>

### 5.1.2.3 Transportation

The transportation sector accounts for one-fifth of China's total energy consumption, making it the nation's third largest greenhouse gas emissions industry. According to the 12th FYP for Transportation Energy Efficiency and Emission Control released by the Ministry of Transportation in 2011, the energy consumption of operational vehicles, ships, and ports will reduce 10%, 15%, and 8%, respectively, compared with the 2005 levels.<sup>10</sup>

According to the plan, energy efficiency in the transportation sector will focus on three aspects—transportation infrastructure, equipment, and network. Similar to the 12th FYPs for other sectors, the plan also identified major tasks and key energy efficiency projects in the transportation sector.

## 5.1.3 Standards and Labeling Programs

### 5.1.3.1 National Energy Efficiency Standards

With improvement of living conditions, the appliances and electronics of Chinese households have become a major drive of residential electricity use in China. This spurred the government to implement China's first mandatory equipment standards in 1990, which covered nine electronic products such as refrigerators, air conditioners, clothes washers, irons, rice cookers, televisions, radios, and fans. As of February 2013, China has complied and implemented 109 national energy efficiency standards. The standards have also expanded from those of household electronic appliances to those of energy-intensive industrial products, and energy measurement and management standards.<sup>11</sup> Very recently in 2015, the State Council issued Opinions on Strengthening Energy Conservation Standardization<sup>12</sup>, which emphasizes a timely update of energy efficiency standards, the Top Runner program to promote the highest energy efficiency and mandatory Minimum Allowable Value of energy efficiency to outdate the backward 20% capacity and products.

### 5.1.3.2 China Energy Label (CEL) System

Since 2005, an energy label system has been introduced to illustrate the energy efficiency grade and typical energy consumption (TEC) values. The energy label, which usually appears on the surface or package of applicable products, allows customers to compare the

energy efficiency levels of different products and helps them identify products with highest efficiency available. The energy labeling system categorizes appliances and electronics into several grades based on their energy efficiency performance. The first grade indicates the highest energy efficiency and the fifth (or third, depending on product categorization) grade indicates the least energy efficiency, and the least one is defined as Minimum Allowable Value of energy efficiency, a mandatory requirement for the product market access in China. Since 2005, products with an energy efficiency level lower than the fifth grade (or third) cannot be put into the market. In some cases, the first grade is required for government procurement or for an energy efficiency subsidy program. At the end of 2012, ten batches of products have been included in the China Energy Label (CEL) system.<sup>13</sup>

On December 31, 2014, the Energy Efficiency Top Runner Implementation Scheme<sup>14</sup> was jointly announced by seven ministries of Chinese government. This scheme was aimed to promote high energy efficiency product based on previous progress of CEL. The product has to meet the Grade 1 requirement of CEL, also be the highest energy efficiency in the same categorization. The criteria will be upgraded annually. The top runner logo will be added to the current CEL, and the certified year will also be specified. The government promised that further subsidy and promotion measures will be implemented to help R&D and product promotion.

#### **5.1.3.3 Building Energy Efficiency Labeling and Evaluation and Green Building**

China began to establish its building energy efficiency labeling and evaluation system in 2006. According to the building energy efficiency labeling regulation issued in 2008, the labeling system mainly covers new and existing government office buildings, large-scale public buildings, national and provincial building, energy efficiency demo projects, and green buildings. Building owners need to apply two types of labels—assets rating label and operational rating label. The former indicates the theoretical value of building energy efficiency evaluated during the acceptance stage, whereas the latter indicates the actual values of building energy efficiency evaluated during the operation of the building.<sup>7</sup> A five star rating system is also introduced in the regulation, with five stars representing the most energy efficiency building. This evaluation and labeling system was updated in 2014 and extended to residential buildings.

Since 2009, the MOHURD has promoted building energy efficiency labeling in newly built government office buildings and large-sized public buildings through pilot projects in selected provinces and cities. Building owners who apply for building energy efficiency labeling must comply with national mandatory standards, including building energy codes (design standards and the acceptance codes), before applying for building energy efficiency labels. As of 2010, 45 building projects had been approved and granted star ratings.<sup>7</sup>

While the U.S. LEED green building rating system is widely used in China, the country also developed its own three star green building rating system in 2004. This rating system is based on the Green Building Evaluation Standards—the first national standards for green buildings and technical guidelines for green building evaluation. Similar to energy efficiency building labeling, there are two types of green building labeling, with one covering building design and the other building operation. By the end of 2010, 113 projects were awarded three star green building label nationwide (Table 5.1).

#### **5.1.3.4 Vehicle Fuel Efficiency Standard System**

China's vehicle fuel efficiency standard system consists of fuel consumption test methods, fuel consumption limits, and labeling. China adopted its first nationwide fuel consumption

**TABLE 5.1**

Energy Efficiency Labeling Rating System Coverage

Energy Efficiency Labeling	Rating System	Coverage
China Energy label	1–5 stars	Ten batches of products ranging from air conditioners to personal computers
Energy Efficiency Building label	1–5 stars	New and existing government office buildings, large-scale public buildings, national and provincial building, energy efficiency demo projects, and green buildings
Green Building label	1–3 stars	Any building at the design, construction, or operation stage
Vehicle Consumption label	N/A	Passenger and commercial vehicles with a gross weight of 3.5 tons or less

limits for passenger vehicles in 2005. They are considered to be the world's third toughest, behind Japan's and Europe's.<sup>7</sup> In 2007 and 2012, fuel consumption limits for light-weight and heavy-weight commercial vehicles were also adopted. According to a new rule issued in March 2013, passenger cars' average fuel consumption is required to reduce to 6.9 L/100 km by 2015 and down further to 5 L by 2020.

Since 2010, vehicle fuel consumption labeling has been implemented for passenger and commercial vehicles with a gross weight of 3.5 ton or less. In addition to some generic information of a vehicle such as brand, make, and rated power, a vehicle fuel consumption label is required to contain information about fuel consumption per 100 km and what test methods are used in determining the vehicle fuel consumption values.

#### 5.1.4 Financial Support and Government Procurement

By the end of the 11th FYP period, China reduced 19.1% of its energy consumption per unit of GDP compared with 2005 level and successfully achieved the energy conservation targets set for the period. This is not only owing to the various energy efficiency policies and programs that the government issued and implemented, but also directly related to the massive capital investment that the government made in energy conservation during the period.

Over the 11th FYP period, about RMB 846.6 billion was invested to support energy conservation projects through different measures and channels. Among them, the central government invested RMB 101.7 billion, amounting to 12.1% of total energy efficiency investment in China, and provincial and local governments contributed RMB 48 billion, amounting to 5.7% of the total energy efficiency investment. And nongovernment sectors contributed RMB 696.9 billion, which comes from company investment, loan from banks, and funds raised by the stock market.

Among all the investments in energy efficiency, 95% was used to fund and subsidize energy efficiency-improving projects and the rest of 5% was used in other related fields such as policy and methodology research, institution and capacity building, promotion of energy efficiency products, and so on (Figure 5.2).

##### 5.1.4.1 Financial Rewards for Energy-Saving Technical Retrofits

In 2007, the NDRC identified 10 types of key energy efficiency projects to receive the government rewards, such as coal-fired boiler retrofitting, waste heat and low temperature steam recovery, alternative oil, energy efficient motor systems, and energy system optimization. The program has been continued and expanded during the 12th FYP (2010–2015)

**FIGURE 5.2**

China's investment in energy efficiency during the 11th FYP (2006–2010). (From Dai, Y. et al., *China Energy Efficiency Financing and Investment Report*, 2010, China Science and Technology Press, Beijing, China, 2012.)

with raised levels of rewards and revised requirements for eligible projects and enterprises. Previously, eligible projects must have been one of those 10 projects, but the new program now covers more energy conservation technical retrofit projects. Energy-using companies used to be the only recipients of the rewards, but in the new program, energy service companies (ESCOs) can also apply for the rewards.<sup>15</sup>

#### **5.1.4.2 Energy Efficiency Product Subsidy Program**

Promoting energy efficient products is the most direct and efficient way of energy conservation. During the 11th FYP period, the Chinese government provided RMB 16.5 billion to subsidize the public and businesses to purchase and provide energy efficiency products such as lights, air conditioners, and low-emission vehicles and engines.

The government initiated the Energy Efficient Product Subsidy Program in 2005 with household refrigerators and air conditioners among the first batch of products subsidized. By the end of 2012, 10 batches of products have been announced and the subsidized energy-efficient products range from rice cookers to automobiles, from household refrigerators to industry pumps and motors. Basically, the subsidies are either provided to purchasers or manufacturers of energy efficiency products. Also the actual amount of the subsidies ranges from RMB 150 to 3000. The program not only helped improve the energy efficiency level of energy-using products, especially electric appliances, but also raised the awareness of the public and business to use energy efficiency products. On May 12th, 2012, the State Council announced an allocation of RMB 36.3 billion for the subsidy program.

#### **5.1.4.3 Fiscal Incentives for Retiring Outdated Capacity**

Retiring the outdated capacity is considered as not only an important way to adjust the economic structure, but also a vital measure to achieve China's industry energy efficiency targets. During the 11th FYP period, the country invested 21.9 billion to wipe out the outdated capacity in 13 sectors. Some remarkable outcomes include the elimination of small thermal power plants with a generation capacity amounting to 80 MkW, and wiping out of outdated production capacities of 121.7 million tons of iron, 69.7 million tons of steel, 100 million tons of cement, and 10.3 tons of pulp.<sup>2</sup>

#### **5.1.4.4 Financial Support for Building Energy Efficiency**

During the 11th FYP period, to promote building energy conservation, the central government allocated RMB 15 billion in the following four major areas—new buildings, heat reform and retrofit projects in northern areas, government office buildings, large-scale public buildings, and renewable energy application in buildings.<sup>3</sup>

#### **5.1.4.5 Energy Efficiency and New Energy Vehicles Subsidy**

During the same period, RMB 2.22 billion was also allocated by the central government to promote energy efficiency and new energy vehicles in the public sector. Initially, only hybrid, electric, and fuel cell vehicles that are used in public transportation are eligible for government subsidy, but later, the subsidy scheme was expanded to include private cars. Also as an effort to speed up upgrading the auto industry, in 2009, the Chinese government launched a program to provide subsidies for replacing old cars and buses in the public domain with more fuel-efficient vehicles.

#### **5.1.4.6 Energy Performance Contracting and Energy Service Companies**

From 2010, the Chinese central government began to issue a series of supportive policies and incentives to foster the energy service industry in China. According to a reward policy for energy performance contract (EPC) projects released in 2010, qualified ESCO companies can receive RMB 240 for every ton of standard coal saved in their EPC projects from the central government and receive at least RMB 60 from the local government.

With government support and investment from financial institutions and private sectors, China's energy service sector has also seen tremendous growth in the past few years. At the end of 2012, there are 4175 companies in China engaging in energy service, among which 2339 are registered with the NDRC and the MOF. The total output of the energy service sector has also reached RMB 165.3 billion in 2012, 32.24% up from a year ago.<sup>16</sup> The Chinese government now considers the EPC model as one of the main market mechanisms for energy efficiency improvement and aims to build an advanced energy efficiency service system by 2015.<sup>17</sup>

#### **5.1.4.7 Demand Side Management Pilot Cities**

In July 2012, the MOF and the NDRC announced a new program to support adoption of energy efficiency power plants (EEPPs), demand response technologies and promotion of related scientific research, training and education, verifications, and evaluation work. In October 2012, the MOF and the NDRC announced the first four pilot cities to receive the incentive as the first step of the program.

According to the program, any pilot projects that use EEPP and load shifting technologies to achieve permanent load reductions and peak load shifting will be awarded RMB 400/kW reduced in eastern provinces or RMB 550/kW reduced in central and western provinces. For any pilot projects that lead to temporary reductions in peak load through demand response, there will be a reward of RMB 100/kW.<sup>18</sup>

#### **5.1.4.8 Energy Efficiency Institution and Capacity-Building Subsidy Program**

In addition to investment in specific sectors, the central government has also provided funding for institution and capacity building at provincial and local levels. The funding is mainly used to improve the energy efficiency monitoring and management capacity of provincial and

municipal energy efficiency management institutions. These bodies, either called energy conservation supervision team or energy conservation center, not only help with the formulation of provincial and municipal energy efficiency planning, policies, and related research, but also facilitate the implementation of government's energy efficiency policies and regulations.

#### 5.1.4.9 Government Procurement Program

Modeled after the U.S. Federal Energy Management Agency (FEMA), a government energy efficiency procurement policy was announced by the NDRC and the MOF in December 2004. Initially, the new policy specified that the products on the energy efficiency procurement list should be given *preferential* consideration in procurement.<sup>19</sup> In August 2007, the procurement policy was made mandatory at all levels of government. The energy efficiency procurement list has been updated several times and expanded from 9 types of products in 2004 to 24 by the end of 2012.

Similarly, the MOF and the State Environmental Protection Administration (now Ministry of Environmental Protection [MEP]) initiated a green purchase policy in December 2006. In July 2008, the MOF and MEP made the use of green purchase list mandatory at all levels of government.<sup>19</sup> There are some overlaps of the energy efficiency government procurement list and the green purchase list with the latter covering a wider range of environmentally friendly products. It is stipulated that the products listed on both lists will be given *preferential* consideration compared to those only listed on one list.

---

## 5.2 Renewable Energy

### 5.2.1 Market Overview

The combination of ambitious renewable energy targets, favorable government policies and entrepreneurial acumen has already made China a global leader in renewable energy. During the 13th FYP period (2015–2020), development of renewable energy and new energy sources will continue to be the government's priority given its importance in environmental protection, combating climate change and sustainable development. According to the 13th FYP for Renewable Energy which is being formulated, renewable energy will play an important role in optimizing China's energy structure and revolutionizing China's energy production and consumption.<sup>20</sup> The status of renewable energy will also shift from what is now called complementary energy sources to alternative energy, displacing a significant portion of fossil fuels.<sup>21</sup>

At the end of 2010, the installed capacities for wind and solar power both exceeded the targets that the Chinese government set in the 11th FYP (2006–2010). 2012 was another pivotal year for renewable energy development in China. The installed renewable energy reached 313 GW, up 11% from the previous year. This includes 248.9 GW of hydropower, 60.8 GW of grid-connected wind, and 3.3 GW of grid-connected solar power.<sup>22</sup> Most significantly, in 2012, wind power replaced nuclear power as the third largest energy source in China, after thermal and hydropower, and accounted for 2% of total energy power generation.<sup>23</sup> By the end of 2014, the installed capacity for renewable energy reached 430 GW, accounting for 32% of the country's total power capacity. The electricity generated by renewable energy reached 1.2 trillion kilowatt-hours, accounting for 22% of the total electricity generated during the same period.<sup>24</sup>

### 5.2.1.1 Wind Power

China ranks second in terms of wind energy resources, only next to the United States.<sup>25</sup> According to the findings of the wind energy resource survey and evaluation, China has 2380 and 200 GW land-based and offshore wind power potential at a height of 50 m.<sup>26</sup> The combined exploitable capacity is larger than that of hydropower.<sup>1</sup> While China is a latecomer to wind power development and deployment compared with many western countries, the country has witnessed tremendous growth in wind power in the past ten years.

At the end of 2010, China surpassed the US to become the world leader in installed wind power capacity, with 16 GW newly added wind power capacity and a total of 41.8 GW wind capacity.<sup>27</sup> According to the Global Wind Energy Council, the US installed about 5 GW of new wind power capacity in 2010 and its total installed capacity was 40.2 GW.<sup>27</sup> In terms of total grid-connected wind capacity, China also surpassed the US in 2012 with 50 GW on-grid wind capacity installed.<sup>28</sup> By the end of February 2014, the cumulative grid connected installed capacity for wind power reached 100.04 GW, which makes China the first country to top the 100GW wind power capacity milestone.<sup>29</sup> With the rapid and continuous increase of wind power installed capacity, China has already positioned itself as the largest wind power market in the world.

China's wind industry has mainly benefited from the favorable market conditions that government policies and regulations helped to foster. After several years of rapid growth, the wind power industry has been transitioning from frenzied initial stage with the emphasis placed on the maximum installed capacity to a new development phase focused more on quality, safety, reliability and efficiency. Manufacturing overcapacity, together with intense market competition and government policy to hold back funding and approval of wind projects have combined to cut the profit margins of many wind manufacturers in China. The growth rate of newly added wind power installed capacity started to slow down in 2011, from 18.92 GW in 2010 to 12.96 GW in 2012. However the downward trend didn't last very long. Data for 2013 show the wind power industry has regained momentum with 16.08 GW of new wind capacity installed during the year. In 2014, the newly added wind capacity reached an all time high with 19.81 GW new wind capacity installed.<sup>30</sup>

One of the challenges of China's wind power development is grid connection. Due to their weak capacity, many local grids are unable to integrate all the electricity generated by wind power. Large-scale wind power integration also creates serious problems in terms of power grid dispatch, reactive power regulation, grid safety and power quality. Furthermore, since the geographical distribution of wind energy resources does not match the country's power load profile, long distance transmission of electricity becomes necessary. Yet this is again restricted by the limited transmission capacity of power grids.

Largely due to insufficient power grid infrastructure, a great amount of electricity generated by wind power has to be discarded each year. National Energy Administration statistics show that more than 10 billion and 20 billion kWh of electricity generated from wind power was discarded in 2011 and 2012 respectively.<sup>31</sup> The grid connection problem not only needs a technical fix, but also calls for a fundamental change in China's overall power system. After the business of power generation was split from grid companies, which now only focused on power transmission and distribution, grid companies have little motivation to integrate renewable energy into their grids because the integration of renewables will cost them more money due to the extra expenses incurred in the grid connection and electricity purchases.

With the implementation of favorable wind power policies, improvement of grid transmission capacity and reduced amount of wind, the average rate of abandoned electricity

fueled by wind power has been decreasing over the past two years from 11% in 2013 to 8% in 2014, which is at the lowest level in recent years.<sup>32</sup> However, the rate climbed again to 18.6% in the first quarter of 2015.<sup>33</sup> The fluctuation of the rate shows wind power grid integration and absorption have been and will continue to be a big challenge for the development of wind power in China.

#### **5.2.1.2 Solar Power**

Since 2007, China has also become the largest PV products manufacturer in the world. Among the world's top 10 solar PV module suppliers, six are based in China.<sup>34</sup> About 90% of PV panels manufactured in China were exported to countries with more favorable incentives, such as North American and European countries. From 2002–2008, there were only a few demonstration solar PV projects in China.<sup>35</sup> This is largely due to the high cost of PV systems and the barriers of grid connection, a problem also faced by China's wind power industry.

The cutback of government subsidies and declining PV demand in the European countries had a great impact on China's PV manufacturers, which rely heavily on the foreign market. What weighed further on China's PV industry are the anti-dumping and countervailing duties against Chinese PV products exported to the US, followed by similar trade investigations launched in the European Union, Canada and India. To offset their export losses and absorb manufacturing overcapacity, the Chinese PV manufacturers quickly turned to the domestic market which was largely untapped at the time and emerging markets which witnessed a surge in the growth of renewable energy in the past few years. Overcapacity has also triggered a new round of merging and restructuring among manufacturers in the PV sector. The Chinese government sees this as an opportunity to eliminate the outdated production capacity and upgrade the country's PV industry. It also released a variety of supportive policies to further encourage the expansion of the domestic PV market.

According to research released in the NPD Solarbuzz quarterly report, the demand for PV panels from the Chinese end-market has already risen to 33% of global demand during the final quarter of 2012.<sup>36</sup> In 2013, China has already become the world's largest market for solar power, outstripping Germany, Japan and the US with the installation of 12 GW of new PV capacity. This represents a 232% increase in generation capacity.<sup>37</sup> In 2014, China added 10.6 GW of newly installed PV capacity, which is one fourth of the world newly added installed capacity that year.<sup>38</sup>

China also made remarkable progress in concentrated solar power (CSP) generation in the past few years. According to the 12th Five Year Plan for Solar Power Generation Development, the installed capacity for CSP will reach 1 GW and 3 GW by 2015 and 2020.<sup>39</sup> In 2010, a 50 MW CSP commercial project in Inner Mongolia was launched through a public tending program. However, as of the time of writing, the project hasn't been constructed. It was not until July 2013 that the first CSP plant was connected to the power grid and began to generate electricity in Qinghai province. With a 50 MW installed capacity, the plant is expected to generate 112.5 million kWh electricity, equivalent to reduction of 394,000 tons of standard coal and about 103,000 tons of carbon dioxide.<sup>40</sup> The CSP plant symbolizes the transforming of CSP projects from a small-scale technology demonstration to a large-scale commercial project.

Compared with other forms of solar power utilization, CSP generation has lagged far behind. This is largely due to the lack of clear and robust government support for CSP. First, there's no fixed feed-in tariff (FIT) for CSP generation, and the FIT for a CSP project is decided on a case by case basis. In September 2014, the FIT was set at RMB 1.2/kWh for the 50 MW CSP plant in Qinghai. Secondly, the approval process of a CSP project can be very lengthy and sucks up a large amount of time and money from CSP project investors.<sup>41</sup>

Solar heat utilization has seen rapid development in China with favorable central government policies and incentives from provincial governments. Major forms of solar heat utilization include solar water heaters, centralized solar hot water supply, solar heating and cooling, industrial application of medium and high temperature solar energy, and solar cookers and solar houses, especially in remote and rural areas.<sup>1</sup> Among all, the solar water heater is the most widely used and commercialized form of solar heat utilization. After years of rapid development, China has already become the largest solar water heater manufacturer in the world with a complete value chain of solar water heater production. In 2012, China's solar water heater production has reached 63.9 million m<sup>2</sup> at a growth rate of approximately 10.7%, with total inventory of roughly 258 million m<sup>2</sup>.<sup>42</sup> Due to overcapacity and shrinking demand, the solar water heater industry has also suffered a major decline since 2012. In 2014, solar heater production declined 17.6% from a year ago, which is the first negative growth in 17 years.<sup>43</sup>

### 5.2.1.3 Biomass

China has abundant biomass resources with an estimated annual amount of more than one billion tce. This is more than 1.3 times the country's annual energy consumption.<sup>44</sup> According to a report released by the Chinese Academy of Science on China's renewable energy development strategy, the capacity of biomass energy resources is twice as much as that of hydropower and 3.5 times that of wind power.<sup>45</sup> While biomass is a prioritized renewable energy together with wind and solar, the Chinese government failed to meet some of the targets for biomass energy set in the 11th FYP of Renewable Energy, such as the targets for methane utilization, nonfood fuel ethanol, biomass pellets and briquettes.<sup>46</sup>

There are many hurdles for large-scale utilization of biomass energy, one of which is the nature of biomass energy, such as low energy density and nonuniform consistency. The principal biomass feedstocks in China are wastes and residues from agriculture and forest industries; animal manure from medium- and large-scale livestock farms, and municipal solid waste.<sup>44</sup> So far, there's still no nationwide survey on the quantity, exploitable capacity and distribution of biomass energy resources. The feedstock of biomass energy is mainly collected manually with small-scale machinery. The collection, transportation and storage of feedstock of biomass energy are extremely inefficient. In addition, the technology of biomass utilization and equipment manufacturing remains a bottleneck for developing biomass energy such as the technologies of biomass gasification and second-generation fuel ethanol.

## 5.2.2 Renewable Energy Policies

### 5.2.2.1 General Policies

Renewable energy was first incorporated into the legislation list as early as 2003. One of the milestones of renewable energy is the Renewable Energy Law that came into force in 2006. The Law not only identifies the strategic role of renewable energy in energy security, environmental protection and sustainable development, but also serves as a framework for renewable energy related government work including resources investigation, target setting, planning, pricing and cost share, fiscal, financial and tax incentive mechanisms for renewable energy. After the Renewable Energy Law took effect, more than a dozen regulations were enacted to help enforce the law. Some of the provisions of the law were also amended in 2009. The majority of these renewable energy related policies are related to wind power and solar PV generation, whereas only a few are focused on bioenergy, geothermal and ocean energies.

The Renewable Energy Law stipulates that China's NRDC is in charge of overall planning of renewable energy development and energy pricing; the China Standardization

Administration manages technical standards and codes related to renewable energy; the MOF is responsible for fiscal and financial incentive mechanisms, like tax breaks and subsidized loans.<sup>47</sup> Established in 2008, the National Energy Administration is under the jurisdiction of NDRC and responsible for drafting and implementing energy development strategies, plans and policies, advising on energy and regulating sector.<sup>48</sup>

According to the Law and regulations, grid companies are mandated to sign grid integration agreements with eligible renewable energy power generation enterprises and to purchase the electricity that is generated. All the extra costs that grid companies paid to integrate and purchase the electricity generated by renewable energy compared to traditional power (also known as renewable energy surcharge or premium) need to be shared by end users of electricity nationwide. The renewable energy surcharge was first set at RMB 0.002/kWh under the Law and was later raised to RMB 0.004/kWh in 2009.

A renewable energy development fund was established under the Renewable Energy Law to promote renewable energy development and utilization. At first, the source of the fund is solely government allocations, but according to a 2009 amendment to the Law, part of the fund will come from the renewable surcharge paid by all electricity users around the country. With the rapid development of renewable energy installed capacity, the shortfall in funding the renewable energy projects has increasingly become a prominent problem. Statistics show the shortfall of the renewable energy development fund reached RMB 1.3 billion in 2009 and 2 billion in 2010.<sup>49</sup> By the end of 2014, the shortfall has expanded to RMB 14 billion. To make up for the shortfall, the renewable energy surcharge was raised twice to finance the fund from RMB 0.004/kWh to RMB 0.008 /kWh in 2010 and further to RMB 0.015 in 2013.<sup>50</sup>

In September 2007, more than eighteen months after China's Renewable Energy Law called for the establishment of overarching renewable energy targets, the NDRC released the Medium and Long-Term Plan for Renewable Energy Development. It was the first time the Chinese government set explicit quantified targets for renewable energy consumption. The plan established a national renewable energy target (including hydropower) of 15% of total primary energy consumption by 2020.<sup>51</sup> A renewable energy quota system was also introduced in the Plan. In the service range of large-scale power grid, nonhydro renewable energy power generation will surpass 3% by 2020. Power generators with self owned installed capacity over 5 GW are required to have nonhydro renewable energy installed capacity accounting for 8% of total self owned capacity by 2020.<sup>52</sup>

As of April 2015, a new version of the renewable energy quota system has been approved by NDRC and is now under the review of the State Council. According to this version, the renewable energy targets, which are categorized as basic targets and advanced targets, will be first broken down by province and then by city and county within a province.<sup>53</sup> Provincial governments and grid companies are responsible for meeting the targets of renewable energy, whereas local governments will exercise their management responsibility. Instead of setting specific and binding renewable energy targets, the new version allows provincial and local governments more flexibility to achieve their targets.<sup>52</sup> Furthermore, governments that are unable to meet their renewable energy targets will be punished, whereas those that meet the targets ahead of time will be rewarded. In addition to the renewable energy quota system at the national level, a few provinces, such as Hubei and Inner Mongolia, also released their own renewable energy quota systems.

In addition to large-scale renewable energy deployment, China has also been promoting distributed utilization of renewables based on the principle "self-generation, self consumption and feeding the surplus into the grid." This effort includes promoting distributed renewable energy technologies, standards and demonstrations, providing subsidies and tax incentives for distributed renewable energy projects.

To further drive comprehensive renewable energy use in urban and rural development, China plans to build 100 new energy demonstration cities and appoint 200 green energy counties according to the 12th FYP for Renewable Energy Development. One of the requirements for a new energy demonstration city is that by 2020, renewable energy will be no less than 6% of the candidate city's total primary energy consumption. According to the plan, China will also deploy 30 new energy microgrid demonstration projects as a way to explore the economic and technological feasibility of renewable energy-powered microgrids.

#### **5.2.2.2 Wind Power Specific Policies**

Wind power is the most commercially available nonhydro renewable energy in China. According to the 12th FYP for Renewable Energy Development released in 2012, China will have a total of 10 GW grid-connected wind installed capacity by 2015, and the annual wind power generation is expected to amount to 190 billion kWh by that time.<sup>54</sup> By the first quarter of 2015, the target for land-based wind installed capacity was achieved with a total installed capacity up to 10.1 GW.<sup>55</sup>

From 2003 to 2009, China mainly implemented a wind power concession program to promote large-scale deployment of wind projects. Under the program, wind power projects with installed capacity smaller than 50 MW is under the jurisdiction of provincial government, and the price of electricity generated from projects was determined through a competitive bidding process. Wind projects larger than 50 MW need to be approved by the central government, NDRC.

Under the Power Purchase Agreement (PPA) signed by a power grid company and a wind power project owner, the former is required to purchase all the electricity generated by the latter. A two-phase electricity rate is applied during the effective period of the PPA. Before the cumulative electricity production of wind power is equivalent to 30,000 full load hours, the electricity rate is the bid price specified in the PPA. Thereafter, the rate is the average price on the power market at the time.<sup>56</sup>

The wind power concession program not only plays an important role in wind power development from demonstration projects to scale up construction, but also helps the government to determine an appropriate FIT for land-based wind power. The price of nonconcession wind projects during the period was either based on the bidding results in the same area or required to be approved by the provincial government on a project by project basis.

In effect since August 2009, a wind power FIT policy for land-based projects was introduced in China. It divided China's territory into four regions with different FITs specified based on wind resources and construction conditions. The tariffs were first set per kilowatt hour at RMB 0.51, RMB 0.54, RMB 0.58 and RMB 0.61.<sup>57</sup> In January 2015, the FIT for the first three categories were lowered to RMB 0.49, 0.52 and 0.56.<sup>58</sup>

As of the end of 2014, China ranks fifth among the world's top offshore wind installation countries. After China's first offshore wind demonstration project was successfully completed and connected to grid in Shanghai, China launched the first concession program for an offshore wind project in China's southeast coastal province of Jiangsu in 2010. A few other provinces have also started working on offshore wind power development plans since then. By the end of 2014, China installed 229.3 MW new offshore wind capacity and the total installed capacity from offshore wind has amounted to 6579 MW.<sup>59</sup>

According to the 12th FYP for Wind Power Development, the installed capacity of offshore wind power will reach 5 GW by 2015 and 30 GW by 2020.<sup>60</sup> With less than one year left and 6579 MW total offshore installed capacity so far, China is unlikely to meet its target of 5 GW offshore installed capacity by 2015 (Table 5.2).

**TABLE 5.2**

Targets of Wind Power Development by 2015 and 2020

Types of Targets	Main Targets	2015	2020
Installed Capacity	Land-based wind power	99 GW	170 GW
	Offshore wind power	5 GW	30 GW
	Total Installed Capacity	100.4 GW	200 GW
Generating Capacity	Electricity Generated by Wind Power	190 Billion kWh	390 billion kWh
	Percentage of Electricity Generated by Wind power	3%	5%

Source: Energy Research Observer Net. (2012) The 12th FYP for Wind Power Development. September 17. Retrieved April 30, 2015 from [http://www.chinaero.com.cn/zcfg/xny/09/127069\\_4.shtml](http://www.chinaero.com.cn/zcfg/xny/09/127069_4.shtml)

In June 2014, NDRC also released the FIT scheme for offshore wind projects commissioned before 2017, which is RMB 0.75/kWh for intertidal and RMB 0.85/kWh for offshore wind projects.<sup>61</sup> Later that year, the NEA issued a national offshore wind power project construction plan to boost the development of offshore wind power. According to the plan, 44 offshore wind projects will be constructed from 2014 to 2016 with a total installed capacity of 10.53 GW.<sup>62</sup>

In addition to the FIT for land-based and offshore wind power, wind power generation enterprises can also enjoy a series of tax incentives such as 50% of value-added tax (VAT) return, exemption from corporate income tax during the first three years after the company earns profit from sales; and a 50% reduction of income tax during the 4–6 years after it earns a profit. Wind power equipment manufacturers can also enjoy some tax exemption or cut on import duty of certain key parts and raw materials of wind turbines. Complementing these favorable policies and regulations at the central government level, local governments also released a series of favorable policies on land use and taxation to encourage wind equipment manufacturers and wind project developers to invest in wind projects.

To address the grid integration and safety issues, the Chinese government has tightened the wind power project approval procedure from 2011, requiring all new wind power projects to be approved by the NDRC. Projects only approved by the provincial government will not be allowed to be connected to the power grid or enjoy renewable energy subsidies. In addition, projects in regions where over 20% of electricity generated by wind power is discarded due to limited integration and transmission capacity will no longer be approved. In May 2013, the NEA transferred authority over wind power project approval from NDRC to provincial or local governments.<sup>63</sup> However, a wind project still needs to be listed in the NEA project approval plan in order to receive government renewable energy subsidies.<sup>64</sup>

### 5.2.2.3 Solar Power Specific Policies

Solar power is the third most commercially viable renewable energy following hydropower and wind. According to the 12th FYP for Solar Power Development issued by the NEA under the NDRC, the target for installed solar power is 21 GW by 2015, among which 10 GW is distributed PV systems, 10 GW is grid connected PV and 1 GW is CSP system.<sup>65</sup> The plan also sets the target of installed solar power generation at 50 GW by 2020. The target of installed solar power by 2015 has been raised several times and the target was raised to 35 GW in 2013. In addition, the 12th FYP also set the total solar heat collection area at 400 m<sup>2</sup> by 2015 (Table 5.3).

Unlike wind power, early policies treated solar power more as one of the supplementary solutions to provide electricity to the remote and rural areas. This mindset was dominant among China's policy makers for quite a long time. It partly explained the reason why China prioritized wind over solar power up to 2008.

**TABLE 5.3**

China's Targets for Solar Power Installed Capacity by 2015 and 2020

Installed Capacity	2015	2020
Grid-connected PV	10 GW	20 GW
Distributed PV	10 GW	27 GW
Concentrated Solar Power (CSP)	1 GW	3 GW
Total	21 GW <sup>a</sup>	50 GW

Source: National Energy Administration. (2012) The 12th FYP for Solar Power Generation Development. July 7. Retrieved April 30, 2015 from <http://zfxxgk.nea.gov.cn/auto87/201209/P020120912536329466033.pdf>

<sup>a</sup> This target was raised to 35 GW in 2013.

To promote large-scale PV application and determine an appropriate FIT for solar energy, the Chinese government also adopted a concession program for large-scale grid-connected PV projects. In 2009, China issued its first tender for two 10 MW utility scale solar power plants in Dunhuang, Gansu province. In 2010, the Chinese government initiated a second round of concession bids for 13 large-scale PV projects for a total of 280 MW. The first project was granted RMB 1.09/kWh for the power fed into the grid. In the second round, the winning bids ranged from RMB 0.728/kWh to RMB 0.991/kWh. Largely due to the advocacy of PV manufacturers and local government, the FIT for solar power was established in July 2011. Under the scheme, projects approved for construction prior to July 1, 2011 is eligible for the FIT of RMB 1.15. Projects that finished construction and began the process of commencing generation prior to December 31, 2011 are also eligible for the FIT.<sup>66</sup> Later in 2011, the FIT was lowered to RMB 1/kWh. In addition to these concession projects, there are also other grid-connected PV projects implemented during the same period, and their power price is set by the government on a project by project basis.

In March 2012, a new solar FIT scheme for utility PV ground power plants was released for comments. The new solar power FITs were set at RMB 0.75/kWh, 0.85/kWh, 0.95/kWh and 1/kWh for each of four regions categorized based on different solar radiation level and construction conditions. In August 2013, NRDC announced a new FIT policy for solar power that was set at RMB 0.9/kWh, 0.95/kWh and 1/kWh for each of three types of regions.<sup>67</sup>

To address the overcapacity of solar power production while preventing further grid integration issues, the government has implemented robust subsidy programs for deployment of distributed PV. The Golden Sun program, initiated by the MOF, the Ministry of Science and Technology and the NEA in 2009, provides capital subsidies to electricity end users for solar PV installations. The Golden Sun program subsidies were granted before the construction of a project and there was very limited monitoring of an approved project's power generation. While the government tried hard to improve the implementation of the program, controversies around the program still exist. In March 2013, the government announced that the Golden Sun program would no longer accept applications. Later that year, the Golden Sun program was officially ended. Statistics show four batches of PV generation projects with a total 60 GW installed capacity were approved under the program. However, there is no public information on the status quo of the projects, the amount of electricity generated, and the total amount of subsidies received by these projects.

As a separate program, the Ministries of Finance and Housing and Urban-Rural Development (MOHURD) are providing subsidies to promote application of rooftop PV and building-integrated PV (BIPV) systems. Like Golden Sun program, this program is also one-time subsidy provided before the construction of the project. Differently, the Golden Roof program only focuses on BIPV whereas the Golden Sun program provides

subsidies to both rooftop PV and BIPV. The two programs used to be one program jointly issued by the MOF, Ministry of Science and Technology, MOHURD and NEA, but was announced and implemented separately due to different views of MOHURD and NEA on distributed PV policies.<sup>68</sup>

For distributed PV projects, a subsidy of RMB 0.35/kWh was first introduced in 2012. In August 2013, NDRC raised the subsidy to RMB 0.42/kWh and made the eligibility period of the subsidy as long as 20 years.<sup>65</sup> In addition to the subsidy at the national level, provincial and local governments also provide additional subsidies to distributed PV projects in their jurisdictions.

During 2014, the Chinese government further issued a series of favorable policies to accelerate the growth of distributed PV. One of the most noteworthy policies is that rooftop distributed PV project owners can choose to sell either excess electricity or all electricity generated to the grid and that the electricity price will be the same as the local FIT for ground PV power plant. In the past, a distributed PV project owner could only sell excess electricity to a power grid after self consumption.<sup>69</sup> By guaranteeing all electricity purchased by the power grid and a fixed price paid to the project owner, the policy shift guarantees the stable revenue of a distributed PV project and thus is welcomed by the distributed PV project developers around the country.

At present, distributed PV projects mainly consist of PV power plants for residential use, rooftop PV projects of public facilities, and industrial and commercial buildings.<sup>70</sup> Due to reasons like difficulties in project financing, grid integration, and uncertainty in power load, distributed PV development has lagged far behind of that of large-scale ground PV power plants. Since China failed to meet its PV installed capacity targets in 2014 mainly because of distributed PV, NEA no longer sets a specific target for distributed PV for 2015.

Besides, a large scale distributed PV application demonstration area program was launched by the NEA in 2012, requiring provincial government to submit a plan on establishing pilot areas for distributed PV power generation. Following the NEA's efforts, the State Grid Corporation of China, the country's largest state-owned utility, released a series of documents to simplify the procedure of grid integration of residential distributed PV power generation no more than 6 MW. As of 2015 the NEA has announced 30 distributed PV application demonstration areas.<sup>71</sup>

#### **5.2.2.4 Biomass Specific Policies**

In China, biomass energy development is an integral part of the government's efforts to develop local economy, improve living conditions in rural areas, and protect the ecology. In the wake of the food crisis, the government issued strict rules to make sure that biofuel development (including fuel ethanol and biodiesel) does not compete with crops intended for human consumption and that the land for developing feedstock should not compete with land for crop production. The government also encourages experimentation with alternative crops such as sweet sorghum and cassava for new ethanol plants.<sup>72</sup>

According to the Chinese government's 12th FYP for Biomass Energy, installed capacity of biomass energy will reach 130 GW by 2015 with annual biomass power generation amounting to 78 billion kWh. The annual production of biogas will reach 22 billion m<sup>3</sup>. In terms of various forms of biofuel, China's fuel ethanol utilization capacity will reach 4 million ton and the capacity of biodiesel and aviation biofuel will reach 1 million ton by 2015. In addition, the government aims at achieving full commercialization and large-scale utilization of biomass energy in its power sector, heat supply, and rural life. In the transportation sector, a larger portion of biomass energy is expected to replace fossil fuel by 2015.<sup>73</sup>

The FIT for biomass was first set at RMB 0.25/kWh premium plus the province-specific coal power generation price. The premium was then increased to RMB 0.35/kWh for biomass. The FIT for biomass energy was later raised to RMB 0.75/kWh in 2010 by NDRC. Like solar and wind, biomass energy can also enjoy a series of tax incentives. For instance, the electricity or heat generated from waste is eligible to receive tax rebates at the time the VAT is levied. The income tax for a biomass energy enterprise is calculated using 90% of the enterprise's total sales income as the base. Qualified biomass enterprises can enjoy a corporate income tax exemption during the first three years after it earns profit and enjoy a 50% cut of corporate income tax during the following three years.

### 6.1 Background

India has traditionally been a low energy and electricity consumption country, notwithstanding its large and fast growing population. This was partly because of the so-called Hindu rate of growth during the several decades after independence. The economic policy changes undertaken since early 1990s with greater participation of private sector and deregulation of infrastructure and industrial sectors resulted in higher growth rates of the Indian economy, which grew in the last decade at an annual rate of about 8%\* although it has declined progressively to about 5% in the last 2–3 years because of the

\* From the Economic Surveys of the period, published by the Ministry of Finance, Government of India every year.

global recession. But the chances are that growth may continue to be between 7% and 9% in the long term. This process is being accompanied by large-scale urbanization, growth of the middle class, and changing life styles, leading to a huge growth in buildings and cars and sale of electrical appliances topped by air conditioners, fridges, geysers, and microwaves. Necessarily therefore, there has been, and will continue to be, significant increases in India's energy and electricity demand. In 2011, India was the fourth largest energy consumer in the world after the United States, China, and Russia.\* India has been ranked by the IMF as the world's tenth largest economy and the third largest in terms of purchasing power parity. India will continue to climb up this ladder. An Indian Planning Commission study in 2006 estimated that based on 8%–9% growth, primary energy demand may go up 4–5 times by 2031–2032, while electricity generation requirements may go up by 6–7 times. It estimated that electricity-generating capacity may have to go up to 7–800 GW.†

Energy services have always remained in focus of successive Indian governments that has resulted in the expansion of the energy infrastructure within the country and steady expansion in total energy use. Commercial energy use increased 21 times and the power generation capacity went up by 100 times during the past 60 years. In 2012, the total commercial energy supply was 537 million tons of oil equivalent (mtoe) and involved coal, oil, gas, and electricity generated from nuclear, hydroelectric, and renewable sources.‡ These figures do not include the energy that is consumed from traditional sources by 56% of Indian households.§ Estimates of energy use from traditional sources tend to be approximate, but figures indicate that in 2012, 174 mtoe of energy came from such sources as fuel wood, dung, crop residue, biogas, and waste.¶ India's energy intensity has been declining over the years. From 1.09 kgoe per U.S. dollar, it has reduced to 0.62 kgoe per U.S. dollar in 2011.\*\*

Nevertheless, the growth of energy sector could not and has not been able to match the growth in economy in spite of impressive progress in the last decade. The energy sector continues to be viewed as an important bottleneck to India's industrial growth that in turn is seen as critical to stimulating the country's economic and social development. While supporting around 17.8% of the world population, India's share in world energy use and electricity consumption is only 5.7% and 4.0%, respectively.†† The per-capita energy use at around 0.60 toe is far below that of industrialized countries, and, more importantly, is almost only a third of the world average. The situation in per-capita electricity consumption is even worse with a per-capita annual consumption of only 710 kWh, which is around a fourth of the world average.‡‡ In fact, in the event of achieving the capacities of 7–800 GW, the per-capita primary energy consumption will rise only to almost 1.25 toe, which would still be much lower than the current world average of about 1.88 toe/capita/annum.§§ Electricity deficit levels have remained consistently high

§§ IEA Key World Energy Statistics 2013.

in recent years with supply trailing requirement by an estimated 8%–10%.\* And this may not even be reflecting the total demand. Another major challenge continues to be providing access to modern energy sources to a large proportion of the country's population. Around 45% of rural households still rely on kerosene for meeting their lighting requirements.† Further, around 86% of rural households and more than 20% of the urban households still rely primarily on traditional fuels such as firewood, wood chips, or dung cakes to meet their cooking needs.

## 6.2 Growth of Electricity Capacity

The Indian power sector has grown significantly since 1947. The power-generating capacity has increased from 1.3 GW in 1947 to over 261 GW by January 2015.‡ However, despite significant growth in electricity generation over the years, shortage of power continues to exist primarily on account of growth in demand for power outstripping the growth in generation and capacity additions in power generation. The average energy deficit was 9.1% and the average peak power deficit was 12.8% between 2003 and 2012.§

The Electricity Act 1910 was the first act that was introduced to govern the Indian power sector. The Electricity (Supply) Act 1948 was introduced after independence, but it did not achieve the desired results. Following the liberalization and reform of the economy in 1991–1992, the electricity sector too witnessed major policy and regulatory initiatives. A regulatory framework was set up with independent regulators in the center and states recognizing that electricity and other infrastructure sectors required substantial investments in the face of resource constraints, investment by the private sector (including foreign capital) was allowed in electricity generation. Now 100% foreign direct investment (FDI) is allowed in generation, transmission, and distribution segments. The most important among all the policies announced by the government was the enactment of the Electricity Act 2003. It opened up the power generation sector and encouraged greater private participation. It unbundled the State Electricity Boards; separated generation, transmission, and distribution; and introduced open access. Over the past few years, the government of India undertook several further measures like the National Tariff Policy, National Electricity Plan, Competitive Bidding Guidelines, and Ultra Mega Power Projects. Incentives were also given to the sector through waiver of duties on capital equipment under the mega power policy. These all resulted in a surge in creation of capacity. A capacity of about 46 GW of thermal power was created between 2006 and 2012. However, this growth in capacity should be seen in the context of what has happened in China. The total capacity of China went up from 725 GW to about 1200 GW from 2007 to 2012, respectively.¶ The growth in power capacity over the years is given in [Table 6.1](#).

Notwithstanding this recent growth, many problems are being faced, which may make it difficult to achieve the capacity that has been estimated to be required by 2032. The problems are caused by forest and environmental and logistical issues for coal. Problems related to the liability law and increasing people's opposition after the Fukushima incident

in Japan suggest that nuclear may increase slowly perhaps reaching about 25–30 GW by 2032, instead of the targeted 60 MW. Gas reserves are not much, exploitation of new fields has been delayed, and production from existing fields has declined, leaving much of newly created gas power capacity stranded. Oil is facing similar problems. Large hydro was forecast to reach 150 GW, but there have been environmental and logistical problems to develop this potential in the Himalayas. Even reaching 100 GW, for which we must make our utmost efforts, may be a problem. With this scenario, meeting increasing demand will require other solutions apart from efforts to maximize use of all above sources.

The Power sector in India is also facing other problems and challenges apart from those of creating generating capacity in the future. First, irrespective of the capacity created, the supply availability of fuels is becoming a problem especially with respect to coal and gas. Second, these problems are necessitating higher imports of all fuels—gas, coal, and oil. Estimates including those made in the Integrated Energy Policy Report suggest that import dependence for energy in 2031–2032 could be as high as around 60%. There is great worry about the likely import dependency on oil of over 80%–90% and coal around 45%. Third, costs of all fuels are increasing. There is perhaps rise of 10%–15% in prices of coal because of imports, and the worry is that this trend may continue. Domestic prices for gas have also increased and imported prices will be more. The price per unit of electricity generated from gas is likely to become even higher than the current solar price. Rising capital costs of nuclear plants also suggest much higher generation costs in the future. Fourth, electricity tariffs have traditionally been lower than costs and have only been revised in the last couple of years in several states, though partially. Yet there is considerable political opposition to this and pressure to reduce. Rural tariffs have been lower still, and the rural irrigation power sector has been the lowest. This has resulted in most of the utilities being in very poor financial health. This restricts both investments in improving infrastructure as also in limiting purchases of power to meet normal demand. Fifth, the rising costs of imported fuels, caused by the increase in quantities has adversely impacted India's current account deficit. Huge subsidies for various oil products have caused serious problems for the revenue and fiscal deficits apart from creating other aberrations. The annual subsidy on kerosene alone is around U.S. \$5 billion (though this is declining because of recent fall in oil prices). Domestic cooking gas has about 30%–40% subsidy.

It is clear from the aforementioned data that India's need for secure, affordable, and environmentally sustainable energy has become one of the principal economic and development challenges for the country. It is also clear that while energy conservation and demand management and energy efficiency will have important roles to play in the national energy strategy, renewable energy will become a key part of the solutions and is

likely to play an increasingly important role for augmentation of grid power, providing energy access, reducing consumption of fossil fuels, and helping India pursue its low carbon developmental pathway.

---

### **6.3 New and Renewable Energy**

After the oil shock of the seventies, there was a global recognition of the need to develop alternative energy technologies. Government of India created the Department of Non-Conventional Energy Sources (DNES) in 1982. The thrust areas identified included research, development, demonstration, and dissemination of renewable energy technologies for providing energy services in the rural areas and also for meeting energy needs of the country through renewable sources. Later in 1992, DNES was upgraded into an independent Ministry of Non-Conventional Energy Sources (MNES), which was further renamed as Ministry of New and Renewable Energy (MNRE) on October 20, 2006. Perhaps this is the only such ministry in the world.

In 1987, a separate financing institution called the Indian Renewable Energy Development Agency (IREDA) was set up as a public sector undertaking for providing institutional finance exclusively in the field of renewables and energy efficiency. IREDA entered the market when lending to the renewables sector was considered a high-risk and low-profit business. Over the years, IREDA has paved the way for broadening and deepening the market for renewables. In the initial years, it received bilateral and multilateral credits. Over the years, other financing institutions also started providing financial assistance for renewable energy projects and consequently, the market share of IREDA-financed projects has at present come to around 15%.

The programs started slowly with mostly concentration on small applications and rural areas—solar lanterns, solar cookers, solar water heating, water mills, etc. Two national programs were started on rural cooking energy viz National Programme on Biogas Development and National Programme on Improved Cook stoves and were initiated in 1981–1982 and 1984–1985, respectively. Alongside programs for deployment of solar energy devices were initiated. Small hydro (below 25 MW) was started in 1988. In the 1990s, path-breaking development started in wind power development, which gathered steam in the last decade and became the main driver of grid renewable energy in India. There were also developments in the cogeneration area with particular success in bagasse being utilized for power generation in sugar mills, particularly in those in the private sector. Biomass-based power plants also started being set up primarily based on rice husk.

The solar cooker program slowly withered away, not being able to establish a regular market. Solar dishes have since come in small sizes as well as large systems. They have also, however, not taken off in a big way, although there is a solar thermal system in the religious place of Shirdi where 20,000 meals are cooked every day. The biogas program continues at slow pace, installing about a lakh of plants annually, partly because of budgetary constraints and partly because of poor progress in northern states of UP, Bihar, and Haryana. The cook stove program was disbanded in the central sector and transferred to the states in 2002 after about 32 million improved stoves had been installed. After that it also quickly withered away. Improved cook stoves are continuing through efforts of some NGOs, etc., in small ways in different parts of the country. The solar water heating program has been expanded, but inroads into the industrial and commercial sector have been difficult and limited. There are some pilots of solar air conditioning, but this has to go a

long way before it can be said to be mature or competitive. Solar lanterns have increased significantly, largely in the private market or locally funded initiatives though the central government and some states also distribute some. Urban waste to energy plants were set up in some towns, but they did not function properly because of difficulties of segregation of waste. This problem continues. There have been some medium and small plants using industrial waste and urban kitchen waste, but this has yet to really spread. One to two megawatt plants have been piloted based on fuel wood or other agri residues using the gasifier technology that has shown promise, though tariff continues to be a problem. There is a huge potential but not much progress. In the last few years, there was a large program to cover 10,000 remote villages where the grid was not likely to go. This was primarily covered by solar home lighting systems. Rural banks have also supported several thousand solar home lights through loans. The record, therefore, is mixed and patchy.

### 6.3.1 Solar Grid Developments

In 2008, India came out with a National Action Plan on Climate Change with 8 missions covering various areas of sustainable development.\* As the Indian prime minister said: at the centerpiece was the proposed National Solar Mission, which would launch an ambitious plan for all-round development of solar energy. This mission was launched in January 2010, with an ambitious target of achieving 20 GW of grid power by 2022, 2 GW of off-grid solar power, covering 20 million households with solar lighting and installing 20 million m<sup>2</sup> of solar thermal collector area.† However, in the Budget 2015–2016, the Government of India has announced much more ambitious renewable energy targets of 175 GW by 2022. This includes scale-up Grid Connected (including roof top) Solar Power Projects from 20 GW to 100 GW. This program is well underway. From virtually zero, a capacity of 3000 MW grid power has already been installed. Both the center and the states have launched different policies and it is expected that the targets of the mission would be substantially met. The most significant development has been the reduction in costs globally for solar PV, and the reduction consequently in India achieved through competitive bidding rather than the prevalent feed-in-tariff (FIT) system. India has perhaps become the lowest cost solar power producer in the world, as acknowledged in a recent World Bank Report.<sup>5</sup> There will be challenges, particularly in relation to transmission infrastructure and land.

### 6.3.2 Capacity Creation

The following table provides details of the progress in renewable energy deployment up to January 31, 2015 (Table 6.2).

In between 2002 and 2013, share of renewable grid capacity has increased more than 6 times, from 2% to around 13% in only 13 years, and is contributing 6% to the electricity

\* The National Action plan on Climate Change (NAPCC) was released on 30 June, 2008 to state India's contribution toward combating climate change. The plan outlines Eight National Missions. The NAPCC consists of several targets on climate change issues and addresses the urgent and critical concerns of the country through a directional shift in the development pathway. It outlines measures on climate change related adaptation and mitigation while simultaneously advancing development. The Missions form the core of the Plan, representing multi-pronged, long termed and integrated strategies for achieving goals in the context of climate change.

† The ultimate objective is to make solar energy competitive with fossil-based energy options. By increasing the share of solar energy in the total energy mix, it aims to empower people at the grass roots level. Another aspect of this Mission is to launch an R&D program facilitating international co-operation to enable the creation of affordable, more convenient solar energy systems and to promote innovations for sustained, long-term storage and use of solar power.

**TABLE 6.2**

Cumulative Progress of Renewable Energy Deployment as of December 31, 2013

S. No	Renewable Energy Programmes/ Systems	Cumulative Achievements
<b>I. Power From Renewables</b>		
<b>Grid-Interactive Renewable Power (in MW)</b>		
1.	Wind power	22,597.68
2.	Small hydro power	4,017.05
3.	Biomass power /cogeneration	4,183.55
4.	Waste to power	107.58
5.	Solar power	3,099.68
	Total	34,005.68
<b>Off-Grid/Distributed Renewable Power (in MW<sub>eq</sub>)</b>		
6.	Biomass (non-bagasse) cogeneration	569.75
7.	Biomass gasifiers	171.63
8.	Waste-to-energy	142.27
9.	Aero-generators/hybrid systems	2.43
10.	SPV systems	229.35
11.	Water mills/micro hydel	15.21
12.	Bio-gas based energy system	4.07
	Total	1,134.71
<b>II. Remote Village Electrification</b>		
	Villages/hamlets provided with electricity/lighting systems	11,308
<b>III. Decentralized Energy Systems</b>		
10.	Family type biogas plants (in lakh.)	47.95
11.	SPV street lighting system (in lakh.)	3.42
12.	SPV home lighting system (in lakh.)	11.94
13.	SPV lanterns (in lakh.)	9.85
14.	SPV pumps (nos.)	19,501
15.	Solar water heating (collection area in million m <sup>2</sup> )	8.73

generation mix. The grid renewable power has been dominated by wind, though now solar is making its presence felt. The important thing to notice in this progress is that the % age of renewables capacity has increased substantially at a time when there was maximum development of conventional power capacity. The high level of penetration of renewable power, after large hydro is added, in India compares favorably with that of the EU and far exceeds that of the United States.

### 6.3.3 Policy Support

The government has been promoting private investment in setting up of projects for power generation from renewable energy sources through an attractive mix of fiscal and financial incentives, in addition to the preferential tariffs being provided at the states' level. These include capital/interest subsidy, accelerated depreciation (AD) and nil/concessional excise, and customs duties. The level of capital subsidy being provided for off-grid depends on the renewable resource and region, and varies from about 10% to 90% of project cost, the higher level being given for projects in North-Eastern Region/special category states.

Electricity Act 2003 provided the necessary regulatory framework for growth of renewable power in India. The act required State Regulatory Commissions to specify renewable purchase obligations (RPOs) and also fix renewable resource-specific FIT. In addition solar-specific RPOs, starting with 0.25% in the first phase of the Solar Mission and leading to 3% by 2022, have also been introduced. The National Electricity Policy 2005 has further provided for progressive increase in these levels and purchases by distribution companies through competitive bidding process. The Tariff Policy 2006 requires fixation by State Electricity Regulatory Commissions (SERCs) of a minimum % age for purchase of energy from such sources taking into account availability of such resources in the region and its impact on retail tariffs and procurement by distribution companies at preferential tariffs determined by the SERCs. As of date, most of the SERCs have specified % ages for purchase of electricity from renewable sources of energy. Preferential tariff for grid interactive renewable power is being given in most potential states. Uniform guidelines by Central Electricity Regulatory Commission (CERC) for fixation of such preferential tariffs have been issued.

Other instruments include AD up to 80% to investors/developers in the first year. This was a tax benefit for profit-making companies and individuals, something akin to the production tax credit in the United States. This model led to substantial development of the wind sector. In 2010, generation-based incentive was also provided as an alternative for such power producers, which could not avail the benefit of AD in order to provide a level playing field. This resulted in more than 3 GW being installed in 2010–2011, the highest ever. However, the AD benefit for wind has since been discontinued, though the generation-based incentive (GBI) has recently been restored.

Renewable energy sources are not evenly spread across the country. On the one hand, there are states where the potential of renewable energy sources is not that significant; on the other, there are states where there is very high potential. Five southern states produce most of today's wind power and solar power's potential is similarly concentrated. This poses economic and operational challenges for these states. In 2010, tradable renewable energy certificates (RECs) have been introduced to address this gap and assist states in meeting RPOs. Renewable energy generators offer REC on the exchange, and the utilities, also of areas where with less renewable energy potential could buy and fulfill their RPO. However, in the absence for any focus on RPO compliance, the REC market is not taking off.

On December 19, 2014, the Government of India introduced the Electricity (Amendment) Bill, 2014 in the Lok Sabha (the National Parliament). It has many provisions for accelerating renewable power deployment in the country including provision for more robust RPO compliance and preparation, review, and notification of the National Renewable Energy Policy.

#### **6.3.4 Solar Power Policy**

Solar power was promoted with some additional measures. Under the Central initiative of the Solar Mission, a central agency was specified to buy the solar power produced by the developers. It then bundled it with cheaper thermal power available to its parent producer NTPC in the ratio 1:4 and sold to utilities with whom it entered into power purchase agreement (PPA). This bundling reduced the cost of power to the utilities tremendously bringing it near to the normal price of purchase. In addition, a separate solar purchase obligation was mandated for the utilities. At the start in 2010, solar PV tariff as calculated by the CERC was almost Rs. 18 per unit,\* levelized over 25 years. But a bidding

---

\* At present 1 U.S. \$ is equivalent to around Rs. 60.

route was also adopted, asking developers to offer discounts to the CERC price. The two rounds of bidding brought down the lowest bids, first to about an average of Rs. 12 per unit (U.S. \$20 cents) and later an average to about Rs. 7 perhaps more per unit (U.S. \$12 cents). This was the policy for the first phase of 1.1 GW.

However, for the second phase of around 750 MW, the tariff has been fixed at Rs. 5.30 per unit. Developers were asked to bid for a minimum viability gap funding (VGF) to achieve this tariff. The bid results suggest that on an average VGF of Rs. 1 crore/MW installed capacity have been asked by the developers. In case of domestic solar cells, the VGF sought is in the order of Rs. 2.50 crore/MW. Power will be purchased and sold as earlier by a newly formed Solar Energy Corporation of India. Both phases had limited quantities and procedures for domestic content to support the hard-hit domestic industry because of low cost manufacture in China, which also damaged their export capability to Europe as also low cost financial support by the U.S. Exim bank for their local thin film manufacturers. This provision of domestic content was only for the National Solar Mission and not for state initiatives. However, the United States has gone out of its way to complain against Indian policies. It is felt that it has not only been overly aggressive and unfair but has also not realized the implications that would favor the Chinese industry rather than their own.

### 6.3.5 Future Projections and Trends

Renewable energy outlook for the country seeks to graduate from the present role of supplementing the fossil fuel based conventional energy sources, to becoming a mainstream source and eventually reaching a stage of substantially replacing them. There are different prognoses about the time frame when such sources could completely overtake conventional fossil fuel-based sources. The 12th Five Year Plan document of the Planning Commission, Government of India (for the period 2012–2017) has already depicted a 2030 outlook which suggests around 33% electricity installed capacity from renewable energy sources. Planning Commission, 12th Five Year Plan: online [http://planningcommission.nic.in/plans/planrel/12thplan/pdf/12fyp\\_vol2.pdf](http://planningcommission.nic.in/plans/planrel/12thplan/pdf/12fyp_vol2.pdf)

The Planning Commissions “Report of the Expert Group on Low Carbon Strategies for Inclusive Growth 2014” has estimated that under low carbon for inclusive growth scenario solar and wind power capacity by 2030 will be around 225 GW out of the total installed capacity of around 700 GW, and in energy terms these will contribute to around 14% in the electricity mix. Planning Commission “Report of the Expert Group on Low Carbon Strategies for Inclusive Growth 2014” online [http://planningcommission.nic.in/reports/genrep/rep\\_carbon2005.pdf](http://planningcommission.nic.in/reports/genrep/rep_carbon2005.pdf). Given the right mix of technology, finance, and necessary improvement in grid infrastructure these estimates could be achievable.

### 6.3.6 Renewable Energy in Off-Grid Mode

The problems with the grid in India, and the unique ability of solar to provide power from the smallest unit onward, offer almost unlimited potential for off-grid solar. There are four prime areas in India. First, simple roof top with the difference that this will be largely for self-consumption rather than being fed into the grid as is the usual practice so far in developed countries. This will both reduce demand for day-time electricity and partly meet the needs of small diesel generators, which are in use in plenty because of power shortages. Second, village electrification is a big problem in India, which we shall briefly discuss shortly. Kerosene supplied at highly subsidized rates meets the lighting through small

ill-lanterns giving very poor light. Solar, whether through mini grids, or solar home lighting systems and lanterns, could provide a much better alternative. It will certainly save billions of liters of kerosene and huge amounts for the government in subsidies, possibly over Rs. 20,000 crores annually at present prices and subsidy rates if large-scale solarization happens. Third, there are a couple of hundred thousand telecom towers in rural areas. Because of unreliable supply of power in many areas, billions of liters of subsidized diesel is used. A lot of it can be saved by solar meeting power needs in the daytime when power cuts are the maximum. Fourth, India has more than 20 million irrigation pumps in the rural areas, with a large number running on diesel. Most of these pumps over time can be replaced by solar-powered pumps. And maybe there will be additional markets. There can be many more pumps, which are currently not installed, because either electricity is not there or diesel is too expensive. As we move toward eastern India from Delhi, the water table is high enough and electricity is scarce. This is a perfect combination and needs to be pursued as a separate mission. Altogether these can create a market of 50 GW, with no land and transmission requirements, no involvement of the grid, and no losses as generation will be at consumption points. But solar companies need to become oriented to provide such small and dispersed services. In fact, this will allow many professional small companies and generate employment and incomes in rural areas. It will simultaneously help India's energy security by saving very large amounts of nonessential use of kerosene and diesel. Besides, huge amounts of undeserved subsidy would also be saved. And the utilities will save a lot of their losses arising out of rural supplies supplied at low tariffs, both for households, and particularly for irrigation. Therefore, in the Indian situation, which may find similarities in many other developing countries, solar off-grid is a completely win-win situation. The best part is that all the beneficiaries will actually be spending less on their fuels than currently, leave alone doing so in the future.

### **6.3.7 Energy Access**

Energy access includes both electricity and cooking energy. The position in India in respect of both is quite dismal. This is also primarily a rural problem. Though it may be difficult to put exact numbers, it is generally expected that 300 million people in India do not have electricity access and 700 million people use biomass in traditional stoves for cooking. India has made rapid progress in rural electrification through the Rajiv Gandhi Grameen Vidyutikaran Yojna in the last several years and we claim that over 90% of the villages have been electrified. However, over 40% of the above poverty line (APL) rural households do not have electricity connections (a large number of below PL households were given connections under the official program). The problem has been the definition, which allows a village to be deemed electrified if 10% of the households have connections. There are additional problems of the number of hours of supply, which sometimes are not many and mostly not in the evening hours when needed most. There are worries that these problems may continue with power supply being short and the utility finances continuing to be affected adversely by low tariffs. It is, therefore, believed by many that solar minigrids or solar home lighting systems may be the answer to India's electricity access problems.<sup>6</sup> Many pilots have been conducted, and there is subsidy support. However, a regular business model is yet to be found as also who could be the possible entrepreneurs. This is going to be an important area for policy development in the next few years. This is also a good area for international funding.

### **6.3.8 Cooking Energy**

As far as cooking is concerned this is a serious problem although there has not been enough recognition of it by the policy makers, and indeed even in public discussion. In 2014, the Global Disease burden study showed that indoor air pollution from combustion of biomass in inefficient cook stoves was the biggest health hazard for India. In general, there has been a belief that the real solution is the supply of cooking gas. However, studies have noted the difficulties of shifting to cleaner fuels, even if subsidized, in a situation where biomass is largely free. Besides, the country simply cannot afford the subsidy either of cooking gas or kerosene for this solution to work. Therefore, biomass will remain the principal fuel. And it is imperative that we move to ultraclean stoves, which will burn all types of biomass and also last for at least 5 years. Some efforts in this direction are ongoing. Efforts are also on to finalize proper standards. Cost of such stoves could be an issue, and they may require subsidies. Had the carbon market been working properly, distribution of improved cook stoves could probably be fully financed. In its absence, the government would have to provide some subsidy as we develop slowly a proper market. The market size could be 100 million, and if the life is about 4 years, there will be a huge replacement market. Unfortunately, the international system has done precious little to deal with this problem, except express concern. More, and decisive, action is needed.

### **6.3.9 Carbon Emissions—Issue of Energy Intensity**

It may be useful in the context of this scenario to briefly examine the issue of India's contribution to carbon emissions. In the climate change negotiations, often India has been painted as a villain. It is true that India has argued for the developed nations to accept their historical responsibility for filling up the carbon space and therefore reduce their emissions substantially even as there needs to be space for her to grow to address the problems of development and removal of poverty. The developed countries initially accepted this argument and promised differentiated responsibilities. However, they have hardly delivered on any of their promises. And, they have now started arguing that the developing countries will become the larger emitters in the future and, therefore, they must restrict or also reduce their emissions. Nothing could be more insidious and ethically unacceptable. But the real problem is that the fingers are pointed at China and India and both of them are put in the same boat. But consider the differences. China emits about 26% of the global emissions now and India about 5%–6%, roughly same as Japan and the Middle East, which is also growing rapidly. The United States is about 16% and the EU about 12%. Moreover, in per-capita emission terms, India is well below the per-capita global average of 4.5 tons, while the United States is well above. Therefore, India is not the problem. The problems of power supply mentioned earlier also suggest that we will not be in the future. Ideally, it would only be equitable if the first ceiling for emissions for countries should be the current global per-capita average multiplied by the current population. This would give India enough space to grow in a reasonably carbon-constrained manner, which would require strong reliance on renewable energy, energy efficiency, and a new transport model. If we did this, we should also be able to meet our commitment of 20%–25% reduction in emission intensity of GDP by 2020. Needless to say, it will also be a much more sustainable model designed to meet more economic and social equity principles also.

---

## 6.4 Energy Efficiency

National interest in energy conservation in India was triggered by the oil crisis of 1973 but was largely concerned initially with petroleum products. The Petroleum Conservation Research Institute (PCRA) was set up in 1978. Much later, in 1989, the Energy Management Centre (EMC) was set up to promote conservation in power. After the opening up of the economy in 1991, and as electricity became important, the need was felt for proper legislative and institutional backing to promote electricity efficiency. In 2001, the Energy Conservation Act was passed. In 2002, the EMC was reconstituted as the Bureau of Energy Efficiency (BEE), which became a statutory body. The Electricity Act 2003 mandated efficiency in generation, transmission, and distribution. The National Electricity Policy 2004 gave demand side management (DSM) a high priority. Periodic energy audits were made compulsory for power intensive industries; emphasis was placed on labeling of appliances and high efficiency pumps in agriculture. The Integrated Energy Policy Report 2006 emphasized that investments in energy efficiency were as important as investments in generation as energy saving was more advantageous in many ways than energy generated. One could say that a view emerged that energy efficiency should be India's primary fuel. Under the National Action Plan for Climate Change in 2008, a new National Mission on Enhanced Energy Efficiency (NMEEE) was proposed that was approved in 2010 and is under implementation.

Industrial and domestic sectors are the two largest consumers of utility generated power, with the latter growing rapidly because of economic growth, rapid urbanization, and changing lifestyles, which is leading to huge growth in personalized transport, residential buildings, and electric appliances. It is estimated that while India's energy consumption may go up by 6 times, its per-capita emissions may only have space for a little over doubling. Therefore, it has become imperative to identify areas where huge reductions are possible, as also where power supply from conventional sources can be replaced by renewable energy sources. Some of the important areas are briefly discussed in the following text.

### 6.4.1 Buildings

Almost 40% of the total energy is utilized in the building sector. As urbanization is growing rapidly, this sector will create great demand for energy in the future. In 2009, the buildings sector consumed one-third of the total electricity, with the residential sector being 25% (BEE). Eighty percent of the electricity is for cooling and lighting, with ACs accounting for 40%–50% having more than doubled in the last few years. This will only increase as it is estimated that 60%–70% of the building stock is yet to be built by 2030. Forty percent savings could accrue if we have energy-efficient buildings.

There are many policy drivers to ensure this. There is a National Building Code. There is the Energy Conservation Building Code that specifies some norms for certain types and size of buildings. This needs to become more stringent and mandatory for more sizes of buildings. Larger complexes require prior environmental clearances, but this is somewhat loosely administered in terms of ensuring final compliances. There are two voluntary rating systems for green buildings. The U.S. LEED-inspired IGBC-LEED system, which is more western oriented and the TERI—MNRE GRIHA system, which is based on traditional Indian architectural and solar passive principles. The latter is more suited to Indian conditions and seeks to reduce also AC and lighting needs. The former focuses on efficient systems and encourages glass facades. The Government of India took a decision that all their new buildings should be at least GRIHA 3\*. This norm has also been accepted by the

Central Public Works Department, which leads the issues regarding specifications and building codes. None of these instruments, however, have created the type of huge impact that is needed, and builders and developers are clearly ignoring these needs; there is neither sufficient knowledge nor interest for consumers to demand such buildings as people do not follow life cycle cost principles. There is an urgent need for municipal regulations and to move tax concession on house building loans toward energy-efficient housing. A few municipalities have taken some steps.

#### **6.4.1.1 Electrical Appliances**

This is going to be a high growth area. McKinsey (2009) has said that household energy demand will spike up to 1300 TWh by 2030. There has been a voluntary labeling program in India for some years. Currently, it is incrementally increasing the norms for each level of star rating. However, even though moderately successful, star label penetration is still low. In 2008, star AC's penetration was 1.5% and fridges 7.5%. This must have gone up since then. Since this will be a huge growth area, and 30%–40% savings are possible, and the use of appliances will spread to washing machines, microwaves, dish washers, etc., it is imperative that norms become stricter and are mandated. Other products should simply not be allowed in the market.

#### **6.4.2 Lighting**

Lighting is a huge electricity load, particularly at evening peak time. The CFL market in India has been growing at about 20% annually. LED is just beginning, including their assembly/manufacturing in India. A lighting/LED revolution must happen in India—both for domestic or institutional lighting and for street lights. There was a very unique CDM project for the period 2009–2011 targeting replacement of 400 million light points converting bulbs to CFLs with a potential saving of 20,000 MW. Twenty million lights were changed, but then the carbon market collapsed. We believe that a program such as this, probably now shifting to LED, and a project for 100 million cook stoves would have been the best possible carbon projects, and should be funded from the voluntary market. Such lighting would make even solar more attractive as lesser modules would be required to provide the same amount of light. A huge program for change in municipal street lighting to LEDs is also required funded by a special tax if need be. Twenty-five to thirty percent of the lighting load of municipalities is from street lights. Steps in this direction are underway.

#### **6.4.3 Industry**

As per Central Electricity Authority, 23% of total electricity is used by industry in the country, of which >60% is by few large and heavy industrial consumers. India's energy intensity in manufacturing sector has fallen consistently over the last 20 years, but there is still a saving potential of up to 25% even as the total energy consumption naturally increases. Under the NMEEE, a Perform, Achieve and Trade (PAT) scheme has been launched that covers the 9 most energy-consuming industries—thermal power plants, iron and steel, cement, fertilizer, aluminum, textiles, pulp and paper, and chlor alkali. Energy consumption reduction of 5%–10% is targeted between 2011 and 2014. All this would lead to 5623 MW of avoided capacity. Clearly, we have to do more and include more industries while also doing everything possible in the medium and small sector also. Motors, pumps, and boilers are the key.

The activities under the PAT scheme provide opportunities for new markets as it devises cost-effective energy efficient strategies for end-use demand-side management leading to ecological sustainability.

#### 6.4.4 Agriculture

This sector uses almost one-third of the electricity while contributing to only about 8%–10% of the revenue. This is predicted to grow at 2%–5% annually till 2020. Seventy percent of irrigated area is from ground water. Since the tariff is extremely low and it is really not metered, the marginal cost of pumping water is zero and farmers have no incentive to restrict or reduce their usage of electricity (and water) or invest in energy efficient pump sets. Rationalization of tariff and mandating production of energy efficient pumps is required. Even in municipalities, energy efficient pumping is important, because 15%–30% of their electricity load comes from this area.

We have suggested that solar irrigation pumps could be a good alternative in the long run.

#### 6.4.5 Future Directions

There are several barriers that are preventing large-scale adoption of energy efficient measures. Some of the most important are as follows:

1. Price distortions including subsidized prices of petroleum products and electricity. Proper energy pricing and reductions of subsidies, though politically difficult, will be very important.
2. High costs of upfront investments. This may be applicable for government agencies or organizations. Absence of development of the RESCO model, where roof top solar or energy efficiency measures can be investments of others paid back in rental mode. Also lack of successful examples and knowledge of interventions.
3. Policies are not fully in place. Mandating is not easy. The mindset, whether of individuals or organizations, is still not sensitized to both the urgent need for saving energy and its conservation, as well as the benefits, both financial and otherwise, which would accrue. This also underlines the need for both behavioral and attitudinal change at all levels.
4. And, as part of the chicken or egg coming story, there is a lack of successful examples and knowledge of interventions that create confidence as well as mitigate an environment of risk.

As far as financing is concerned, there are a number of options to accelerate pace of energy efficiency program. Establishment of state level Clean Energy Funds using the Public Benefit Charge concept could be an area of action. Such funds may be established as special purpose funds by national or state governments and regulators for financing clean energy projects. Internationally also the most common, reliable, and sustainable source of funding is a tariff surcharge, cess, or levy established by the regulator and collected by the utility via the customer's electricity bill. Such a surcharge or levy is known as a Public Benefit Charge. The funds could be utilized for leveraging commercial financing, interest *buy-down* on commercial loans, loan guarantees, grants for public sector projects, and rebate. Other options could be development of regulatory schemes to acquire

energy efficiency resources using a Standard Offer Programme, promoting utility financing of energy efficiency projects by establishing energy efficiency obligations, encouraging Indian banks and financial institutions to mainstream energy efficiency in corporate loans, creation of a facility to provide energy savings insurance, establishment of a *clean Energy Financing Facility* for debt financing of energy efficiency projects, and designation of energy efficiency financing as Priority Sector Lending.

Simultaneously, there is a need to have a much more comprehensive program of awareness building and education.

---

## 6.5 Conclusion

Historically, India has initiated systematic programs for renewables including for research and development and also for energy efficiency. The challenge for India is gigantic and exciting. Considerable progress has been made but actions are required on many fronts. Policy issues related to all sectors of conventional electricity generation are urgently needed. Renewable energy has already caught the imagination and with proper policy framework and planning, India could be in a position to meet significant portion of its energy needs through these sources. There must also be a large-scale off-grid program. The successful implementation of the National Mission on Enhanced Energy Efficiency could also yield similar results, but simultaneously, its coverage needs to be substantially increased. Curtailment of consumption of oil products by various methods in the transport sector and some suggested here in the electricity sector have to be prioritized. All these would also lead to substantial reduction of, or less increase in, carbon dioxide emission. While budgetary support for renewable energy and energy efficiency have progressively increased over the years, particularly for large-scale grid connected power, these need to be further enhanced for both grid and off-grid to achieve the large upscaling that is required. Subsidy reform would automatically provide substantial funds. But some critical policy and structural gaps remain, particularly for decentralized distribution in the areas of access to capital, technology development and adaptation, innovation induction, and strategies to upscale deployment. However, new opportunities and compulsions will lead to think beyond the government-centric programs and to create new instruments, strategies, and pathways.

Bioenergy is regarded as one of the key options to mitigate greenhouse gas (GHG) emissions and to substitute fossil fuels [1,2]. While there are many renewable energy technologies available for large-scale electricity production with low or no direct GHG emissions, the transport sector, which is responsible for 23% of GHG emissions [3–5], is almost entirely based on fossil fuels, and has fewer alternatives.

Transportation represents some 27% of the world’s secondary energy consumption (21% of primary), grows 1% per year on average, and is almost exclusively fuelled by petroleum [4,5]. Biofuels can play an important role in addressing both the GHG emissions of transport and the dependency on petroleum. However, currently marketed, first-generation biofuels represent only around 3% of global road transport fuels, and can be regarded as a transition technology. This limited penetration of first-generation biofuels is due in part to the potential competition with food crops and market prices (sugar  $\times$  ethanol prices in international markets). Concerns that these technologies are falling short of expectations have led to the development of second-generation (cellulosic ethanol, biomass-to-liquids, pyrolysis oil, dimethyl ether) and third-generation (algal-biodiesel, biofuels from third-generation processes) biofuel technologies [4], which still need to be scaled up in order to become cost-competitive.

With the exception of sugarcane ethanol, the traditional biofuels have a number of severe disadvantages that are related to the feedstock. The current costs of rapeseed biodiesel and ethanol from cereals or beets are much higher than the costs of gasoline and diesel, and substantial subsidies are needed to make them competitive. These high costs are a result of the low net energy yield of most annual crops (100–200 GJ/ha year in the long term [6]), the high-quality agricultural land required, and the intensive management. The lower productivity per hectare and high fertilizer requirement also limit the well-to-wheel reduction of fossil energy use, which limit the environmental benefits [7,8]. The net energy of perennial crops (220–550 GJ/ha year), grasses (220–260 GJ/ha year),

and sugar cane (500–650 GJ/ha year) is considerably higher, and Brazil has been a world leader in promoting biofuels for over 30 years under its *Proálcool* program.

---

## 7.1 *Proálcool* Program in Brazil

Since 1975, Brazil has mandated that ethanol be blended with all gasoline sold in the country. Although the required blend level is adjusted frequently, it has been in the range of 20%–25%, and all filling stations are required to sell gasohol (E25) and pure ethanol (E100). Tax incentives have been given to vehicles that run on pure ethanol in the early days of the *Proálcool* program, and more recently, the introduction of the so-called *flex fuel* vehicles by most of the local automakers allows for any proportion between ethanol and gasoline (E25–E100) to be used any time. This has led to the growing share that *flex fuel* cars hold in the Brazilian market [9,10], which should reach over 96% by the end of 2014 [11,12]. In 10 years, U.S. \$16 billion were invested in genetic research for sugar cane improvement, alcohol subsidies, and agrobusiness, and policies have included blending mandates, retail distribution requirements, production subsidies, and other measures [13].

After a rocky period in the 1980s and 1990s, when high demand resulted in a seller's market, which led to high alcohol prices and delivery shortages [13], the escalating oil prices and the event of the *flex fuel* car have brought attention back to ethanol. Advances in electronic fuel injection technology solved many of the technological problems associated with ethanol engines (in cool mornings, drivers had to wait precious minutes for their car engines to warm up before they could drive). In 1985, with falling oil prices, the Brazilian government was not able to keep up with the required subsidies, and in 1989, ethanol shortages and high prices resulted in very disappointed drivers and the near collapse of this promising technology. In 1990, the sector was deregulated, and the *Alcohol and Sugar Institute* (IAA—*Instituto do Açúcar e do Alcool*), which regulated export quotas and subsidies, was closed down. In a free, deregulated market, ethanol producers chose to turn back to sugar when the international price of that commodity recovered, and the automakers reduced alcohol-driven car production to negligible levels. More recently, with the boom in *flex fuel* car sales, ethanol prices soared once again. This time however, with *flex fuel* cars came the choice for consumers to avoid abusive price increases from alcohol producers, and whenever ethanol prices go over the mark of 70% of gasoline price, *flex fuel* car drivers fill up with the traditional fossil fuel. While at present 9 out of 10 cars produced in Brazil run on both fuels, ethanol has not been the choice of most drivers. This is mostly because the price difference between ethanol and gasoline has been below 20% in the last few years, due to the more profitable sugar market. Furthermore, because *flex fuel* cars running on pure ethanol have a ~30% lower mileage than when running on gasohol, there is no real advantage in filling up with the so-called green fuel.

---

## 7.2 Bio-Oil

Brazil has more recently begun to target increased use of biodiesel fuels, derived primarily from domestically produced soybean oil, with recent legislation mandating blends of 5% biodiesel in diesel fuels (B5). Brazil has the potential to be a world leader in biodiesel

production, as it will be able to produce bio oil from many different sources. The issue fuel  $\times$  food, however, will always persist, and might be even more pronounced in the case of biodiesel than it has been so far in the case of bioethanol.

---

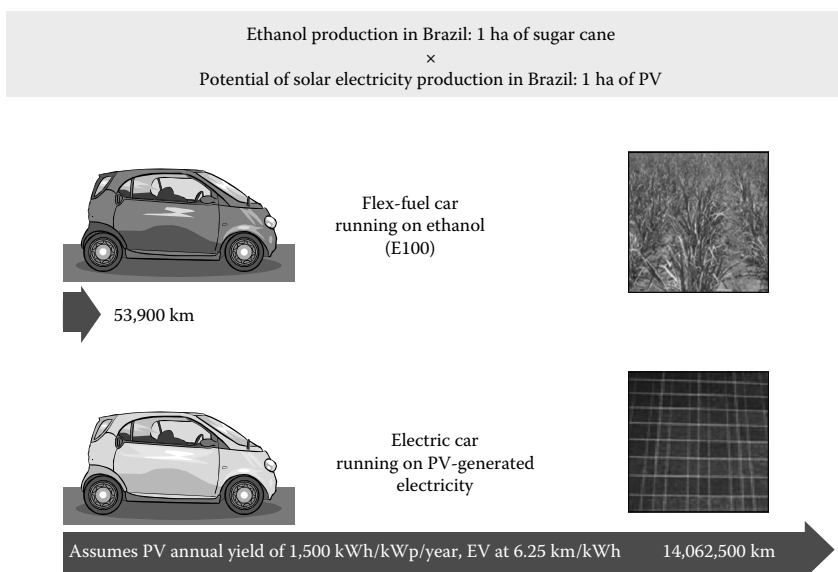

### 7.3 Photovoltaic Generation and the Net Metering Law in Brazil

In early 2012, Brazil has enacted new legislation allowing for solar photovoltaic (PV) generators of up to 1 MWp to be connected to the public distribution grid and to feed excess electricity to the grid under a net metering scheme [14]. The excellent solar radiation resource availability in the country, ranging from over 1,500 to nearly 2,200 kWh/m<sup>2</sup>/year [15], and the extensive rooftop availability in the residential, industrial, commercial, and public sectors, complemented by considerably high electricity tariffs in most parts of the country, should make building-integrated, grid-connected, and net metered PV generation an attractive option for a large number of consumers in the near future.

---

### 7.4 Prospects

In addition to Brazil, mandates for blending biofuels into vehicle fuels have been appearing in several other countries in recent years, mostly driven by GHG reduction targets. In the long term, however, it can be argued that biofuels will play a transitional role toward electric vehicles and solar PV generation. In terms of energy conversion efficiency, biofuels for transportation can be largely regarded as a transition technology. A direct comparison between sugar cane ethanol + *flex fuel* cars, and sunlight-to-electricity (PV) conversion + electric cars is illustrated in the following figure: a 1 ha (100 m  $\times$  100 m) sugar cane plantation will yield from 6,800 to 8,000 L of ethanol per year, allowing a medium-size *flex fuel* car to drive up to 53,900 km/year in a best-case scenario. If the same area is covered with commercially available solar PV modules at 15% conversion efficiency and a 1,500 kWh/kWp/year energy yield, the electricity produced over 1 year on the same 1 ha will allow the electric version of the same medium-size car to drive over 14,000,000 km/year (over 260 times more!). The reasons for this overwhelming difference are related to both the orders of magnitude larger efficiency of PV conversion over photosynthesis, and the considerably larger efficiency of electric motors over internal combustion engines. While fully electric, plug-in vehicles are still in the early stages of large-scale production, battery technologies are continuously being improved, and volume production should lead to the necessary cost reductions for this benign technology to be adopted worldwide. In a sunny and large country like Brazil, building-integrated PV in the urban environment can not only cover the additional electricity needs represented by a new fleet of electric vehicles, but can also supply on site a considerable fraction of the urban electricity needs, without any further area requirements and without competing with arable land.

### 8.1 Introduction

Israel is a country of 8.0 million inhabitants in an area about 20,000 km<sup>2</sup> located on the eastern Mediterranean coast. Israel's electric grid and overall energy economy are isolated from those of its neighboring countries. The precarious political situation has led in the past to the country being subjected to energy and other economic boycotts. Until recently, Israel's economy has depended almost entirely on imported coal and petroleum. Despite the political difficulties, Israel's economy is the fastest growing in the Middle East, leading to an ever-increasing demand for energy. Israel's total energy consumption has almost doubled in the last 20 years, and electric power production and consumption have increased by a factor of 2.75 in that period of time [1].

Israel has learned to use the one abundant and inexhaustible energy resource it has—solar energy. Israel has been a pioneer in developing solar technology, leading the world (together with Greece and Cyprus), and until recently is number one in the world in per capita utilization of solar energy. According to the Ministry of Energy and Water Resources (MEW) Division of Energy Conservation [2], about 85% of households (i.e., about 2,100,000 households) use domestic solar water heating, accounting for 3% of the country's primary energy consumption. Government encouragement and regulations, along with over 50 years of proven experience, have made this application widespread. Other forms of solar energy utilization are considered, with the potential of supplying a much larger portion of the country's energy demand.

Israel faces a number of choices in securing reliable, clean, and efficient sources of energy over the next 25 years. Recent discoveries of offshore natural gas have generated interest in developing this resource for domestic consumption to reduce dependence on imported coal and petroleum, which involves both economic and environmental risks. According to a MEW-commissioned forecasting study on Israel's energy demand [3], the overall merits of developing these gas reserves entail a number of trade-offs involving energy security, the environment, and cost. Development of renewable sources is free of these concerns and holds a great promise to supply the country with long-term clean and secure energy.

## 8.2 Israel's Energy Economy

The Israeli economy is largely fueled by imported coal and petroleum. Prior to 1982, only a small amount of coal was consumed and the country's primary energy source was oil and its derivatives. At present, coal accounts for about 35% of Israel's primary energy. It is almost entirely used in electric power generation. Recent discoveries of offshore natural gas fields have added this important resource, which at present is used mainly for electric power production.

Central Bureau of Statistics (CBS) data [1] show that the total primary energy supply to the country for the year 2009 was about 17.4 million tons oil equivalent (MTOE). Total end use was about 13 MTOE, consisting roughly of 8 MTOE of petroleum products and 5 MTOE of electric power. Among petroleum products, gas oil and diesel oil comprise the largest category. Electric consumption is about 1/3 for residential and 2/3 for industrial use (goods and services), the latter comprising a significant portion for agriculture and water pumping. Fuel consumption other than for electric power generation is split at 60%, 36%, and 4% among the transportation, industrial, and residential sectors, respectively. The same consumption pattern has been in effect for the last 10 years. According to forecast [3], it is likely to change in the coming years, with the introduction of natural gas, which will replace heavy oil in the electric power and industrial sectors.

Another component of the energy economy—relatively small in quantity but important in significance—is solar energy, utilized mainly for domestic water heating. As mentioned earlier, it accounts for about 3% of the country's energy demand and saves about 5% of the electric power. Israel is currently one of the three largest per capita users of solar energy in the world, challenging the notion that solar energy is not yet economical.

The government MEW's stated goals and objectives with regard to energy are the following [2]:

- Expansion of the supply and diversification of energy sources for the national economy and consumers
- Advancement of the well-being of the national energy and mining economy, while improving product quality and prices and the service provided
- Minimization of environmental effects created by energy facilities in the national economy
- Aiming to satisfy demands reliably and stably while conducting activity to reduce demand through economizing in the use of energy resources
- Analysis of opportunities in natural resource inventories in Israel and securing their availability while conducting licensing processes and encouraging exploration and excavation activity
- Activity for securing Israel's social, economic, and physical strength, which will allow for coping with the inevitable occurrence of strong earthquakes, while minimizing possible loss of life, reduction of the extent of damage to property and infrastructures, and rapid transition to an ordinary life routine
- Promotion and support of studies for expanding knowledge in soil and sea scientific fields

A number of measures have been initiated to promote renewable energies in electric power generation. A government resolution dated January 2009 set an objective to produce at least

10% of the total electric power from renewables by the year 2020. An intermediate goal is to produce 5% of the total electric power from renewables by the year 2014. Accordingly, the Public Utilities Authority has instituted a set of premiums for licensed electricity producers employing renewables, proportional to the achieved reduction in pollution. Another government resolution dated August 2008 endeavors to develop technologies for electric power generation from renewables, with dedicated funding under a 5-year plan. A further government resolution dated September 2008 promotes energy conservation and reduction in national electricity consumption. Energy conservation by the public is encouraged by market transformation—increasing public awareness of energy efficiency in appliances and the like.

A number of laws, regulations, directives, and legal instruments have been introduced to implement energy policy. Most of them regulate the use of petroleum and petroleum products, natural gas, and electric power and deal with licensing and safety issues. Some deal with energy efficiency, minimum standards, and labeling. Recent regulations encourage cogeneration and distributed generation. Noteworthy is Article 9 of the Law for Planning and Building (1970), mandating the installation of solar water heating systems in all new constructions [4]. This article has contributed a great deal to the advancement of solar energy utilization and will be discussed further in the next section.

---

### 8.3 Solar Energy Utilization in Israel—The (Incomplete) Success

A visitor to Israel will unavoidably notice the urban landscape bursting with solar collectors and hot water storage tanks covering the roofs of buildings. Almost all residences in Israel are equipped with solar water heaters. The most common is the thermosyphonic system, a completely passive, stand-alone unit consisting of one or two flat plate solar collectors and an insulated storage tank. Large multistory apartment buildings often use a central system with a collector array on the roof and a storage tank in the basement, employing a pump controlled by a differential thermostat. Other arrangements are also available. In most of the country, the solar system will supply the full demand for hot water during 9–10 months per year, with an electric resistance backup employed the rest of the time. Freeze protection is never required, except in some isolated locations. The economics: the installed cost of a typical single-family system comprising a 150 L storage tank and 2–3 m<sup>2</sup> of flat plate collectors is about \$700; an equivalent electric-powered system costs about \$300. The difference of \$400 is recovered by the owner in about 4 years (on a simple-payback basis); these systems carry a manufacturer's warranty for 6–8 years, and if properly maintained can last over 12 years. Several decades of nationwide experience have generated consumer confidence and acceptance to the point that a domestic solar water heater is perceived as a common, reliable household appliance.

There is no single legislation concerning solar energy utilization in Israel. The aforementioned Article 9 of the Law for Planning and Building (1970) [4] is probably the most important solar legislation, and has been the government's predominant contribution to Israel's success in the solar area. The law requires the builder (not the homeowner), since 1980, to install a solar water heating system in every new building up to nine stories tall. The MEW is currently leading a move designed to extend the requirement to multistory buildings. This is driven by the clear tendency in recent years to build high-rise buildings. Other laws and regulations describe in detail the size of the installation required for the various types of buildings, set minimum standards for the quality of the solar equipment and installation,

and provide the regulations for retrofit installation of solar water heaters in existing multiapartment buildings. Based on government data [5], an average single-family domestic solar water heater saves 1250 kWh of electric power per year; the total contribution to the country is about 1.6 billion kWh/year, 21% of the electricity for the domestic sector or 5.2% of the national electricity consumption, providing for 3% savings on primary energy consumption. This amounts to about 270 kWh/year/capita—one of the highest in the world.

Israel's example in domestic solar water heating provides an impressive demonstration of what can be achieved (in countries with similar or even more favorable climates), if the government makes a commitment to clean and environment-friendly technologies [5]. However, while solar for residential use has become an everyday reality in Israel, the much larger industrial/commercial sector uses very little solar energy, despite the fact that the industrial user is much better suited to do so than a homeowner. Some key considerations are: industry works mostly during the day, requiring little storage relative to a residence; the economy of scale provides a significant capital advantage to large industrial installations; industry generally has plenty of roof area in one-story buildings located in areas where architectural considerations do not hinder the installation of solar collectors; the industrial user is equipped to perform small maintenance jobs, thus eliminating the need for a full-proof system and reducing first cost. While some industries require high-temperature process heat, there are many who need the same temperature range as the domestic user; these include textile, food, pharmaceutical, chemical, and many more. The same applies, of course, to the commercial sector. It is estimated that widespread solar energy utilization in industry for process heat and the like, and in commercial applications, could increase the country's utilization by a factor of five, if not more.

Unfortunately, current tax considerations create a negative incentive for businesses to use solar energy. An industry burning polluting fuel can write off the cost as a business expense, thus reducing its tax liability, whereas an investment in a solar heating system can only be amortized over 8–12 years, making it considerably less attractive economically. Moreover, the law currently exempts industrial plants, shops, hospitals, and high-rise buildings (height over 27 m) from the requirement to install a solar water heating system in new buildings [5]. The government could play an important role in changing this situation, by introducing appropriate measures, closing tax loopholes, and creating positive incentives for renewable energy. This can be achieved within a short time—there is no need for long-term investments and development of new technologies. Solar energy is a reality here and now, as already demonstrated by the country's residential sector.

### 9.1 Energy Sector in Australia

Australia is resource rich in both minerals and energy. It is a net energy exporter with 68% of total energy production being exported and with a value of AUD\$71.5B in 2012/2013. It is the eighth largest energy producer in the world but is a net importer of crude oil and refined petroleum products. Coal is Australia's largest energy export earner, with a value of around AUD\$40B in 2012–2013, down AUD\$8B from 2011 to 2012. China is the largest importer of Australia's coal. Australia is also one of the world's largest exporters of uranium, though it does not have any installed nuclear power plants of its own.

Over the past 10 years, Australia's real export earnings have increased, on average 10% a year. However, they fell 12% in 2012–2013 largely as a result of lower coal prices but then rose by 6% in 2013–2014 supported by higher LNG prices [1].

In 2012–2013, fossil fuels, coal, oil, and natural gas made up about 94.4% of energy consumption. However, there has been a gradual shift away from coal to natural gas. The penetration of renewable energy is still small on a primary energy level at 5.6%—bioenergy and hydro making up 4.7% of this. See [Table 9.1](#) and [Figure 9.1](#) [1].

The high fossil fuel penetration in the energy mix has led to Australia to become one of the world's highest greenhouse gas emitters per capita. However, the contribution from

wind and solar is starting to increase particularly in the electricity sector (see the following). It is well endowed with a range of possible renewable resources—solar, wind, geothermal, wave, and tidal power. Currently, hydro is the largest source of renewable electricity, but its growth is limited and confined mainly to the State of Tasmania and some parts of the eastern seaboard, and the biomass at present is mainly bagasse from sugarcane in Queensland and landfill gas from around the country.

The electricity sector is also dominated by fossil fuels (86.9% in 2012–2013)—see [Table 9.2](#) and [Figure 9.2](#) that was derived from Table 9.2 [1]—but renewable energy is on the increase, in particular large-scale wind and rooftop solar. A number of successful policy initiatives were put in place between 2000 and 2013 that enabled the growth of renewables in Australia. However, between 2013 and 2015, growth and investment in renewables has stalled due to government policy uncertainties—see later.

The electricity network in Australia is divided into two main sections—the national grid in the East, extending over 5,000 km with 40,000 km of transmission line and cable—and the western Australian (WA) grid. The two grids are not connected because population between the two grids is extremely small ([Figure 9.3](#)).

## 9.2 History of Renewable Energy Policy in Australia

### 9.2.1 National Renewable Energy Policies

The main support for renewables on a national level has been the Renewable Energy Target (RET) scheme. Brought into effect in 2001 as the Mandatory Renewable Energy Target (MRET), it was a certificate-based scheme designed to increase the contribution of renewable energy to Australia's electricity demand from 10.5% in 1997 to 12.5% in 2010. During the development of the legislation, the target was fixed at 9500 GWh. Fixing the target was aimed at providing certainty to the energy industry. The MRET created a market for Renewable Energy Certificates by placing an obligation on electricity retailers and other wholesale electricity purchasers to source a proportional share of the target from eligible renewable energy sources (1 Renewable Energy Certificate or REC = 1 MWh).

In 2009, the national RET was expanded by nearly five times to become a target of 45,000 GWh in 2020 to support the Commonwealth Government's policy commitment that "at least 20 per cent of Australia's electricity should come from renewable sources by 2020." At this time, a Solar Credit "multiplier" was applied to the number of certificates received from certain small-scale generation technologies. The creation of Small-scale Technology Certificates (STCs) is a tradable commodity attached to eligible installations of renewable energy systems (including solar panels, solar water heaters, and heat pumps), with the number of STCs based on the amount of electricity in MWh that is

- Generated by a small-scale solar panel, wind, or hydro system over the course of its lifetime of up to 15 years or
- Displaced by a solar water heater or heat pump over the course of its lifetime of up to 10 years

The number of certificates that can be claimed may vary, depending on geographic location.

At the beginning of the program, the PV solar multiplier was 4× and delivered quite a significant capital cost reduction together with the 15-year deeming. In July 2013, the multiplier was reduced to 1 STC per MWh.

The STC multiplier program resulted in a large number of “virtual” certificates being generated, especially when the added state and territories feed in tariffs (FiTs) were introduced around 2009 thereby escalating growth in residential PV. The overall effect was to depress REC prices and discourage investment in large-scale projects, wind and solar farms, etc. So in June 2010, two separate markets were established—the Large-scale Renewable Energy Target (LRET) and the Small-scale Renewable Energy Scheme (SRES). These new markets began operating on January 1, 2011 with the LRET being capped at 41,000 MWh.

The SRES is uncapped, but with an implicit target of 4000 MWh. All PV systems up to 100 kWp are, currently, able to claim STCs up-front for up to 15 years of deemed generation, based on location. This means that the STCs for such systems act as an initial capital cost reduction.

From 2011, the two schemes no longer competed with one another.

On July 1, 2012, a price on carbon was introduced in Australia as part of a broad energy reform package called the Clean Energy Plan, which aimed to reduce greenhouse gas emissions by 5% below 2000 levels by 2020 and 80% below 2000 levels by 2050 plus provide funding to achieve the 20% of electricity from renewables by 2020. The price on carbon aimed to accomplish these targets by encouraging Australia's largest emitters to increase energy efficiency and invest in sustainable energy. The price started at \$23.50 in 2012/2013 and was to reach \$24.40 in 2014/2015 and then transition to an emissions trading scheme. However, in 2013 there was a change in Federal Government, from Labor to Liberal. One of the first things the Liberals did on achieving power was to fulfil their election promise of “axing the carbon tax,” and a “Direct Action” program was introduced instead—see later. They also introduced in 2014 a scheduled RET review headed by a well-known climate skeptic who recommended that the RET be considerably cut back. One rationale for this was that the growth in the electricity sector had slowed down, and it was anticipated that the target of 41,000 GWh in 2020 would be greater than 20% of sales. At the time of writing, April 2015, there were intense political negotiations as to what the new target should be. The new government does not want to go above 32,000 MWh, which would have quite a significant impact on the RE industry. Opponents want a higher target but have suggested a compromise of 33,500 GWh—which has not been accepted.

Historically, the Large-Scale Generation Certificates (LGCs) commanded prices between \$40 and \$50/MWh but dropped to almost \$20/MWh with the uncertainty of the RET, but the price has been steadily increasing in the hope of an imminent resolution of the target. The STCs have remained around \$40/MWh since mid-2014 when the number of certificates reduced due to the phasing out of the multiplier and FiT in most states.

The RET uncertainty has had a significant impact on RE investment in Australia, and though globally renewable energy sales increased 16% in 2014 [3] in Australia, Kane Thornton, CEO of the Clean Energy Council, announced in January 2015 that “Investment in large-scale renewable energy projects such as wind and solar farms last year was down 88 per cent to just \$240 million (it was \$2.1 billion in 2013)—the worst levels we have seen for more than a decade. Australia's renewable energy investment is now lagging behind countries such as Panama, Honduras and Myanmar” [4].

### 9.2.2 Australian State-Based Renewable Energy Policies

Each state and territory in Australia has its own renewable energy policy, incentives, and energy efficiency programs.

By far, the most effective program has been the FiT—mainly confined to small-scale PV programs. The FiT was first legislated in South Australia in 2008 and came into being in 2009. Most other states then followed. There was no federal FiT program and no consistency in programs around the country. As what happened in many places globally, high incentives were initially introduced, but then as expected targets were rapidly exceeded, the FiT was either reduced or phased out—having a damaging effect on PV installation businesses.

A review of FiT incentives for mid-2013 can be found at <http://www.ecosmartelectricians.com.au/index.php?page=what-is-the-feed-in-tariff>.

The FiT has been criticized as being the source of increased electricity tariffs and being a mechanism whereby the low-income population subsidize the rich. However, in reality, the FiT contribution to the average retail electricity price in Australia has been estimated to be about 2.3% and the combined RET scheme and FiT about 5%, compared to a network cost contribution of 45.7% [5]. In addition, the majority of the purchasers of PV systems are the middle- to low-income demographic rather than those with high-income demographic; nevertheless, programs are underway to try and reduce cost impacts on disadvantaged sectors of the community.

Though Australia has, as a whole, a target of 20% of its electricity from renewable sources by 2020, two regions of the country have higher targets. The Australian Capital Territory—90% by 2020 and South Australia—50% by 2025 [8] and [http://www.environment.act.gov.au/\\_\\_data/assets/pdf\\_file/0004/581701/Renewable-energy-brochure\\_ACCESS.pdf](http://www.environment.act.gov.au/__data/assets/pdf_file/0004/581701/Renewable-energy-brochure_ACCESS.pdf).

---

## 9.3 Renewable Energy Penetration in Australia: Detail

The penetration of renewable energy in the primary energy mix of Australia has been reasonably constant at around 4%–6% for about two decades (see [Table 9.1](#)). However, the composition has changed from predominantly hydro and biomass around 2000 to currently hydro and wind electricity generation from large-wind farms. The latter having been installed as a result of RET program support—wind being more cost effective than solar technologies to date. So far, no large-scale solar thermal electricity generation projects have been installed in Australia but many projects have been proposed. Though most of the growth in renewable electricity generation has been from wind, its penetration as a percent of total electricity generation in Australia is small, ~3% of total. However, in the state of South Australia (SA), wind averaged 31% of electricity generation during 2013/2014 [6] and 33% by the end of 2014—<http://www.renewablessa.sa.gov.au/>—up from zero 10 years ago. Additionally, the contribution of rooftop solar to electricity generation has been 6% from 25% of SA households over 2013/2014 giving a total of 39% of intermittent generation on the SA grid. Per capita, this is one of the highest penetrations of intermittent generation globally and has come about not only due to the exploitation of a good wind resource but because of good State Government policy support and legislation in the early years.

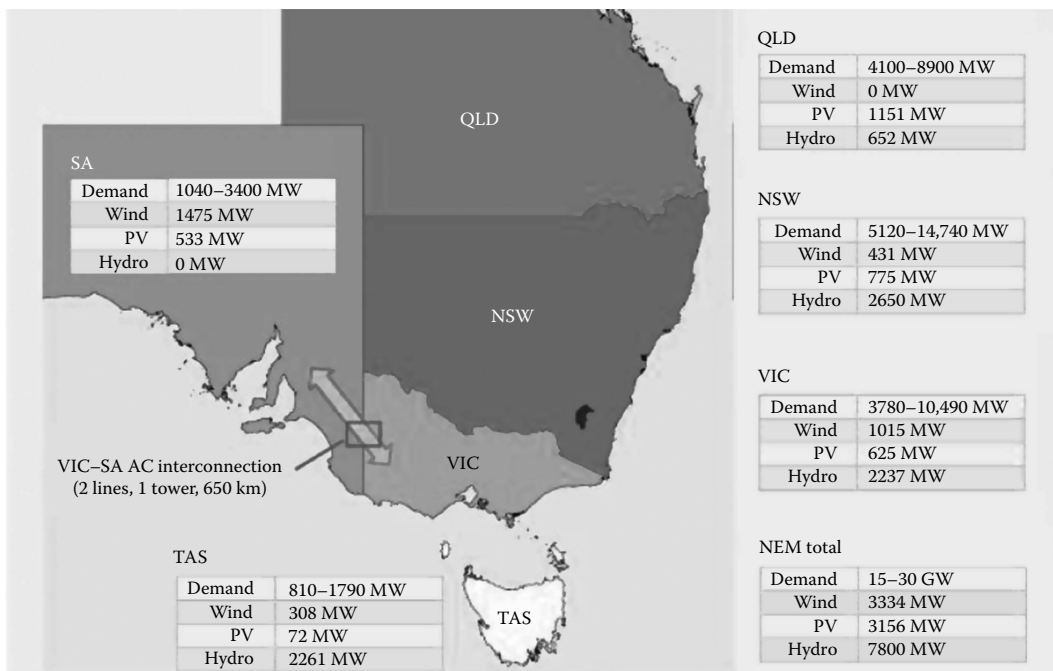

The growth of wind in Australia is shown in [Figure 9.4](#) and now is approaching 3500 GW, with about 40% of installed capacity being in South Australia [7].

(For those interested, daily performance data of wind generators on the National Grid can be seen at <http://windfarmperformance.info/>.)

**FIGURE 9.4**

Cumulative installed wind capacity in Australia.

The installed renewable electricity generating capacity from hydro, wind, and PV (mainly rooftop solar) on the National Energy Market (NEM) grid is shown in Figure 9.5 [7] and totals, excluding large hydro, 12,875 and 28,476 MW, including hydro (August 2014). Adding in Western Australia and the Northern Territory to get an Australia wide total, increases installed renewable capacity by about another 1000 MW. See [8].

**FIGURE 9.5**

Renewable generation on the NEM (National Energy Market grid).

## 9.4 The Solar Energy Resource in Australia

Australia has a very good solar resource—better in central regions where the population is very sparse and there is no electricity grid. In these locations, the average annual DNI can be as high as 30 MJ/m<sup>2</sup>/day, compared with the populated coastal regions where the DNI averages, annually, 18–20 MJ/m<sup>2</sup>/day.

Geoscience Australia in collaboration with the Australian Bureau of Meteorology and funded by the Australian Renewable Energy Agency has developed the “Australian Solar Energy Information System (ASEIS) Online” <http://www.ga.gov.au/solarmapping>. Figure 9.6 shows a representative picture of the mean DNI solar resource in January. Maps can display distance to transmission line, topographic information, etc. Metadata are also available. More detailed 1 min solar data can be obtained from the Bureau of Meteorology website at <http://www.bom.gov.au/climate/data/oneminsolar/about-IDCJAC0022.shtml>.

Despite the good solar resource, only about 0.2% of Australia’s primary energy use is from solar energy—about 90% of this being used in the residential sector for solar water heating and rooftop PV. Over the 10-year period to 2012–2013, electricity generation from solar PV grew at an average annual rate of 56.4%, from a very low base to 1.5 TWh in 2012–2013—see Table 9.2 [1].

Figure 9.7 shows very clearly how the introduction of the FiT in Australia in 2009 increased the number of residential grid-connected PV installations. In 2013, typical PV module prices were \$0.50–\$0.75/W AUD and installed costs \$1.8–\$2.5/W AUD [9].

**FIGURE 9.6**

January mean DNI—Direct Normal Irradiance on a horizontal plane.

**FIGURE 9.7**  
Cumulative installation of PV in Australia 2004–2013. (From Muriel Watt et al., June 2014, APVI Report: National Survey Report of PV Power Applications in Australia, 2013, <http://apvi.org.au/wp-content/uploads/2014/07/PV-in-Australia-Report-2013.pdf>, accessed April 1–16, 2015.)

**FIGURE 9.8**  
Cumulative installed solar water heaters in Australia.

Australia has no local commercial manufacturer of PV cells and one module assembler—Tindo Solar (South Australia).

There has also been a rapid growth in recent years of solar water heaters—see Figure 9.8. This growth has been helped by the phasing out of high emission storage electric and low-efficiency gas water heaters [10].

### 9.5 Large-Scale Solar Installations

In October 2012, the 10 MW Greenough River PV Solar Farm near Geraldton, Western Australia was completed using First Solar modules. At that time, it was the largest PV installation and the only one with greater capacity than 1 MW in Australia. In July 2013,

it was announced by electricity Retailer and Generator AGL that two solar farms would be installed in New South Wales, 100 MW at Nyngan, and 50 MW at Broken Hill both using First Solar PV modules, with supporting funding being provided by the Australian Renewable Energy Agency, ARENA, and others. By May 2015, 25 MW of the Solar Farm had been installed and started generating at Nyngan, and the Broken Hill plant was under construction.

The largest grid-connected concentrated PV (CPV) installation in Australia is the 1.5 MW demonstration system in Mildura Victoria, commissioned in April 2013 by Silex, previously Solar Systems. It was hoped to upgrade this to a 100 MW system; however, uncertainty in the Federal Government's RET has meant that this upgrade has been abandoned. Project used ultra-high-efficiency (43%) "multi-junction" PV cells, technology originally developed by Boeing to power satellites.

At present, there are no Solar Thermal Electric Power Stations in Australia. However, at the 2000 MW Liddell coal-fired power station 260 km north of Sydney, a 9.3 MW thermal solar-concentrating system based on Fresnel solar collector technology has been installed. (Total mirror surface of 18,500 m<sup>2</sup>.) The solar boiler acts as a fuel saver by feeding steam into the existing coal-fired power station and reducing the coal required to operate the facility. The Fresnel collector system was a development out of Sydney University and the University of NSW. The original company formed was "Solar Heat and Power"; it is now owned by Novatech.

A good review of the current status of concentrating solar thermal power technologies, their potential costs, benefits, grid impacts, and market development in Australia is the May 2012 report prepared for the Australian Solar Institute by IT Power (Australia), "Realising the potential of Concentrating Solar Power in Australia." The cover photo on the report, Figure 9.9, shows the solar gas research facility at the CSIRO Solar Thermal Research Hub of the CSIRO National Research Centre at Newcastle NSW.

**FIGURE 9.9**

Solar gas research facility at the CSIRO solar thermal research hub of the CSIRO National Research Centre at Newcastle NSW.

## 9.6 Renewable Energy Research in Australia

Australia has a long history of renewable energy research particularly in Solar Energy with groundbreaking work having been conducted on the following:

- High-efficiency PV research—University of New South Wales
- Evacuated tubular collectors—Sydney University
- Solar Thermal “Big Dish”—Australian National University
- Solar Gas Research —CSIRO
- Cooperative Research Centre for Low Carbon Living

to name but a few.

In July 2012, the Australian Renewable Energy Agency (ARENA) was established with a budget of AUD\$3 billion extending to 2022 for

- Research, development, demonstration, deployment, and commercialization of renewable energy and related technologies
- Storage and sharing of knowledge and information about renewable energy technologies

The website <http://www.arena.gov.au> outlines the projects, initiatives, and reports funded by ARENA.

In mid-April 2015, the Australian Federal Government released its Energy White Paper [11] in which less than one page of the 74-page document was devoted to Renewable Energy. An extract from the page is given in the following:

The Australian Government is providing over \$1 billion toward the research, development and demonstration of renewable energy projects. The Australian Renewable Energy Agency (ARENA) was established as a statutory entity to make renewable energy solutions more affordable and increase the amount of renewable energy used in Australia. It has currently committed over \$1 billion to more than 200 projects. The Clean Energy Finance Corporation invests in projects that use a commercial approach to overcoming market barriers and mobilising investment in renewable energy, energy efficiency and low emissions technologies. The Australian Government has announced that it will abolish these agencies, but maintain a commitment to existing projects.

The Energy White Paper does not address climate change; this is left to the “Direct Action” program in the Federal Department of the Environment.

---

## 9.7 Direct Action

The Australian Government intends to reach its emissions reduction target through its Direct Action Plan “to efficiently and effectively source low cost emissions reductions and improve Australia’s environment. This will be done primarily through the Emissions Reduction Fund.” See <http://www.environment.gov.au/clean-air>.

The Emissions Reduction Fund (ERF) is the centerpiece of the Government's climate action policy. It will work with other incentives under the Direct Action Plan to help meet Australia's target of reducing emissions by 5% below 2000 levels by 2020. Design options for the Safeguard Mechanism for the ERF fund are currently in the consultation phase.

A large part of the ERF will be soil carbon and carbon offsets through revegetation programs.

---

## 9.8 Conclusion

Australia's energy sector is dominated by fossil fuels, in particular coal. Although the contribution by renewables to primary energy in Australia is small, about 5.6% in 2013, they represented 13.1% of electricity generation. There is a very large renewable energy potential that could be exploited in Australia, with significant natural resources for solar, wind, geothermal, and marine energy and with more limited resources in hydro and bioenergy.

Electricity consumption in Australia has been declining over the past few years due to the increased implementation of energy efficiency programs, installation of rooftop solar and solar water heater systems, and a downturn in the industry sector. In addition, this has led to the shutdown or reduced usage of some coal-fired power stations around the country. It is also behind the reasoning of the Federal Government desire to reduce the RET.

Up to 2013, the RET had already attracted about \$18.5 billion of investment in RE into Australia and created about 21,000 jobs. However, after over a year with no target having been decided on and with uncertainty in Government support for renewable energy programs and R & D, investors and investment in large-scale renewable energy programs have significantly declined and there have been many job losses. There has, however, been an increasing interest in community-driven programs, and it is likely that change will be driven by the people. Additionally, it has been found that the electricity grid can support high penetrations of intermittent renewables—up to almost 40% in South Australia already exists. Though problems have been created they can be solved and a paradigm shift in how electricity distributors and retailers will operate in future is likely to come sooner rather than later.

Many are following with interest how renewable energy in Australia will develop in the next few years. There is potential that some areas of Australia could be a model of how to integrate successfully and reliably a range of renewable energy sources into the energy mix if old business models are not followed.

### 10.1 Introduction

Japan's approach to greenhouse gas (GHG) mitigation long advocated not only for energy efficiency and renewable energy, but also for nuclear energy. This three-pronged approach, along with the contributions from Kyoto mechanisms and economic stagnation, had been effective in meeting the Kyoto Protocol obligation. However, in response to the massive earthquake and associated nuclear accident in March 2011, the Japanese government issued a moratorium on the restart of nuclear reactors and new construction, and the share of nuclear power in electricity generation declined sharply from 29% in FY 2010 to 11% in FY 2011, and to only 1.0% in FY 2013.<sup>1</sup> A nationwide electricity-saving campaign slashed demand by 5%, and Japan was able to avert an electricity shortage due largely to successful nationwide energy saving campaign. Still, the sustained moratorium on nuclear energy caused the increased mobilization of thermal plants fueled by natural gas and petroleum, resulting in adverse impact on electricity costs and GHG emissions<sup>2</sup> (Figure 10.1).

Under these circumstances, the Noda administration of the Democratic Party of Japan (DPJ) in 2012 drafted a new energy plan called *the Innovative Strategy for Energy and the Environment*, which aspires to phase out all nuclear power plants during the 2030s through accelerated renewable energy deployment (17.7% in total electricity generation by 2020 (Table 10.1)) and rigorous energy conservation measures (total energy consumption 19% below 2010 levels by 2030).<sup>3</sup> Nonetheless, its forecast however shows that without nuclear power, the emissions in 2020 will be below 1990 levels only by 5% at most, far short of the reduction goal of 25% below 1990 levels by 2020, set in 2009. Furthermore, electric utilities and energy intensive industries raised the concerns over the grid stability and economic costs of such a drastic change in the electricity generation fuel mix.

For these reasons, the subsequent Abe administration of the Liberal Democratic Party (LDP) shelved this ambitious phase-out plan and instead revised *the Basic Energy Plan*,

Note: No nuclear in 2020 and 2030, robust growth, and before additional measures.

a long-term vision previously drafted in 2010. The revised *Basic Energy Plan* repositions nuclear power as an important baseload electricity source and describes the prospect of renewable energy to be further above the past forecasts, footnoting 13.5% by 2020 and 20% by 2030 as a reference, in lieu of the explicit numerical target set by the Noda administration. In 2015 the Abe administration plans to establish new targets of electricity generation fuel mix as well as GHG emissions for 2030, and the new mix is likely to have a significant share of nuclear energy while showing less ambitious role of renewable energy.

In practice, in spite of the first approval of the restart of a reactor under the new safety regulation by the politically-independent Nuclear Regulation Authority in 2014, a more

risk-averse public makes it unrealistic to count on the restart of high-risk reactors or new construction for the foreseeable future. Moreover, the authority established the so-called 40-year rule which requires *special safety checks* on the restart of reactors after 40 years of operation that in principle makes the restart impossible without costly retrofits; in fact, several utilities are leaning toward decommissioning outdated reactors after experiencing the complex and lengthy approval process for relatively new reactors. When combined with the continuing needs to reduce GHG emissions, these tight limits on Japan's nuclear future prompted the country to roll out a number of policy actions accelerating renewable energy development and energy efficiency investment.

---

## 10.2 Feed-In Tariff

A feed-in tariff (FIT) program for renewable energy, introduced in July 2012, is perhaps the most drastic policy change after the accident, replacing a facile renewable portfolio standard (RPS). The FIT aims at stimulating renewable energy development through government-guaranteed 20-year power purchase contracts\* with a predetermined purchase price (tariff). An independent expert panel determines the tariff rates for each technology type and facility scale to expedite investment in a diverse array of renewable energy projects, and it revises the rates every year to reflect various changes such as a fall in solar panel costs (Figure 10.2).

Due to the urgent need for new power generation amid the moratorium on the restart of nuclear power plants, the expert panel granted premium rates in the first year to enable investors to secure financing promptly. The rates were then trimmed each year for PV, after the premium rates and the legally-binding purchase system resulted in extraordinary growth of utility-scale PV, whereas new categories were created in FY 2014 and FY 2015 for several costly but promising technologies such as offshore wind and small-scale biomass.

The outcome of the FIT has been mixed thus far. According to the Agency for Natural Resources and Energy (ANRE), the cumulative installed capacity of renewable energy jumped from 20.3 GW at the program start to 35.2 GW in November 2014, plus 58.6 GW worth of authorized projects in the pipeline. PV was responsible for most of this growth, showing that other energy sources have yet to gain traction (Figure 10.3). The likely causes of the apparent favoritism for PV are (1) favorable tariff structure, (2) an environmental assessment waiver, and (3) siting advantages. The basis of the tariff rates was the national study of life cycle costs of electricity generation in 2011,<sup>4</sup> but the costs of solar panels have fallen sharply since then, enabling the investors to exploit the price differentials between the actual and assumed costs. The second factor favors utility-scale PV by waiving the lengthy environmental assessment process, which normally takes at least 3 years for most renewable energy development, for PV projects covering an area of 50 ha or less and having no adverse impact on land use. Utility-scale PV also has siting advantage as it can be built on most vacant property, whereas wind, geothermal, and biomass power plants typically have to be located in remote areas with little transmission infrastructure to major energy consumption centers. These factors gave PV competitive advantage over other renewable sources, causing the concentration of investment in a single generation technology, at least for now.

The heavy growth in PV is causing several complications. First of all, the capacity factor, a ratio of its actual output over a period of time (e.g., kWh) to its potential output (e.g., kW), is

---

\* For small-scale photovoltaic and geothermal, the contract duration is 10 and 15 years, respectively.

**FIGURE 10.2**

Tariff rate of the FIT program. (From Agency for Natural Resources and Energy, Avoidable cost calculation method and facility certification system reform, 2014, [http://www.meti.go.jp/committee/sougouenergy/shoene\\_shinene/shin\\_ene/kaitoriseido\\_wg/pdf/003\\_s01\\_00.pdf](http://www.meti.go.jp/committee/sougouenergy/shoene_shinene/shin_ene/kaitoriseido_wg/pdf/003_s01_00.pdf).)

so low for PV that the development figure in capacity basis tends to mislead the public about the impact on national fuel mix. In fact, despite the massive introduction of renewable energy in capacity basis, the share of renewable energy (excluding large-scale hydropower) in electricity generation increased only by 0.8% between FY 2011 and FY 2013, from 1.4% to 2.2%.<sup>1</sup>

Lastly and most importantly, the impact on grid stability is also a concern for electric utilities, as the current intraregional grid system is designed to balance the load and generation within a single region and thus can integrate only a limited amount of variable energy sources. In fact, in late 2014, several major electric utilities declared the moratorium for granting grid-access for new renewable energy developments despite the legal obligation, citing the limitation of the grid ability to handle variable energy sources. In response, ANRE established new rules in January 2015, allowing electric utilities to curtail grid-access for PV and wind energy producers for up to 360 hours per year without compensation, along with possible unlimited curtailment without compensation for future project developers if the

**FIGURE 10.3**

Cumulative renewable energy capacity development. (From Agency for Natural Resources and Energy, Avoidable cost calculation method and facility certification system reform, 2014, [http://www.meti.go.jp/committee/sougouenergy/shoene\\_shinene/shin\\_ene/kaitoriseido\\_wg/pdf/003\\_s01\\_00.pdf](http://www.meti.go.jp/committee/sougouenergy/shoene_shinene/shin_ene/kaitoriseido_wg/pdf/003_s01_00.pdf).)

utility determines that its grid is saturated with existing generation capacity. While major curtailment is unlikely to occur in near future due to the slow approval process for restart of nuclear reactors, this new rule crowds the long-term financial certainty for variable energy developers and thus is expected to stagnate new developments, especially utility-scale PV.

These circumstances suggest that there needs to a fine-tuning to provide more incentives for other renewable energy sources and new mechanisms to promote load and generation shaping measures that enable grid integration of more variable resources, such as expanded use of demand management strategies, flexible backup energy sources, inter-regional power interchange, and energy storage facilities. Secondly, the high costs of PV could possibly compromise Japan's global economic competitiveness through increased electricity prices, particularly in energy-intensive sectors such as the steel industry. ANRE reports the national costs of the FIT program amount to 130 billion yen (approx. U.S. \$1.3 billion) for FY 2012, which is anticipated to grow to 313 billion yen (approx. U.S. \$3.1 billion) in FY 2013,<sup>5</sup> and the increasing economic burden could adversely impact low-income households and energy-intensive industries in the coming years.

### 10.3 Energy Conservation Law

Since the 1970s oil crisis, Japan has made massive investments in energy conservation technologies and practices, leading Japan to achieve one of the lowest energy intensities (per GDP) in the world<sup>6</sup> despite the presence of energy-intensive manufacturing industries

**FIGURE 10.4**

Energy use per nominal GDP in 2010. (From Energy Data and Modeling Center, *Handbook of Energy and Economic Statistics in Japan*, 2013.)

(Figure 10.4). The energy conservation law has been the primary policy instrument propelling energy efficiency investment; it was first enacted in 1979 and amended in 1998, 2002, 2005, 2008, and 2013 to expand the target and enhance the enforcement mechanism. The law not only targets specific emitting equipment such as trucks and refrigerators, but also requires businesses to draft and implement energy conservation plans for their factories, buildings, and fleets. For example, businesses reporting total energy use of 1,500 tons of oil equivalent (toe) per year must draft and implement a long-term plan to improve efficiency by 1% or more annually, and the latest amendment in 2013 encourages a *peak cut*—curbing electricity demand during peak hours through measures such as demand shift, cogeneration, and storage battery installation.

For equipment, the law establishes the *Top Runner Program*, which sets energy efficiency standards based on the performance of the best available technologies (*top runners*) for each item.<sup>7</sup> The program began in 1999 with standards for 11 items, and expanded the coverage over time to 27 items (Table 10.2). The focus of the program has been on automobiles and office and home appliances, but the latest amendment in 2013 added building materials as an enabling item to save energy used in other equipment. The impact of the program has been outstanding: for instance, the energy use of a standard air conditioner decreased by 43.3% between 1995 and 2012,<sup>6</sup> and the average fuel efficiency of a passenger car rose by 58.5% between 1993 and 2012.<sup>8</sup>

The regulatory approaches under the energy conservation law have been successful in Japan due largely to the unique cooperative relationship between businesses and regulators, and the law gained popularity among the general public as a plain and transparent regulation.<sup>9</sup> Nonetheless, some businesses claim the uniform reduction mandate on commercial energy use is unfair, as the difficulty in achieving the target depends on the baseline energy use, where those who acted early to reduce their energy use now have to work harder to meet the requirement. The *Top Runner Program* now applies to roughly half of the energy use in the residential and commercial sectors, but misses some energy-intensive equipment such as washers, dryers, commercial refrigerators, and commercial freezers. The program sets separate standards for size-based subcategories,

TABLE 10.2

Target Items in Top Runner Program

Start Year	Item		
FY 1999	Passenger vehicle	Freight truck	Air conditioner
	Television	Fluorescent lamp	Copying machine
	Magnetic disk unit	Video cassette recorder	Computer
	Freezer	Refrigerator	
FY 2002	Space heater	Gas stove	Electric toilet seat
	Petroleum water heater	Gas water heater	Vending machine
	Transformer		
FY 2006	Rice cooker	Microwave oven	DVD recorder
FY 2008	Router	Switching unit	
FY 2012	Printer	Multifunction printer	Electric water heater
FY 2013	Thermal insulator		

Source: Agency for Natural Resources and Energy, Comprehensive energy and environmental strategy research report, 2013, [http://www.meti.go.jp/meti\\_lib/report/2013fy/E003456.pdf](http://www.meti.go.jp/meti_lib/report/2013fy/E003456.pdf).

and some analysts have argued that it may be discouraging downsizing of passenger cars, televisions, or other items. These criticisms suggest that, though the 36-year-old law has made important contributions to energy conservation in Japan, it still has room for improvement.

## 10.4 Carbon Tax

In response to the oil crisis, Japan imposed heavy taxes on petroleum, but not on other fossil fuel sources. In October 2012, however, Japan introduced a carbon tax (*tax for global warming countermeasures*), whose rate is based on carbon content, and thus giving largest impact on coal prices due to its high carbon intensity. The tax rate began at 95 yen (approx. U.S. \$1) per t-CO<sub>2</sub> and is slated to reach a cap of 289 yen (approx. U.S. \$3) in 2015. While it is still relatively small compared to CAN \$30 per t-CO<sub>2</sub> in British Columbia, Canada, Japan's carbon tax covers all fuel uses, including aviation and industrial use, which are often exempted or taxed differently in other areas, and is in addition to a variety of other high energy taxes (Figures 10.5 and 10.6). It is expected to raise 262 billion yen (approx. U.S. \$2.62 billion) in FY 2015 and thereafter, and its revenues are dedicated for energy efficiency and renewable energy programs, unlike British Columbia's revenue-neutral approach where the revenues are offset by reductions in other taxes.

The major intent of the tax is to incentivize energy efficiency and renewable energy investment by sending price signals to favor energy-saving technologies and behaviors. In addition, the elevated costs of fossil fuels are expected to impact electricity generation fuel mix in favor of other sources, and the revenues allocated to various R&D and rebate programs are expected to accelerate the development and deployment of new, low-carbon technologies. The Ministry of the Environment (MOE) estimates that the tax will lower 2020 emissions by 0.5%–2.2% relative to a no-action baseline,<sup>10</sup> but this estimate does not account for impacts on fuel mix and behavioral change, so the impact could be substantially larger if accounting for these factors.<sup>11</sup>

**FIGURE 10.5**

Energy taxes on gasoline (2014). (From Ministry of the Environment, Interim report from the environmental tax commission, 2013, <https://www.env.go.jp/policy/tax/conf01.html>.)

**FIGURE 10.6**

Energy taxes on coal (2014). (From Ministry of the Environment, Interim report from the environmental tax commission, 2013, <https://www.env.go.jp/policy/tax/conf01.html>.)

A carbon tax is an economy-wide policy tool to curb GHG emissions, and the resulting price signal can incentivize low-carbon technologies and behaviors without the significant implementation cost and economic inefficiency of regulatory approaches. While MOE's expert panel recommends more extended use of a carbon tax,<sup>12</sup> energy-intensive industries argue that a higher tax could lead to a leakage problem in which economic activities, and their GHG emissions, are shipped overseas. For this reason, worldwide implementation or some form of a border tax may be needed for more extended use of a carbon tax.<sup>13</sup>

**TABLE 10.3**

Target Items in Green Investment Tax Break

Area	Item	
Renewable energy	Photovoltaic	Wind, hydrothermal
	Snowpack storage	Biomass
Transportation	Hybrid electric truck	Plug-in hybrid vehicle, electric vehicle
	EV charging system	Hybrid electric construction machinery
Commercial Building	Insulated window	Efficient ventilation system, solid state lighting (LED)
	Efficient air conditioner	Building energy management system (BEMS)
Industrial and power sector	Cogeneration system	Combined-cycle gas turbine, efficient industrial furnace
	Efficient processing tool	High-voltage transmission system

## 10.5 Tax Incentives and Subsidies

The government has long adopted various tax incentive and subsidy programs for individual items such as the Eco-car Tax Break and the Residential PV Installation Support Subsidy. The Green Investment Tax Break\* is perhaps the most comprehensive tax incentive program for corporations, targeting a variety of items in renewable energy, transportation, building, and industrial efficiency (Table 10.3). The government launched the program in 2011 to reduce the tax burden through bonus depreciation—30% of purchase and installation costs—or 7% tax credit for corporate income tax. This tax scheme is similar to the Business Energy Investment Tax Credit in the United States but covers a broader set of low-carbon technologies.

The total tax break from the program amounted to 97.6 billion yen (approx. U.S. \$976 million) in the first year, and a survey estimates it induced 7%–45% of additional investment, depending on the item.<sup>14</sup> The same study forecasts the annual GHG reduction to total 3.1 million t-CO<sub>2</sub> in 2015, equivalent to 0.2% of the national emissions, from the FY 2011 tax break alone. Although the impact of the program will become larger as it continues to induce more investment, the major concern is that the beneficiaries are limited to profit-making firms paying corporate income tax. The worldwide recession and the 2011 earthquake collaborated to put over 70% of Japanese enterprises reporting losses or accumulated losses in FY 2011,<sup>15</sup> so the vast majority of businesses were simply not eligible for the program. The economic recovery is broadening the coverage, but a fundamental problem remains that many small and startup businesses tend to report losses. For this reason, a tax break on other taxes such as property tax may be a better policy instrument to attract investment from all businesses.

## 10.6 R&D

Japan has been one of the R&D leaders in low-carbon technologies, successfully commercializing various low-carbon technologies such as hybrid and electric vehicles, heat pump water heaters, PV cells, carbon fiber, power electronics, hydrogen fuel cells, and

\* Translated from the original name, *Green Toshi Genzei*.

**FIGURE 10.7**

Focus areas in the *Environmental Energy Technology Innovation Plan*. (From Council for Science and Technology Policy, The Environmental Energy Technology Innovation Plan, 2013, <http://www8.cao.go.jp/cstp/gaiyo/kankyo/20130809.html>.)

LED light bulbs. To build on these successes, in 2013, the Abe administration revised a comprehensive R&D roadmap for low-carbon technologies called the *Environmental Energy Technology Innovation Plan*.<sup>\*</sup> The plan is a basis for government R&D funding allocation, and lists 37 technology areas to cut today's world GHG emissions in half by 2050 (Figure 10.7),<sup>16</sup> of which five are new for 2013: (1) innovative materials such as carbon-fiber-reinforced plastic (CFRP) and high tensile strength steel (HTSS), (2) artificial photosynthesis to produce various chemicals such as hydrogen and olefin, (3) geothermal energy including enhanced geothermal system (EGS) and advanced exploration and drilling techniques, (4) solar thermal energy such as concentrated solar power (CSP) and direct use of thermal energy in heating and cooling, and (5) ocean energy such as tidal and current power.

Shifting attention to ongoing R&D activities, the government is boosting funding for the following prospective technologies: (1) offshore wind, particularly massive floating wind farms tested off the shore of Fukushima and Nagasaki, (2) hydrogen and fuel cells for residential application branded as Ene-Farm and for automobile use, rolled-out for the mass in 2014, (3) advanced thermal power such as advanced ultrasupercritical (A-USC) and integrated coal gasification combined cycle (IGCC) demonstration, (4) advanced electronics such as normally off computing, organic light-emitting diodes (OLED), and ultralow voltage devices, and (5) cost reduction and capacity enhancement of various types of battery such as Li-ion, sodium-sulfur, and redox flow batteries. The government envisions these technologies to play a pivotal role in curbing the emissions not only in Japan but also elsewhere in the world through export and technology transfer.

<sup>\*</sup> Translated from the original name, *Kankyo Energy Gizyutsu Kakushin Keikaku*.

## 10.7 Conclusion

The earthquake and associated nuclear incident in 2011 triggered a variety of policy changes to propel energy efficiency and renewable energy investment. The policy instruments covered in this section will be crucial in curbing GHG emissions in Japan, but it is difficult to assess if the nation as a whole will be able to achieve significant reduction amid the uncertain future of nuclear energy. To maximize Japan's contribution to the world's efforts to reduce the emissions, Japan needs to actively share its technologies through export, licensing, and mostly notably a technology transfer instrument called Joint Crediting Mechanism (JCM). Moreover, the lessons learned from policy implementation in Japan, including the benefits, drawbacks, and areas for improvement, could be valuable for other nations to craft optimal strategies to encourage energy efficiency and renewable energy investment.

### 11.1 Introduction

Decentralized energy\* (DE) is showing ever-increasing promise as a cost-effective method of electricity supply, resulting in significant environmental benefits. Though every sector of the DE industry is showing impressive growth, the total share of DE in overall global electricity capacity remains at only about 7.2%.<sup>1</sup> Lack of clear policy in the energy sector is one of the main barriers preventing greater investment in DE. It is clear that adopting policies that ensure an independent regulator combined with open

---

\* DE technologies consist of the following forms of power generation systems that produce electricity at or close to the point of consumption:

- High efficiency cogeneration/CHP
- Onsite renewable energy systems
- Energy recycling systems, including the use of waste gases, waste heat, and pressure drops to generate electricity onsite

WADE classifies such systems as DE regardless of project size, fuel or technology, or whether the system is on-grid or off-grid.

markets that reward investors for noneconomic benefits of DE will be key in driving future growth in the sector.<sup>2</sup>

In June 2004, the largest renewables energy event to date was held in Bonn, Germany. Over 3000 attendees from 154 nations were present. Though the conference dealt only with renewables, to a large extent, the recommendations would also hold true for all forms of DE, including cogeneration. Arising from that event were some guidelines for policy makers as to what must be put in place in order for DE policy to be effective. For DE to become an integral part of the energy mix, policymakers must\*

1. Integrate DE into overall energy policy
2. Establish clear goals
3. Establish transparent market conditions
4. Reduce or eliminate subsidies for conventional centralized energy
5. Address cost issues
6. Create incentives that are eventually phased out
7. Ensure that energy issues form part of the basis of decisions in *nonenergy* sectors such as urban planning and infrastructure, etc.
8. Educate the public on the benefits and costs of DE
9. Promote DE jobs and training
10. Develop public organizations to promote DE
11. Strengthen regional and international cooperation on DE matters
12. Secure grid access for DE
13. Do not omit thermal energy in decision making
14. Support research and development in DE
15. Involve a range of actors in promoting DE including local governments, financiers, international bodies, and multilateral and bilateral banks and institutions
16. Harness the power of public procurement

However, in general, it is important that a policy be stable enough in the long term to foster confidence to everyone that the rules will not change after they have committed to one plan of action. Involving locals in the establishment of DE policies is the other key to both garnering public support and establishing a basis of shared experience on which future policy revisions can be made.

The aforementioned list illustrates some of the goals of policies to promote DE. There are a multitude of approaches that can be used to achieve these goals and the following section provides many examples from all over the world. For each of the nations covered in this chapter, there will be a short summary paragraph followed by a table with three major headings: Technical, Financial, and Others.

The Technical heading will discuss policies that address technical issues such as mandated technologies, interconnection procedures, manufacturing and interconnection

---

\* [http://www.renewables2004.de/pdf/policy\\_recommendations\\_final.pdf](http://www.renewables2004.de/pdf/policy_recommendations_final.pdf).

standards, and safety rules. Technical policies if designed carefully can be important drivers for DE investment just as poorly designed policies or lack of policies can stifle investment in DE.

The Financial heading will cover policies that exist in the area that are based on economic incentives such as rebates for investing in certain technologies, tax breaks for eligible investments, and pricing arrangements for power produced by on-site generators. Although project economics is affected by a multitude of factors (including fuel prices, capital expenditures, opportunity costs, etc.) financial policies can often make the difference between a project that is feasible and one that is not.

The Others section will discuss all remaining issues relating to DE policy including more general policy guidance and legislation mandating DE use or energy efficiency/renewables.

The general organization of each section will take the form of the following table.

In some cases, no examples for the specific category of policy/technology were found for a given jurisdiction in which case the given cell was left blank.

General Organizational Structure for Country Policy Summaries	
Technical	DE in general
	Large-scale cogeneration
	Domestic cogeneration
	PV
	Wind
	Hydro
Financial	DE in general
	Large-scale cogeneration
	Domestic cogeneration
	On-site PV
	On-site Wind
	Hydro
Others	DE in general
	Large-scale cogeneration
	Domestic cogeneration
	PV
	Wind
	Hydro

It is very difficult to separate policies that aim to promote renewables and efficiency in general from those aimed at promoting DE. For example, many policies aim to promote renewables in general including large-scale wind farms, which should not necessarily be considered as DE. Likewise some policies are aimed at only cogeneration and do not affect renewables. In other cases, for example, in the case of rooftop PV, renewable policy and DE policy is one in the same. In most cases, however, policies that affect DE will be framed in the context of policies to promote renewables or general efficiency (in the case of cogeneration). Currently, there remains a shortage of concrete policy examples that target on-site power or DE. In order for DE to truly reach its potential, laws and policies will have to be increasingly aimed at DE specifically.

## 11.2 Canada

With a low population density and wide climatic variations, Canada has one of the world's highest energy use per capita. The Canadian government has taken some steps to promote DE using financial mechanisms, but coordinated policy cooperation between the various provincial governments and the federal government may prove most effective for promoting DE.

Canadian Distributed Generation Policy by Technology and Type		
Technical	DE in general	The federal government in Canada has control over interprovincial gas pipelines and transmission lines crossing international borders. Because the Canadian constitution enshrines energy as a provincial jurisdiction in all other cases, each utility tends to have its own interconnection policy. Interconnection policies tend not to be technology specific. The government funds the <i>micropower</i> connect initiative, which aims to harmonize interconnection rules in the provinces.
	Large-scale cogeneration	Interconnection rules vary by province.
	Domestic cogeneration	Interconnection rules vary by province
	PV	Interconnection rules vary by province.
	Wind	Interconnection rules vary by province.
	Hydro	Interconnection rules vary by province.
Financial	DE in general	There is no federal law, which guarantees retail electricity prices. In most cases, on-site generators feeding excess power to the grid obtain wholesale electricity price or less, and in some cases, retail price is earned. Various funding schemes exist to promote energy innovation including: the technology Early Action Measure program, the Climate Change Technology and Innovation Program, the Federation of Canadian Municipalities Green Fund, and a program to promote on-site generation at government facilities. In many cases, the utility companies of a province have much influence over provincial electricity policy so that policy is often determined by the private sector.
	Large-scale cogeneration	Under Canadian renewable and conservation expenses (CRCE), regime development of a cogeneration equipment may have tax benefits. CRCE generally includes intangible expenses incurred by a <i>principal-business corporation</i> (as defined in the act) and payable to an arm's length party in connection with the development of an energy project wherein at least 50% of the capital cost of the depreciable property in the renewal energy project is property described in Class 43.1 (a <i>Class 43.1 Asset</i> ) or Class 43.2 (a <i>Class 43.2 Asset</i> ), under the Canadian taxation system for capital cost allowance (CCA) under Schedule II to the Regulations. Recent amendments have expanded Class 43.2 with respect to waste-fuelled thermal energy equipment and equipment of a district energy system that uses thermal energy provided primarily by eligible waste-fuelled thermal energy equipment. These amendments have also expanded Class 43.2 to include equipment that uses the residue of plants, generally produced by the agricultural sector, to generate electricity and heat (biowaste). These measures should encourage investment in technologies that can contribute to a reduction in emissions of greenhouse gasses and air pollutants in support of Canada's targets as set forth in the Federal Sustainable Development Strategy. These measures may also contribute to the diversification of Canada's energy supply.

(Continued)

Canadian Distributed Generation Policy by Technology and Type	
	<p>The 2013 Canadian Federal Budget proposes to expand Class 43.2 by making biogas production equipment that uses more types of organic waste eligible for inclusion in Class 43.2, including pulp and paper waste and wastewater, beverage industry waste and wastewater and separated organics from municipal waste, and the range of cleaning and upgrading equipment used to treat eligible gases from waste that is eligible for inclusion in Class 43.2, to all such cleaning and upgrading equipment.</p> <p>These proposed measures will apply to property acquired on or after March 21, 2013, that was not used or acquired for use before March 21, 2013.<sup>a</sup></p>
Domestic cogeneration	Cogeneration equipment is listed as Class 43.1 assets: they are eligible for accelerated depreciation rates for capital costs (30%).
On-site PV	Various feed-in tariffs (FiTs) exist depending on the type (rooftop, free field) and the capacity of the panels.
On-site wind	Financial incentives vary province by province, some offer net metering (which allows small wind turbine owners to offset their electricity consumption, or earn credit from their local utility if they produce excess power through their turbine), others have special loans, or FiTs. The Canadian federal government also supports the research, development, marketing, and deployment of small wind turbines in Canada through R&D initiatives.
Hydro	In 2009, Ontario enacted FiT for hydropower. Under the new FiT rules, hydropower producers are paid 13.1 cents/kW h for up to 10 MW over a 40-year term. The rate is 12.2 cents for 10–50 MW over the same period. According to the order of the Minister of Energy in fall 2013, changes to the FiT program are expected.
Others	<p>DE in general</p> <p>The Government of Canada has set a goal of generating 90% of Canada's electricity from zero-emitting sources by 2020, while various provinces have their own goals to improve their zero emission sources. (e.g., Ontario plans to end coal generation by 2014, and is expecting to reach 2650 MW of solar PV by 2015.)</p> <p>In 2011, Canada announced its withdrawal from the Kyoto Accords, but participated in Durban talks, which were leading to a new binding treaty with targets for all countries to take effect in 2020.</p>
Large-scale cogeneration	
Domestic cogeneration	
PV	Between 2014 and 2018, installed solar capacity in Canada is expected to reach 3.48 GW, which presumes an annual growth of 450 MW.
Wind	Current installed wind capacity in Canada is 6500 MW, which is only 1.3% of the total energy demand.
Hydro	Canada is the world's largest producer of hydroelectricity in the world (before China and Brazil), and one of a few countries to generate the majority of its electricity from hydroelectricity. Some provinces and territories, such as British Columbia, Manitoba, Newfoundland and Labrador, Quebec, and Yukon, produce over 90% of their electricity in this manner.

<sup>a</sup> <http://www.millerthomson.com/en/publications/newsletters/tax-notes/april-2013/canadian-renewable-conservation-expense>.

### 11.3 Mexico

Mexico is resource rich for many DE sources including natural gas, sunshine, wind, and biomass, but little of that potential has been realized. To date there has been limited success in developing a strong policy foundation for DE. The recently announced intention of the Mexican government on energy reform, to open the market for foreign investors, may result in fundamental changes on power generation as well.

Mexican Distributed Generation Policy by Technology and Type		
Technical	DE in general	In 1992, a law was established which permitted nonutility generation and on-site generation for the first time. The <i>Ley del Servicio Público de Energía Eléctrica</i> (LSPEE) forbids bilateral trading of electricity between individuals but allows companies to generate for their own demand and cogeneration with a permit from the Comisión Reguladora de Energía (CRE) provided they meet the conditions as defined by Art. 36 of LSPEE. However, in 2012, certain amendments were made to this law, and in 2008, the <i>Ley para el aprovechamiento de energías renovables y el financiamiento de la transición energética</i> has been approved, there are still serious barriers that exist for DE.
	Large-scale cogeneration	The Mexican government defined cogeneration in the 1992 law permitting private sector involvement in the electricity sector <sup>a</sup> but stated that the power must be used on-site. Interconnection, wheeling, and backup services are allowed but require permits from the CFE and the energy secretariat (SENER). Interconnection standards for cogeneration plants are based on the U.S. IEEE 1547.
	Domestic cogeneration	
	PV	
	Wind	
Financial	Hydro	
	DE in general	Mexico's income tax law (ITL) provides a 100% deduction incentive for taxpayers who carry out investments in renewable energy equipment. Qualifying sources like sun, wind, water, and geothermal energies, as well as biomass fuel equipment, are eligible for this incentive.  To finance sustainability projects, the Fund for Energy Transition and Sustainable Exploit of Energy was created in 2009. Companies or individuals may request incentives from the fund by submitting proposals for projects that involve renewable energies and energy transition.  Every fiscal year, the Ministry of Energy (SE) and the National Council of Science and Technology (CONACYT) establish a special fund for energy sustainability projects in which universities and research centers are the potential participants and beneficiaries. The resources for the fund are provided by the Mexican oil company PEMEX. <sup>3</sup>
	Large-scale cogeneration	The Mexican government incentivizes cogeneration by treating it as a renewable energy source. Pollution control equipment or equipment for research and technological development in renewable energy are exempt from general import and export taxes.  Mexican policy outlines accelerated depreciation for investments in renewable energy, allowing 100% depreciation on investment for machinery and equipment for generating energy from renewable sources.

(Continued)

Mexican Distributed Generation Policy by Technology and Type		
		Incentives and funding programs for cogeneration projects can also be found through the Mexican Secretariat of the Environment and Natural Resources, SEMARNAT. <sup>b</sup>
	Domestic cogeneration	
	On-site PV	The country offers tax incentives for solar projects and a so-called net metering system, as well as the possibility of long-term power purchase deals with CFE.
	On-site wind	
	Small hydro	
Others	DE in general	<p>Investors have to secure a wide array of permits, which can be very costly. In some cases, more than 100 permits are required (an existing plan is to reduce to 31) including local/municipal planning permission, environmental permitting, gas supply and connection permits, power generation authorization and network interconnection permits, etc. According to a recently published analysis by Frost and Sullivan, insufficient centralized electricity, which has compelled several consumers to generate their own power, along with incomplete grid facilities in large isolated areas, offers huge scope for the distributed power generation (DPG) market in Mexico; however, DE providers' reliance on electricity subsidies coupled with grid integration issues in isolated areas makes market development uncertain. Energy subsidies have added to the challenge, as artificially low electricity prices for most consumers in the country reduce opportunities for DE technologies, which have become a costly alternative to grids.</p> <p>In fact, although DE technologies reduce transmission costs and provide the benefit of local energy management and economies of scale, their start-up costs are higher than that of centralized electricity production, further affecting adoption.<sup>c</sup></p> <p>A 2012 law requires 35% of electricity from renewable resources by 2024. At the Solar Power Mexico conference in 2012, it was said that PV electricity and solar will comprise up to 5% of Mexico's energy by 2030 and up to 10% by 2050.</p> <p>By the announcement of the Mexican government at the beginning of August 2013, Mexico is ready to change its constitution to let foreign private companies to find and produce oil and gas in the country. The initiative also seeks to liberalize Mexico's electricity sector by allowing private firms to produce and sell electricity to consumers. These changes might open up more opportunities for cogeneration to flourish in the country.</p>
	Large-scale cogeneration	In March 2013, SENER, Spain, published an <i>Initiative for the development of the cogeneration potential in Mexico</i> , which accepted an action plan with main actions such as: energy surplus remuneration methodology, interconnection process standardization, private sector participation in PEMEX projects, and development of transportation network and natural gas distribution, and secondary actions such as measures for financial support for combined Heat and Power (CHP) projects in the short term and communication plan and pilot projects to eliminate current cultural and information limitations. <sup>d</sup>
	Domestic cogeneration	
	PV	By the end of 2012, installed PV capacity was 38 MW, which is expected to increase up to 60 MW or even more in 2013.
	Wind	By the end of 2012, installed wind capacity was 1370 MW.

**Mexican Distributed Generation Policy by Technology and Type**

---

Hydro	<p>Recently Mexico's congress has changed its renewable energy and energy transition law to include larger hydroelectric projects in the country's definition of <i>renewable</i>, provided they satisfy a certain criteria. According to the modifications, hydropower plants with capacities about 30 MW are to be classified as <i>renewable</i>, but only if they meet a generation density standard.</p> <p>Mexico's current total installed hydropower capacity accounts for about 11.5 GW, which is expected to increase by as much as 4 GW with regard to its small hydroelectric capacity and 40 GW with regard to its large capacity.</p>

## 11.4 United States

The United States remains highly influential in international energy policy development. As the single largest energy-using nation, policy to promote DE is clearly needed to develop capacity to meet the United States' rising demand. Many innovative policy developments have been introduced at the state level that have effectively buoyed DE markets, and the United States remains one of the world leaders in renewable energy development. Recent results of shale gas and oil research, impacts of climate change, and express government intention to increase the ratio of unconventional energy may elevate DE to a more important position. However, steps to harmonize state level policy with policy at the federal level still will be the main factor for successfully advancing DE.

---

**USA Distributed Generation Policy by Technology and Type**

---

Technical	DE in general	Section 1254 of the Energy Policy Act of 2005 requires that electric utilities offer grid interconnection based on a nationwide standard. Currently to connect DE units must be IEEE P1547 compliant, which requires <i>automatic and rapid disconnection in the event of a fault</i> .
	Large-scale cogeneration	
	Domestic cogeneration	
	PV	
	Wind	
	Hydro	
Financial	DE in general	At a state level, the United States has many promising policies in support of renewables and distributed generation. Grant programs, financing, R&D funds, net metering, FiTs, and tax breaks are some of the financial measures that have proven successful for promoting DE technologies at a state level. The Energy Act of 2005 grants tax credits for developers who build energy efficient buildings that could have ramifications for DE especially microcogeneration.

(Continued)

---

**USA Distributed Generation Policy by Technology and Type**

---

In details, the following support schemes are available:

**PTC** is applicable for wind, geothermal, landfill gas, trash combustion, open-loop biomass, closed-loop biomass, hydropower, and wave tide. The PTC provides a tax credit for the production of electricity from renewable sources and the sale of that electricity to an unrelated party. Credit amount is 2.2 cents/kW h for wind, closed-loop biomass, and geothermal, and is 1.1 cents/kW h for other renewable energy resources. PTC is available for facilities placed in service before January 1, 2014 (2013 for wind), and available for a 10-year period beginning with the year the facility is placed in service.

**Investment tax credit (ITC)** is applicable for solar, geothermal, qualified fuel cell or microturbine property, CHP systems, small wind, geothermal heat pumps, and PTC-eligible facilities placed in service after 2008 and before 2014 (2013 for wind). The ITC provides a credit for qualifying energy property. For any taxable year, the ITC is the energy percentage of the basis of each energy property placed in service during the taxable year. Credit amount is 30% of eligible costs for fuel cell, solar, and small wind property, 10% of eligible costs for CHP, microturbine property, and geothermal heat pumps. The ITC is generally available for eligible property placed in service on or before December 13, 2016.

**Grant in lieu of PTC and ITC** is applicable for tangible personal property or other property that is an integral part of a qualified facility (as defined by the PTC and ITC rules). The American Recovery and Reinvestment Act (ARRA) enacted a new grant program, which provides a cash grant in lieu of the PTC or ITC. ARRA permits PTC or ITC projects to elect a grant of up to 30% of costs of construction of PTC or ITC energy property in lieu of tax credits. Projects must begin construction before 2012 and submit a grant application no later than October 1, 2012. Projects must be placed in service before their PTC or ITC credit expires, PTC before 2014 (2013 for wind), ITC before 2017.

**Renewable portfolio standards (RPSs)** generally place an obligation on electric supply companies to produce a specified fraction of their electricity from renewable energy sources and enumerates mechanisms that are permitted to achieve compliance, such as renewable energy credits (RECs). Currently, no federal RPS legislation has been enacted. A total of 29 states and the District of Columbia have an RPS.<sup>3</sup>

Large-scale cogeneration

Microturbines and CHPs are eligible to corporate tax incentive with the following conditions:

Credit for microturbines equals 10% of expenditures, with no maximum credit limit stated (explicitly). The credit for microturbines is capped at \$200/kW of capacity. Eligible property includes microturbines up to 2 MW in capacity that have an electricity-only generation efficiency of 26% or higher.

(Continued)

---

**USA Distributed Generation Policy by Technology and Type**

---

		<p>Credit for CHP equals 10% of expenditures, with no maximum limit stated. Eligible CHP property generally includes systems up to 50 MW in capacity that exceeds 60% energy efficiency, subject to certain limitations and reductions for large systems. The efficiency requirement does not apply to CHP systems that use biomass for at least 90% of the system's energy source, but the credit may be reduced for less efficient systems. This credit applies to eligible property placed in service after October 3, 2008.</p>
	Domestic cogeneration	
	On-site PV	<p>No federal FiT exists; however, certain states or voluntary companies offer FiT both for domestic or commercial PV generators.</p> <p>Solar generators are eligible to corporate tax incentive. The credit is equal to 30% of expenditures, with no maximum credit. Eligible solar energy property includes equipment that uses solar energy to generate electricity, to heat or cool (or provide hot water for use in) a structure, or to provide solar process heat. Hybrid solar lighting systems, which use solar energy to illuminate the inside of a structure using fiber-optic distributed sunlight, are eligible. Passive solar systems and solar pool-heating systems are not eligible.</p>
	On-site wind	<p>No federal FiT exists; however, certain states offer FiT for wind power producers.</p> <p>Wind power generators may apply for corporate tax incentives. The credit is equal to 30% of expenditures, with no maximum credit for small wind turbines placed in service after December 31, 2008. Eligible small wind property includes wind turbines up to 100 kW in capacity.</p> <p>On January 1, 2013, the production tax credit (PTC) was extended for another year.</p>
	Small hydro	<p>Various incentives are available for hydropower plants. These can be PTCs, stimulus funding, and clean renewable energy bonds.</p>
Others	DE in general	<p>PURPA of 1978 provided the foundation for competition in the electricity sector allowing DE investors to participate in the market for the first time. The Energy Act of 2005 made several amendments to PURPA including the retraction of the mandate that utilities must buy power from <i>qualifying facilities</i> (which included many cogeneration facilities). Section 1253 states that as long as the utility can prove that the facility has fair access to the grid, there is no longer any obligation to buy power (nondiscriminatory access to the grid is guaranteed in section 1231). The bill also requires all utilities to offer net metering to small on-site generators (section 1251) and offer time-differentiated rate schedules upon request so that customers can take advantage of technologies such as <i>smart metering</i>, which also must be supplied by the utility (section 1252). And, without proving any clear guidance the utilities are disallowed from relying on a single fuel, that is, there is a federal mandate to diversify energy portfolios.</p>

(Continued)

---

**USA Distributed Generation Policy by Technology and Type**

---

	<p>A total of 29 states and the District of Columbia have enacted RPSs according to section 203 of the Energy Act of 2005, the federal government must ensure that not less than 3% of its total energy consumption is derived from renewables in the fiscal years of 2007–2009, not less than 5% in the fiscal years of 2010–2012, and not less than 7.5% in the fiscal year of 2013 and each fiscal year thereafter.</p> <p>There is a federal mandate to study the potential from renewable energy (Section 201). There is a goal to develop at least 10,000 MW of nonhydro renewables on public lands by 2015.</p>
Large-scale cogeneration	<p>According to Environmental Protection Agency in 2012, the United States had an installed capacity of 82 GW of CHP, with 87% of those in manufacturing plants. This number may tremendously increase in the future due to the executive order of President Barack Obama in 2012, that would increase the number of cogeneration plants in the United States by 50% by 2020.</p> <p>The economic success of shale gas in the United States since 2000 might strongly motivate CHP developments, presenting cheap combustible gas for a long time. It has been postulated that there may be a 100-year supply of natural gas in the United States (however, only 11 years of gas supply is in the form of proved reserves).</p>
Domestic cogeneration	
PV	<p>According to North America PV Market Report, in 2013, the United States passed the 10 GW installed solar PV milestone, and now only Germany, Italy, and China have more installed PV capacity.</p> <p>Solar PV has become one of America's fastest-growing energy sources in recent years. The solar PV market has expanded at a compound annual growth rate of 50% since 2007, and 83% of the 10 GW capacity was installed within the past 14 quarters. Only in the first half of 2013, more than 1.8 GW of new solar PV capacity was installed. In the future, further significant growth of an additional 80% by the end of 2014 is expected, putting the United States on track to pass 17 GW installed solar PV capacity.</p>
Wind	<p>Construction of new wind power generation capacity in the fourth quarter of 2012 totaled 8,380 MW bringing the cumulative installed capacity to 60,007 MW by the end of 2012. This capacity is exceeded only by China.</p> <p>The U.S. Department of Energy's report <i>20% Wind Energy by 2030</i> envisioned that wind power could supply 20% of all U.S. electricity, which included a contribution of 4% from offshore wind power.</p>
Hydro	<p>Hydropower is the largest renewable energy generation resource in the United States, providing nearly 8% of the electricity generated. Including pumped storage facilities, there are approximately 100,000 MW of current installed hydropower capacity in the United States.</p>

---

## 11.5 Argentina

The energy sector in Argentina, though subject to wholesale competition, remains largely dominated by a few large players. In recent years, the additional investment required to keep the power on has been shortcoming as result of market uncertainties, but plentiful natural gas as well as some new policy developments promise to buoy DE investments in the near future.

Argentinean Distributed Generation Policy by Technology and Type <sup>4</sup>		
Technical	DE in general	Ley 24065 guarantees access to the grid for generators including investors in DE. All generators must meet the same technical standards to participate in the power pool including reactive power, frequency control, etc., and must bear the cost of real-time metering equipment. <sup>5</sup>
	Large-scale cogeneration	Rules have been established to allow larger DE investors to take advantage of seasonal, weekly, and daily electricity markets (including spot markets) with the Argentine power pool, the Mercado Eléctrico Mayorista MEM, required to take and provide fair compensation for power fed into the grid.
	Domestic cogeneration	
	PV	
	Wind	
	Hydro	
Financial	DE in general	In Argentina, various supports are available for renewable energy sources including biofuels, solar, wind, hydro, and geothermal, among others.  At the local tax level, there are anticipated VAT refunds for the new depreciable property included in the project and accelerated income tax depreciation. The property used for the project will not be part of the minimum presumed income tax taxable base. In addition, biofuel producers will not be subject to the hydric infrastructure tax, the tax on liquid fuels, and the gasoil tax for the amount of fuel that is marketed in the national territory.  At the provincial level, there are real estate tax exemption, stamp tax exemption turnover tax exemption/deferral, and tax stability.  The type of benefit depends on the geographic area in which the renewable energy plant operates, so the plant's specific location must be supplied for a proper tax classification.  Subsidies at the national level are for wind: 0.015 Argentine peso (ARS)/kW h, for solar: 0.9 ARS/kW h, and for hydro for less than 30 MW installed capacity: 0.015 ARS/kW h, while for others: 0.015 ARS/kW h.  Several provinces have different incentive FiTs according to the kind of energy they want to promote.  There is also a quota obligation with the aim to reach a contribution of sources of renewable energy equal to 8% of the total national consumption of electric energy within a term of 10 years, starting in 2006, the effective date of the regime. <sup>3</sup>
	Large-scale cogeneration	
	Domestic cogeneration	

(Continued)

Argentinean Distributed Generation Policy by Technology and Type <sup>4</sup>		
	On-site PV	The PERMER project, cofinanced by World Bank, GEF, and local governments (national and provinces), promoted investment in solar panels for rural households and small public buildings. The project was closed on December 31, 2012, and is considered to be very successful.
	On-site wind	<p>Law 190/2006, passed in December 2006, introduced FiTs for wind. The FiTs, set in 2009, provide generation developers with \$5–\$10/MW h above the spot price on the wholesale energy market. As this FiT scheme failed, in 2009, the government established a state utility (ENARSA) to purchase at least 1 GW of renewable energy capacity. Renewable energy developers bid for power purchase agreements (PPAs) at fixed rates, guaranteed for 15 years. (GENREN program). The first PPAs were signed under GENREN in 2010. Seventeen wind farms with a combined capacity of 754 MW were awarded PPAs for prices between \$120 and \$134/MW h.</p> <p>The second stage of GENREN was established under Law 108/2011. It enables CAMMESA to sign sPPAs via ENARSA with renewable energy providers. Under this program, wind project owners will be paid around U.S. \$125/MW h for their power, guaranteed for 15 years.</p>
	Small hydro	FiT introduced by Law 160/2006 was also applicable for small-scale hydropower, and those may also be awarded under GENREN program.
Others	DE in general	<p>As a response to the economic situation of the country Law 26.190, Promotion of Renewable Sources of Energy for Electricity Production, has been passed on December 6, 2006.</p> <p>The new law includes financial incentives in terms of deferred tax payments and defined FiT premiums, but for a larger range of renewable technologies and with an entitlement period of 15 years. Thereafter, the Argentine government launched the GENREN program (Generación por Energías Renovables), another initiative to promote public–private investment in renewable energy. The state electricity company ENARSA (Argentine Energy, PLC, of the National Secretary of Energy) launched GENREN in 2009 in order to tackle the shortfall in energy supply, deal with organic waste (e.g., bagasse in the provinces of Tucumán and sawdust in Corrientes), reduce GHG emissions, and increase electricity access to rural areas (Río Negro, 2009). The initiative attracted unexpected interest from national and international investors, and before the end of 2009, more than half of the projects (49 in total) had been sold (Renou, 2009). It is predicted that, due to the low generation power of each individual project, the GENREN scheme will have an impact on both remote rural populations and people with low-energy demand.</p>

## 11.6 Brazil

Brazil has for a long time been a world leader in alcohol fuels, and some recent policy developments suggest that it may be well on its way to showing similar leadership in development of cogeneration. The plentiful biomass resources along with newly accessible supplies of onshore and offshore natural gas, combined with feed-in laws for renewables and gas-fired cogeneration, are likely to drive significant investment in DE in the near future.

Brazilian Distributed Generation Policy by Technology and Type		
Technical	DE in general	All DE plants including gas and biomass are guaranteed a market for surplus power based on law 10848.
	Large-scale cogeneration	On April 17, 2012, the Brazilian Federal Energy Regulatory Agency (ANEEL) enacted new rules aimed at reducing barriers for the incorporation of DPG (DG Regulation) into utility procurement and into Brazil's distribution planning processes. To achieve the goal of enabling production of renewable energy on a broad scale but without reliance on long-distance transmission lines, the DG Regulation establishes the following measures: A net metering program (Sistema de Compensação de Energia) allowing small-scale power production generators of 1 MW or less to offset their electricity bills with credits from the energy they provide to the grid. Ease the interconnection regulatory burden and improve grid integration for small-scale renewable energy production generators
	Domestic cogeneration	
	PV	
Financial	Wind	Although the DG Regulation covers other <i>incentivized</i> renewable energy sources such as wind and biomass, it was essentially designed to stimulate solar power generation. Brazil has made it clear that it wants to add solar energy generation to its energy mix at a fast pace. Since net metering might significantly spur consumer investment in solar without the need to construct new long distance transmission lines, it is not surprising that ANEEL released another resolution in conjunction with the DG Regulation that provides specific tax benefits for solar power deployment.
	Hydro	
	DE in general	Law 10848 guarantees DE systems access to the grid and are guaranteed the average price of the larger market.

**Brazilian Distributed Generation Policy by Technology and Type**

---

		<p>The PROINFA (Alternative Sources of Energy Incentive program) program implemented in 2002 and still ongoing, sought to establish 3300 MW from renewable energy (wind, biomass cogeneration, and microhydropower 1100 MW each) by 2007. Purchase contracts for qualifying facilities would have their contracts guaranteed by Eletrobras for 20 years.<sup>6</sup> Qualifying projects are also eligible for grants from the National Economic and Social Development Bank (BNDES). The <i>Luz para Todos</i> program aimed to subsidize the electrification of some 2.5 million households in Brazil by 2008, and there is a target to employ renewable energy for at least 200,000 of those households. Until today the program brought electricity to almost 12 million people, is still ongoing, and is now serving communities living in isolated areas.<sup>a</sup></p>
	Large-scale cogeneration	Biomass CHP plants are expected to benefit from the PROINFA program.
	Domestic cogeneration	
	On-site PV	ANEEL will increase the existing discounts in transmission and distribution system usage charges (TUST and TUSD, respectively) from 50% to 80% for qualifying solar systems up to 30 MW and those applicable up to the first 10 years of operation.
	On-site wind	
	Small hydro	
Others	DE in general	<p>In 2004, the Brazilian government passed law 10848 with regard to electricity sector reform. The law in effect created two separate market structures for electricity exchange: the bilateral contract environment (ACL), where individual generators and consumers can negotiate PPAs, and the regulated contract environment (ACR) where distribution companies must purchase the power they need to meet their contract from public auctions. The Decree 5163 dealt specifically with distributed generation, and states that in the ACR, scenario distribution companies must also buy power from <i>alternative sources</i> at prices set by the government and are permitted to buy up to 10% of their required supply. The clause was designed to create incentive for CHP and other designated alternative sources. The decree states specifically that cogeneration plants with an efficiency of over 75%, as well as hydro plants with a capacity below 30,000 kW and other renewable sources all qualify as <i>alternative energy</i> for the purposes of the law. The additional costs incurred by the grid owners are, by law, built into the formula used to calculate end-user tariffs.<sup>6</sup></p>

(Continued)

---

**Brazilian Distributed Generation Policy by Technology and Type**

---

The new law requires each distribution company to disclose 5 year plans for power supply and up to 10% of the supply needed to meet total loads can come from direct bilateral agreements with cogeneration plants instead of the typical power auctions.<sup>b</sup>

In addition, the revised auction structure is likely to favor cogeneration plants, because winning tenders for supply must have supply on line within 3 years—too short a lead time for most central plants.

Brazil has set a target of 3.3 GW of capacity from wind, biomass, and small hydro as a national target for 2007.<sup>7</sup> By early 2005, the first phase of PROINFA was completed and 3300 MW were completed (1266 MW Solar, 655 MW Biomass, 1379 Wind). Second phase of PROINFA is to reach 90% nationalization rate and a 10% Brazilian electrical energy annual consumption rate is to be supplied by renewable sources. Time frame for the second phase is 2009–2030.

## 11.7 Chile

Chile was the first nation in the world to break up vertically integrated monopolies into separate markets for generation and wires. Strong policy is still lacking to directly promote DE, which partly explains the lack of investment in the area. Gas shortages in the early 2000s in Chile have been creating somewhat of an energy crisis that should encourage gas conservation (and thus efficient gas cogeneration) but will likely reduce interest in gas-fired cogeneration in the near future. Other DE sources such as biomass and on-site renewables will likely gain added attention and perhaps policy support as a result. In 2013, certain investments were initiated but those are mostly to supply self-consumption, thus may not have significant effect on the energy sector.

Chilean Distributed Generation Policy by Technology and Type		
Technical	DE in general	The <i>Superintendencia de Electricidad y Combustibles</i> (Secretariat of Electricity and Fuels) sets and enforces the technical standards of the system. The Chilean Electricity Law guarantees open access to the transmission system, but must contribute to investment in the system. It is unclear if DE is included in the system.
	Large-scale cogeneration	
	Domestic cogeneration	
	PV	
	Wind	
Financial	Hydro	
	DE in general	In 2008, Chile enacted the Non-Conventional Renewable Energy (NCRE) Law number 20,257, which made it mandatory for electricity companies selling energy to final customers to assure that a minimum of 5% of the energy they sell comes from NCRE sources, directly or indirectly. This percentage will increase by 0.5% per year as from 2015 to reach 10% in 2024. The Chilean Economic Development Agency (CORFO) offers various incentives for investments in NCRE projects: Grants to fund preliminary preinvestment feasibility studies or specialized consultancy required before the materialization of NCRE projects that involve investments of more than U.S. \$400,000. The amount of the subsidy is up to 50% of the total cost of the study or consultancy with a cap of U.S. \$60,000 per project submission, and provided that it does not exceed 2% of the total estimated investment. The wind prospecting studies have a maximum subsidy of U.S. \$20,000 for monitoring in a point, or U.S. \$30,000 for two points. Grants to fund advanced preinvestment feasibility studies. The grant covers up to 50% of the total cost of the study or consultancy with a maximum of 5% of the estimated investment, provided that it does not exceed U.S. \$160,000 per project submission. This grant applies for projects that have been submitted to the preliminary processes and does not apply to studies measuring the availability of resources or for prefeasibility studies. During the second half of 2011, the Ministry of Energy implemented a fund to promote NCRE projects; specifically, it will finance instruments that will directly support initiatives of this type.
	Large-scale cogeneration	There are certain regulatory barriers of the commercialization of the energy surpluses. At present, there is no legal regulation for the sale of electricity surpluses, but a net metering law is under discussion in the Chilean congress in July 2013.
	Domestic cogeneration	
	On-site PV	No FiT exists, but PV investments are supported by CORFO, financing feasibility studies for projects. According to published forecasts, by 2016, installed solar capacity is expected to reach 1520 MW.

(Continued)

Chilean Distributed Generation Policy by Technology and Type		
	On-site wind	No FiT policy exists, but instead a long-term mechanism granting renewables priority access to the grid, together with a solid structure for long-term PPAs, serves as a financial incentive for wind investments.
Others	Small hydro	<p>The 1982 Energy Act law DFL N° 1 provided the legal foundation for separate generation, transmission, and distribution, including wholesale competition in the generation side.</p> <p>Smaller generators are not allowed representation on the Centro de Despacho Económico de Carga (Centre for Economic Load Dispatch) committees, which has raised some questions of fairness.<sup>a</sup></p> <p>The Chilean National Energy Commission (CNE) is responsible for implementing regulations outlined in Chile's General Electricity Services Law. It proposes regulated tariffs twice a year in April and October, and prepares the overall plan for new generation capacity. The SEC is responsible for ensuring all generators, distributors, and transmission operators are in compliance with the law.<sup>b</sup></p> <p>Chile is a participant in TECH4CDM project, developed over 2008 and 2009, and financed by the European Union under the Sixth Framework program of R&amp;D, with a primary goal, to promote renewable and efficient energy technologies, paying special attention to overcoming technological barriers, as well as the analysis of the Clean Development Mechanisms (CDM) of the Kyoto Protocol that may assist in projects based on wind energy, cogeneration, solar thermal, and rural electrification through renewable energies.</p> <p>Both European and Latin American institutions participate in the project, which is coordinated by the Spanish Institute for Energy Diversification and Saving (IDAE).<sup>c</sup></p> <p>Law 20.257 was published on April 1, 2008, and modified the LGSE (Ley General de Servicios Electricos/General Law on Electricity Services) with respect to power generation based on ENERC sources. The law states that companies trading electric energy on the grid, and have a installed capacity of more than 200 MWs, are obliged to verify annually: that a certain percentage of the total of their trade on the grid, originates from renewable and non conventional sources, either it is their own generation or from any contracted partner. This percentage is 5% between 2010 and 2014, and from 2015 that shall be increased gradually, 0.5% every year, until 10% is reached in 2024.</p>
	DE in general	
	Large-scale cogeneration	<p>The <i>Ley Corta</i> law also sets new efficiency standards, which may benefit cogeneration.<sup>d</sup></p> <p>According to the applicable laws, it can be stated that cogeneration is not differentiated from other conventional power generation. Furthermore, cogeneration plants can get access to the grid and sell the generated power if the installed capacity is higher than 9 MW. This hinders the access to the grid of the majority of the possible cogen plants, as most of them would be installed in the 0.1–5 MW range. This kind of regulations could not serve as a catalyst for improvement of this technology. On the other hand, the Chilean electricity policy made great efforts to promote the improvement of energy efficiency, where cogeneration could be an ideal alternative of the conventional power generation.</p>

## 11.8 Czech Republic

The Czech Republic's DE heritage remains largely as a leftover from the Soviet era. There is much existing cogeneration, especially in district heating applications, but much of it will be in need of refurbishment in the coming years. In the early 1990s, Czech Republic saw a boom in the development of smaller cogeneration plants and policy is now playing an important part in once again fostering cogeneration investment in the country. As an EU member, Czech Republic is bound to the EU legislation, which pushes on DE improvement.

Czech Distributed Generation Policy by Technology and Type <sup>a</sup>		
Technical	DE in general	
	Large-scale cogeneration	All DE systems are guaranteed <i>nondiscriminatory</i> access to the grid.
	Domestic cogeneration	A European standard for microcogeneration is currently being drafted under the auspices of Cenelec technical committee TC8X WG2. The standard has been worked out, implementation process is going on.
	PV	
	Wind	
Financial	Hydro	
	DE in general	All DE is guaranteed to be purchased by the utility. The rates depend on technology. In addition, distributed technologies are awarded an extra amount depending on what voltage level they are interconnected to.
	Large-scale cogeneration	Since January 1, 2006, a new support scheme has been introduced for CHP units, based on a feed-in premium on top of the market price of electricity for cogenerated electricity paid by network operators (distribution or transmission). The premiums are divided into three categories according to the installed electric capacity: up to 1 MWe, 1–5 MWe, and above 5 MWe. The premium is higher if producers sell electricity only in peak time. Producers can sell electricity to the market or use it themselves. The system of price regulation is controlled by the Energy Regulatory Office (not as state aid).

(Continued)

Czech Distributed Generation Policy by Technology and Type <sup>a</sup>		
Others	Domestic cogeneration	
	On-site PV	Currently a FiT of 21.91–58.44 cent (EUR)/MW h shall apply for PV power in the Czech Republic. <sup>a</sup>
	On-site wind	Currently, a FiT of 8.71–10.94 cent (EUR)/MW h shall apply for wind power in the Czech Republic. <sup>b</sup>
	Small hydro	Currently, a FiT of 7.46–11.95 cent (EUR)/MW h shall apply for small hydro power in the Czech Republic. <sup>c</sup>
	DE in general	Currently, the utility CEZ holds about two-thirds of the generation market in the republic and also owns a majority stake in six of the eight existing distribution companies. The government-owned CEPS operates the transmission system.
	Renewables in general	<p>March/April 2005 law passed to promote renewables. Sets out an 8% target of total gross consumption by 2010 and 13% by 2020. Guarantees 15 years of FiT for renewables, a premium for green electricity will also be paid. Prices are not set in law but are to be determined by the Energy Regulatory office.<sup>d</sup></p> <p>The EU and the Czech government provide special incentives for biogas plant projects in the Czech Republic. One of the main reasons is that the carbon dioxide emissions per capita are rather high compared to other countries. Czech farmers receive financial support for the establishment of biogas plants from an EU environmental fund and an EU rural development fund. By 2015, biomass is to become the Czech Republic's primary source of renewable energy.</p> <p>Since 2005, the feed-in law for decentralized eco-power has resulted in an increase in the energy production from regenerative sources. In 2010, a share of about 10% of the energy was already produced from alternative sources, compared to only 4% in 2008.<sup>e</sup></p>
	Large-scale cogeneration	The Czech Republic is bound by the EU cogeneration Directive 2004/8/EC, which states that member states are obliged to address key market barriers such as ensuring grid access for cogeneration. The directive also states that in order for cogeneration to be considered high efficiency, it must provide an energy saving of at least 10% compared to separate production of heat and power. Czech Republic is also bound to EU Directive 2012/27/EU, which set as a target to strengthen the regulations of Directive 2004/8/EC, and ordered member states to complete until December 31, 2015, the evaluation of the feasibility potential of high efficiency cogeneration and efficient district heating/cooling.

## 11.9 Denmark

Denmark is one of the world's leading renewable energy champions and has had strong policy in support of renewables longer than most countries. Furthermore, Denmark is one of the few countries with policies established to specifically encourage wind cooperatives. Denmark is also one of the world's leaders in cogeneration. Despite its strong track record in DE, there is still much room for improvement and the evolution of Denmark's policy on DE reflects this. Economic competitiveness and energy security could prove to be the most important drivers for DE along with environmental concerns.

Danish Distributed Generation Policy by Technology and Type		
Technical	DE in general	
	Large-scale cogeneration	
	Domestic cogeneration	A European standard for microcogeneration is currently being drafted under the auspices of Cenelec technical committee TC8X WG2. The standard has been worked out, implementation process is going on.
	PV	
	Wind	
Financial	Hydro	
	DE in general	Denmark established the first feed-in law requiring utilities to buy electricity from onsite renewable generators at a set price in 1999.  Currently, Denmark does not have a coherent FiT scheme. Biogas finds one solution, onshore wind a second that may be quite different from offshore. For PV, the net metering principle is the rule. The tariff for wind energy in Denmark depends on several variables: <ul style="list-style-type: none"> <li>• On which year the turbine went into operation</li> <li>• How many full-load hours they already delivered</li> <li>• Whether they are offshore or onshore</li> </ul> The tariff comprises a market power price element, power balance compensation, and a government subsidy. There is no governmental support for fossil fuel CHP.
	Large-scale cogeneration	A state subsidy for small cogeneration was introduced in 1992 for all plants fuelled by waste incineration, natural gas, and renewables. At the start of the program, the tariff was 10 øre/kW h but was subsequently reduced to 7 øre/kW h, for all but plants smaller than 3 MW. <sup>3</sup>  In 2005, Denmark updated the way it provides incentive for CHP, whereas before distribution companies were obligated to purchase all power from CHP facilities via a FiT, the FiT has been phased out with the 2005 market reforms to better reflect free market principles. Now CHP plants are guaranteed the right to sell power to the grid but only if they can find interested buyers.  According to a recent decision, in late 2018, state subsidies will be removed.
	Domestic cogeneration	
	On-site PV	

(Continued)

Danish Distributed Generation Policy by Technology and Type		
	On-site wind	<p>New wind turbines as well onshore as offshore receive a price premium of 3.3 cent (EUR)/kW h for 22,000 full-load hours. Additional 0.3 cent (EUR)/kW h in the entire lifetime of the turbine to compensate for the cost of balancing, etc. Household wind turbines below 25 kW receive a fixed FiT of 8 cent (EUR)/kW h.</p> <p>For special wind parks at sea, the support is settled by a tendering procedure. In previous tenders, the Horns Rev II wind park of 200 MW ended at a fixed FiT of 6.9 cent (EUR)/kW h in 50,000 full-load hours, while the Rødsand II wind park in the Baltic Sea of 200 MW ended at a fixed tariff of €8.4/kW h for 50,000 full-load hours.</p> <p>The replacement scheme for wind turbines on land is very complicated. A scrapping certificate can be earned by replacing old and inappropriately situated wind turbines with new and more efficient turbines. This grants the right to an extra price supplement. The energy policy agreement of March 2004 on wind energy and decentralized CHP is the background for the scrapping scheme. The scrapping scheme provides an extra price supplement to new onshore wind turbines, provided the owner has a scrapping certificate for a wind turbine with an installed capacity of 450 kW or less, which was decommissioned in the period December 15, 2004 to December 15, 2010.</p> <p>A price supplement of 1.6 cent (EUR)/kW h is granted for electricity production corresponding to 12,000 full-load hours for double the installed capacity of the decommissioned wind turbine. However, the total amount of payment should not exceed 6.4 cent (EUR)/kW h; then the price supplement will be reduced.<sup>a</sup></p>
	Small hydro DE in general	<p>Denmark is the most energy-efficient country in the world, and also considered the leader in the co-gen sector, with about 55% of its total energy use coming from cogeneration.</p> <p>Energy liberalization began in 1996 in Denmark and as of 2003, all electricity customers are free to choose their supplier. Denmark's overall goal is to increase its share of renewables from 8% in 1996 to 30% in 2025.<sup>b</sup> Municipal waste and geothermal energy receive special mention in the plan. Denmark has introduced a demand-side RPS: all customers must source at least 20% of their electricity from certified renewables sources.<sup>c</sup></p>
Others	Large-scale cogeneration	<p>The Danish Energy Authority and two main utilities have developed a research and development strategy for a range of renewable energies including fuel cells, biomass, wind energy, and photovoltaics. Strategies for biofuels, wave energy, hydrogen, and system integration are being developed. The 1988 Heat Supply Act encourages renewable fuelled district heating using by prohibiting electric heating in specified residential areas.</p> <p>Denmark is bound by the EU cogeneration Directive 2004/8/EC, which states that member states are obliged to address key market barriers such as ensuring grid access for cogeneration. The directive also states that in order for cogeneration to be considered high efficiency, it must provide an energy saving of at least 10% compared to separate production of heat and power.</p>

## 11.10 Germany

Germany is one of the world's leaders in renewables with especially strong growth over the last decade. There is evidence that the German policy makers continue to work at creating the right policy environment for DE to thrive. Nevertheless, there is still much unrealized potential especially for small on-site renewable applications and cogeneration, whereas most policies to date have focused on larger-scale, often remote, renewables. Climate change negotiations and security of supply concerns will continue to be the key drivers for DE in the coming years.

Germany already gets 25% of its electricity from renewable sources and is headed for 80% by 2050.

---

**German Distributed Generation Policy by Technology and Type**

---

Technical	DE in general	The federal Ministry of Education and Research heads up a program aimed at integrating DE successfully into networks. Federal states also undertake their own research funding.
	Large-scale cogeneration	
	Domestic cogeneration	A European standard for microcogeneration is currently being drafted under the auspices of Cenelec technical committee TC8X WG2. The standard has been worked out, and implementation process is going on. Germany is also developing their own regulations for the installation of microcogeneration.
	PV	
	Wind	
	Hydro	
	Biomass	

(Continued)

German Distributed Generation Policy by Technology and Type		
Financial	DE in general	By 2013, the German government has allocated a €750 million budget to underpin its objective of raising the market share of CHP installations to 25% by 2020. <sup>a</sup>
	Large-scale cogeneration	<p>To obtain tax relief, operators need to prove that the efficiency level of the CHP plant exceeds 70%.</p> <p>According to current rules (valid up to 2020), operators of bigger plants are entitled for proportional compensation, whereby they get 5.41 cent for the first 50 kW; 4 cent for the next 200 kW, 2.41 cent for the next 1750 kW; and 1.8 cent for the exceeding power capacity.</p> <p>If the plant is subject to the EU emission trading rules, operators can claim for 2.1 cent/kW h.</p> <p>MiniCHP (≤50 kW) operators can opt for 30,000 full operation hours support.</p> <p>A new class of small-scale of CHP plant between 50 and 250 kW has also been introduced.<sup>b</sup></p>
	Domestic cogeneration	<p>German FiTs for the generation of electricity from renewable sources, under the Act on Granting Priority to Renewable Energy Sources (<i>the EEG</i>)—accepted in 2012, are entering their third phase of existence.</p> <p>In Phase One (2000–2009), Germany focused on scaling up domestic renewable electricity generation. During Phase Two (2009–2011), rapid declines in the cost of solar PV modules prompted Germany to more actively adjust its PVFIT in order to manage the volume of annual PV installations under its FiT programs (e.g., linking FiT degenerations for PV to the volume of PV installations in previous periods and reviewing the PV policy more frequently).</p> <p>In Phase Three (2012–), continued cost declines are making solar PV, wind, and biomass increasingly competitive with traditional sources of electricity; in response, the key elements of Germany's 2012 EEG—including reduced FiT payments, a market premium option, a 90% cap on FiT-eligible PV electricity, and addition of a 52 GW PV capacity threshold—all mark an evolution of German FiTs toward a <i>grid parity</i> future where policy is more flexible and may offer less TLC (Transparency, Longevity, Certainty) to investors.<sup>c</sup></p> <p>However, FiTs are dropped in 2013 compared to 2012, no retroactive effect on existing facilities.</p>
	Renewables in general	
	On-site PV	FiT rates for PV electricity vary depending on the size and locations of the systems. Since 2009, there are additional tariffs for electricity immediately consumed rather than supplied to the grid with increasing returns if more than 30% of overall production is consumed on-site. This is to incentivize a demand side management and help develop solutions to the intermittency of solar power. Duration of tariff is usually 20 calendar years plus the year of installation. Systems receive the tariff in effect at the time of installation for the entire duration.

	On-site wind	<p><b>Onshore FiTs</b></p> <p>According to the EEG, the initial tariff of 8.8 cents (EUR)/kW h is paid for at least 5 years. This period is extended according to location and reference yield. Thereafter, the final tariff of 4.8 cents (EUR)/kW h is paid for the time remaining.</p> <p>The law also provides bonuses of 0.47 cents (EUR)/kW h for improved network integration and 0.49 cents (EUR)/kW h for wind energy facility repowering. For installations commissioned in the subsequent calendar years, the tariffs and bonuses will be reduced degressively each year by 1.5%.</p> <p><b>Offshore FiTs</b></p> <p>The initial 20-year long guaranteed EEG FiT is equivalent to 15 cents (EUR) for the first 12 years or 19 cents (EUR) for the first 8 years and extended subject to location. The larger the water depth of the wind turbine and the further from shore it is located, the longer the higher initial tariff compensation paid level. Thereafter, the sum payable amounts to 3.5 cents (EUR)/kW h. The annual percentage degression for tariffs and bonuses for electricity generated from offshore wind installations shall be 7% from the year 2018 onward (commissioning date).<sup>d</sup></p>
	Small hydro	<p>Rates are depending on the share of capacity of the plant and differing for existing and newly built facilities. A yearly degression of 1.0% shall apply.<sup>e</sup></p>
Others	DE in general	<p>The German government has played a lead role in the renewable energy policy network an international policy network arising from the Bonn 2004 renewable energy conference.<sup>9</sup> Disclosure law states that all generators must state generation portfolio including cogeneration and renewables. In September 2010, the federal government adopted the Energy Concept, a comprehensive new strategy for a long-term integrated energy pathway to 2050. Following Fukushima accident, Germany plans to close all of its nuclear power plants by 2022. This decision resulted in the adoption of a suite of new policy measures and determined renewable energy as the cornerstone of future energy supply, a set of policy instruments commonly known as the Energiewende.</p> <p>Presently 25% of electricity is from renewable sources and Germany set up a plan to reach 80% by 2050.</p> <p>In 2008, new CHP Law has been published in Germany. The changes entered into effect from August 21, 2009. The changes mainly concerned the clarification that belong to the eligible consumers leaving the heat network law to accelerate the development of high voltage electricity network</p>

**German Distributed Generation Policy by Technology and Type**

---

	The main support for CHP in Germany is a stepped FiT in which the first kW h generated in a given year are rewarded at a higher level than subsequent generation. The result of such a mechanism is that fixed costs can be accounted for during the initial run time, and therefore, the investment presents less of a risk for developers. The model used here is unable to reflect the value of this FiT design as it smoothes value over total annual generation.
Large-scale cogeneration	During the process of electricity market restructuring in Germany, the main goal with respect to CHP was to maintain the existing capacity and renovate existing plant. Germany is bound by the EU cogeneration Directive 2004/8/EC, which states that member states are obliged to address key market barriers such as ensuring grid access for cogeneration. The directive also states that in order for cogeneration to be considered high efficiency, it must provide an energy saving of at least 10% compared to separate production of heat and power. Germany is also bound to EU Directive 2012/27/EU, which set as a target to strengthen the regulations of Directive 2004/8/EC, and ordered member states to complete by December 31, 2015, the evaluation of the feasibility potential of high efficiency cogeneration and efficient district heating/cooling.
Domestic cogeneration	
PV	As a result of the earlier improvements, on June 16, 2013, 60% of the total electricity supply was produced by PV and wind plants.
Wind	As a result of the earlier improvements, on June 16, 2013, 60% of the total electricity supply was produced by PV and wind plants.
Hydro	At The 2004 Renewable Energy Conference in Bonn, Germany announced its Mini-Hydro Programme. <sup>10</sup>

### 11.11 Hungary

The majority of Hungary's existing DE capacity is in the form of district heating applications, though many have already reached the end of their life. However, in the past 6 years, some new installments have been connected to the grid. Due to recent regulatory decisions, the proportion of cogeneration in the total national generation has fallen down from 20.9% in 2010 to 10% in the first half of 2013, whereas, pursuant to the latest EU regulations,

member states should elaborate long-term national plans on the possible ways to improve cogeneration and on the conceptions of the subsidies thereto.

Hungarian Distributed Generation Policy by Technology and Type		
Technical	DE in general	However, technical requirements of grid connections are clearly set out; in certain cases, DSOs may hinder the connection by their noncooperative behavior.
	Large-scale cogeneration	
	Domestic cogeneration	A European standard for microcogeneration is currently being drafted under the auspices of Cenelec technical committee TC8X WG2. The standard has been worked out; implementation process is going on.
	PV Wind Hydro	
Financial	DE in general	Pursuant to the Electricity Act (86 of 2007) and the Governments Decree nr. 389/2007 (XII.23), the Hungarian Energy and Public Utility Regulatory Authority (HEPURA) has the right and is obliged to publish until the 7th workday of December every year, the applicable FiTs for the subsequent year. Tariffs shall be adjusted by the average of the yearly consumer price index.
	Large-scale cogeneration	HEPURA publishes tariffs for cogeneration in eight categories. Rates depend on the combination of installed capacity, usage of the generated heat, and the type of the permission issued to the power plant.
	Domestic cogeneration	Domestic generators have free access to the grid; DSOs shall grant free and nondiscriminatory access. Very few programs are existing to support domestic generation; thus low FiTs, long return periods, do not promote such kind of investments.
	On-site PV On-site wind Small hydro	
Others	DE in general	In 2012, the government published its new National Energy Strategy until 2030. Aim of the strategy is to increase the proportion of renewable energy within primary energy use from 7% (in 2012) to 20% until 2030—with an interim proportion of 14.56% until 2020. Among renewable, biogas and biomass CHPs and technologies using thermal energy shall have priority. The strategy also states that in order to define directions of district heating and combined generation development, a district heating action plan has to be elaborated; furthermore, improvement of the level of supply shall not be delayed any more.  The strategy is partly in line with the effective European goals, as the EU, however, earlier established goals until 2010 could not be fulfilled by the members states, is still committed to keep the 20% ratio of renewable energy use within the entire consumption until 2020.

## 11.12 Portugal

After joining the EU in 1986, Portugal's economy grew steadily. However, since the financial crisis, Portugal is continuously listed between the critical financial status countries. Nevertheless in the first quarter of 2013, Portugal had recorded green power production.

Portuguese Distributed Generation Policy by Technology and Type		
Technical	DE in general	However, free access to the grid is secured by the law to any suppliers, TSOs and DSOs have hindering practice of refusing access to the grid with the reason of security of the transmission and distribution system.
	Large-scale cogeneration	
	Domestic cogeneration	A European standard for microcogeneration is currently being drafted under the auspices of Cenelec Technical Committee TC8X WG2. The standard has been worked out; implementation process is going on.
	PV	
	Wind	
	Hydro	
Financial	DE in general	In Portugal, the generation of electricity from renewable energy sources is mainly promoted through a guaranteed FiT. Operators of renewable energy plants are contractually entitled against the grid operator to payment for electricity exported to the grid. (The grid operator is obliged to enter into a contract on the purchase of electricity at a price set by law). There is also a regime for micro- and a miniproduction units, which is also under review and had a few changes recently introduced by DL 25/2013.  The guaranteed FiT, which is calculated by a formula, is the only means of promotion. The calculation is based on various factors like plants' output and capacity. The formulas and payment rates for some technologies have been revised in 2007.

(Continued)

Portuguese Distributed Generation Policy by Technology and Type	
	<p>There are individual tariffs for electricity generated from renewable sources by so-called microproduction units and for electricity combined with heating systems.</p> <p>Microproduction units are installations that use a single production technology and have a single-phase or three-phase load operating at a low voltage, and a capacity of no more than 5.75 kW solar energy installations, wind power plants, hydroelectric power plants, or biomass-fuelled CHP plants whose capacity is &lt;3.68 kW are eligible for a special tariff. The operators of microproduction units receive the special tariff for 15 years.</p>
Large-scale cogeneration	Cogenerated electricity exported to the grid benefits from FiTs. These FiTs are applied for a period of 10 years and it is indexed to the price of oil, to reduce fuel-price risks. As the price of oil rises, so will the FiT for cogenerated electricity.
Domestic cogeneration	Micro-CHP in Portugal benefits from a higher level of support than larger cogeneration.
On-site PV	FiTs for mini (3.68 kW) PV generators in 2013: 0.196 EUR/kW h for the first 8 years and 0.165 EUR/kW h for the following 7 years (FIT granted for total of 15 years); FiTs for micro (3–68 kW—20 kW) PV generators in 2013: 0.151 EUR/kW h for a period of 15 years.
On-site wind	<p>In comparison, these tariffs are 30% lower than the previous year's tariffs.</p> <p>In case of micro-and miniproduction units, the producer receives a tariff based on the reference tariff in place at the time of the issuance of the certification of exploitation.</p> <p>Microproduction units: in general, the reference tariff in 2013 is €272/MW h for the first period of 8 years and €150/MW h for the second period of 7 years.</p> <p>Miniproduction units: in general, the reference tariff in 2013 is €185/MW h:</p> <p>Microproduction unit: 80% of the reference tariff</p> <p>Miniproduction unit: 80% of the reference tariff</p>
Small hydro	
Others	<p>DE in general</p> <p>Decree-law 23/2010 transposes into Portuguese Law Directive 2004/8/CE on the promotion of cogeneration.</p> <p>Decree-Law 34/2011, called the Mini Production Law, regulates the production of electricity from renewable energy sources in small units of less or equal to 250 kW, utilizing only one type of technology and excluding the microproduction, cogeneration units and innovation and proof of concept systems. ESCOs are allowed to apply to this law. The regulation simplifies the licensing regime through the new SRMini electronic platform managed by DGEG. Any entity that has a contract for purchasing electricity with a relevant consumption of electricity can apply to this law, provided that injected power does not exceed 50% of the contracted power. The law included two types of FiT systems for the remuneration of renewable electricity. First, the general regime whereby the tariff depends on the conditions of the market and no special tariff is applied. Second, the <i>bonafide tariff</i>, where a special reference tariff of EUR 250/MW h is provided for systems below 20 kW. As for systems larger than 20 kW, a tender process is used to select the systems that offer better discount against the reference tariff. An annual ceiling of 50 MW is used for the Bonified Regime. The Bonified Regime is also dependent on the realization of energy efficient audits in the place of the installation and implementation of the suggested energy efficiency measures. Annually 1% of the registered installations will be fiscalized.</p>

Large-scale cogeneration	Portugal is bound by the EU cogeneration Directive 2004/8/EC, which states that member states are obliged to address key market barriers such as ensuring grid access for cogeneration. The directive also states that in order for cogeneration to be considered high efficiency, it must provide an energy saving of at least 10% compared to separate production of heat and power. Portugal is also bound to EU Directive 2012/27/EU, which set as a target to strengthen the regulations of Directive 2004/8/EC, and ordered member states to complete by December 31, 2015, the evaluation of the feasibility potential of high efficiency cogeneration and efficient district heating/cooling.
Domestic generation	An annual quota of 25 MW was implemented in the microgeneration segment (up to 3.68 kW inverter capacity), which represents approximately the requested capacity. In 2012, the capacity was lowered to 10 MW.
PV	Limitation in microgeneration segment created serious problems for the PV sector, as it is below the demand for licenses. The main barrier is the application of technical rules, which creates high costs for the change of the grid connection.  Nevertheless each consumer can install a system with a capacity of 50% of the capacity contracted for consumption. The production capacity is limited to 25% of the medium voltage transformer capacity.

### 11.13 United Kingdom

The United Kingdom was the first in Europe to experiment with competitive electricity markets, and some DE investment arose as a direct result of that policy. Like other European nations, key DE drivers in the near future for the U.K. remain climate change and energy security. The United Kingdom has pioneered some interesting policy in defining high-quality cogeneration, but there is much more room for policy reform to spur investment in DE to meet environmental and national security objectives.

British Distributed Generation Policy by Technology and Type		
	Domestic cogeneration	A European standard for microcogeneration is currently being drafted under the auspices of Cenelec Technical Committee TC8X WG2. The standard has been worked out; implementation process is going on. The United Kingdom has also developed changes in legislation, and published Engineering Recommendations in this area. <sup>a</sup>
	PV	Grid interconnection of PV systems is governed by G.59/2. Latest version is 3.4, issued in January 2013.
	Wind	Grid interconnection of wind systems is governed by G.59/3. Latest version is 3.4, issued in January 2013.
	Hydro	Grid interconnection of hydropower systems is governed by G.59/2. Latest version is 3.4, issued in January 2013.
Financial	DE in general	<p>The Climate Change Levy is a tax on energy introduced in 2001. All businesses have to pay 0.456 p/kW h unless the producer has a Levy Exemption Certificate.</p> <p>A Carbon Price Floor, from April 1, 2013, has been introduced and is applied as a levy for electricity generators based on the carbon content of each fuel type. Such supplies are charged at the relevant carbon price support rate depending on the type of fossil fuel used, which is determined by the average carbon content of each fossil fuel equivalent to GBP4.94/tCO<sub>2</sub> for 2013–2014. Proposed rates for 2014–2015 and 2015–2016 are GBP7.28/tCO<sub>2</sub> and GBP9.86/tCO<sub>2</sub>.<sup>b</sup></p> <p>The U.K. government announced details of reforms to the U.K. market in late June 2011. Key features of the paper included</p> <ul style="list-style-type: none"> <li>• Introduction of a two-way FiT with Contracts for Difference for each low-carbon generation technology, likely to replace the Renewable Obligation Scheme by 2017</li> <li>• Disincentives on fossil fuel generators such as the Carbon Price Floor (a proposal that the effective price of carbon should be GBP70/tCO<sub>2</sub> in 2020) and an Emissions Performance Standard (EPS) (set at 450 g CO<sub>2</sub>/kW h).</li> </ul>
	Large-scale cogeneration	<p>EU Emissions trading scheme will have an uncertain effect on cogeneration investment. Cogeneration schemes that have been certified as <i>good quality</i> (see the following) are exempt from the climate change levy.</p> <p>From April 2009 under the U.K. renewables Obligation (RO), electricity generated by Good-Quality CHP fuelled by biomass is eligible for additional renewables Obligation Certificates (ROCs) for each MW h of renewable electricity generated. As a rule, revisions to the RO have aimed to award CHP generators with a premium of 0.5 ROCs per MW h over power-only plants, except in the case of so-called Advanced Conversion Technologies, where there is no marginal incentive. In addition, grants for capital purchases of biomass-fuelled heat-only or CHP equipment have been made available through the Bioenergy capital grants scheme run by the U.K. Department for Environment, Food and Rural Affairs (Defra).<sup>c</sup></p>

(Continued)

British Distributed Generation Policy by Technology and Type	
Domestic cogeneration	FiTs are available for small-scale, low-carbon electricity generated by private/business users (maximum capacity 5 MW) providing payment of up to 41.3 p/kW h generated (depending on the type and size of the system used to generate renewable energy) plus a guaranteed 3 p/kW h sold on to the U.K. electricity grid. Typically, the tariffs last for 20 years (the exception is the Solar PV tariff, which currently lasts for 25 years). <sup>d</sup>
On-site PV	Exempt from climate change levy. Each MW h generated via renewable energy also creates a tradable <i>Renewable Obligation Credit</i> , which can be sold on the market to generators who have not reached their legal obligation to generate every-time prescribed volume of their output from renewable. VAT on PV installations systems has been set at the reduced rate of 5% since April 2000. In February 2012, the U.K. government reduced the FiT from 41.3 to 21 p/kW h and stipulated an efficiency requirement for Solar PV schemes registered after March 2012.
On-site wind	Exempt from climate change levy. Each MW h generated via renewable energy also creates a tradable <i>Renewable Obligation Credit</i> , which can be sold on the market to generators who have not reached their legal obligation to generate every-time prescribed volume of their output from renewable.
Small hydro	Exempt from climate change levy. Each MW h generated via renewable energy also creates a tradable <i>Renewable Obligation Credit</i> , which can be sold on the market to generators who have not reached their legal obligation to generate every-time prescribed volume of their output from renewable.
Others	<p>DE in general</p> <p>Generating electricity from renewable and energy-efficient sources is a key part of the British Government's strategy to tackle climate change.</p> <p>The 2009 Renewable Energy Directive sets a target for the United Kingdom to achieve 15% of its energy consumption from renewable sources by 2020, implying substantial growth in distributed generation and investment in the network infrastructure.</p> <p>Many stakeholders have expressed concern that the government's targets may not be met because of major difficulties relating to unit pricing, delays in obtaining planning consent and the fact that the current regulatory framework does not incentivize DNOs to connect distributed generation.</p> <p>Large-scale cogeneration</p> <p>The United Kingdom is bound by the EU cogeneration Directive 2004/8/EC, which states that member states are obliged to address key market barriers such as ensuring grid access for cogeneration. The directive also states that in order for cogeneration to be considered high efficiency, it must provide an energy saving of at least 10% compared to separate production of heat and power. The United Kingdom is also bound to EU Directive 2012/27/EU, which set as a target to strengthen the regulations of Directive 2004/8/EC, and ordered member states to complete by December 31, 2015, the evaluation of the feasibility potential of high efficiency cogeneration and efficient district heating/cooling.</p>

---

Nevertheless, the U.K.'s own model for defining cogeneration deserves mention.

The United Kingdom has established a cogeneration quality assurance scheme,<sup>e</sup> a voluntary methodology for determining which arrangements or projects can be defined as cogeneration and which are therefore eligible for cogeneration incentives and financial support. The scheme assesses cogeneration projects using two thresholds. The power efficiency threshold states that when a project's power efficiency is greater than 20%, then all fuel used in the project is *good quality*. The second threshold, the quality index threshold, considers both power and heat efficiency, which encourages good environmental practice. Though complex, the cogeneration QA scheme is robust in its consideration of technologies and fuels.

## 11.14 China

Market potential for DE in China is enormous, but clear policies will be required in order for it to be realized. Demand for electricity has been growing at rates and scales that dwarf those of Europe and North America. China has issued a series of policies to promote CHP/DHC. As a result, China has become the second-largest country in terms of installed CHP capacity, and now installed capacity exceeds 100 GW and getting very close to 200 GW. Increasingly, high electricity prices, rotating blackouts, coal shortages, emerging gas availability, and the growing appeal of renewables for their environmental benefits are all factors that will drive Chinese investment in DE. Policies to promote renewables have recently had a high profile, but other forms of DE still require attention. International climate change negotiations may also rise in influence in Chinese energy policy.

Chinese Distributed Generation Policy by Technology and Type		
Financial	DE in general	<p>With the Renewable Energy Law as revised in April 2010, the State Bureau of Energy and other departments of the State Council will promulgate guidelines on the full purchase of electricity generated by new energies. According to the revised law, the price of on-grid electricity generated by renewable energies shall be determined by the competent price department of the State Council. The council will consider the difference in areas and the electricity generated by different types of renewable energy companies.</p> <p>In China, some financial funds and financial subsidies are available for renewable energy projects and for energy conservation technologies improvement.</p> <p>A reduced corporate income tax rate of 15% is given for qualified advanced and new technology enterprises. Applicable fields include solar energy, wind energy, biomaterial energy, and geothermal energy.</p>
	Large-scale cogeneration	Throughout the 1990s, the government provides capital grants and tax benefits for cogeneration, but the program has since been withdrawn.
	Domestic cogeneration	
	On-site PV	<p>In March 2009, the China government introduced the <i>Solar Roofs Plan</i> for promoting the application of solar PV building. The Ministry of Finance in July of the same year re-introduced the <i>Golden Sun Project</i> with more specific details of the related policy. The policy provides that for the grid-connected photovoltaic power generation project and its supporting transmission and distribution system, the state will provide subsidies of 50% of the total investment. The subsidy will rise to 70% for solar power systems in remote areas that are not currently connected to the grid. Projects with a minimum capacity of 500 MW would be eligible for the related incentive.</p> <p>The corporate income tax reduction shall also be applied.</p>
	On-site wind	Wind projects currently receive a 50% reduction in sales tax as well as corporate and income tax.
Others	Small hydro	
	DE in general	<p>From 2008 to January 2012, China held the top spot in clean energy investment. The Renewable Energy Law passed in 2005 explicitly states in its first chapter that the development and the usage of renewable energy is a prioritized area in energy development. Detailed incentive policies and programs include Golden Sun program providing financial subsidies, technology support, and market incentives to facilitate the development of solar power industry; the suggestions on promoting wind electricity industry in 2006 offering preferential policies for wind power development; and many other policies. Besides promoting policies, China has enacted a number of other policies to standardize renewable energy products, to prevent environmental damage, and to regulate price of green energy. These policies include, but are not limited to, Renewable Energy Law, Safety Regulations of Hydropower Dams, and National Standard of Solar Water Heater.</p> <p>The Twelfth Five-Year Plan, the current plan, also gives great emphasis on green energy. According to the plan, China will build up microgrid demonstration zones in areas redundant of solar and wind power. Meanwhile, China will push forward the construction of 100 new energy demonstration cities. National Energy Administration proposed that up to 2020, China will promote the use of distributed generation systems all over the country with the installed capacity to hit 50 GW. Besides, China plans to build 10 distributed energy demonstration zones of various characteristics.</p>

(Continued)

---

**Chinese Distributed Generation Policy by Technology and Type**

---

Large-scale cogeneration	<p>Besides the aggressive growth of energy need, China is committed to reduce its emission, but renewable sources will not be able to keep up with the needs, large-scale cogeneration shall have an important role in securing China's need for energy and in avoiding energy shortages in the next years. Coal-fired plants still will have a significant role; the aim is to reduce participation of such kind of plants in power generation.</p> <p>However, earlier gas-fired power plants were traditionally used in offshore oil drilling platforms, or as peak load power plants; in recent years, a strong trend toward gas-fired power plants as a main electricity and heat resource has been recorded.</p> <p>In 2011, gas-fired power plant capacity reached 33 GW: a growth of 24% compared with 2010. By 2015, the installed capacity of gas-fired power plants will reach at least 60 GW, implying a compound annual growth rate of around 20%.</p> <p>District heating is also expected to drive considerable growth in gas-fired equipment demand. As of 2010, district heating with CHP supplies over a third of total construction areas in northern cities and towns, the rest being heat-only boiler stations fuelled by coal or natural gas. To reduce energy waste and pollution caused by coal-fired localized boilers and improve energy efficiency, cities including Beijing, Tianjin, and Taiyuan have planned to restrict new heat plants to gas-fired only. As shown in currently released plans, new heating plants in these areas have all adopted gas-fired cogeneration.</p>
Domestic cogeneration	
PV	<p>According to plans unveiled by the National Development and Reform Commission in 2007, the country's installed solar capacity was to grow to 1800 MW by 2020. Due to recent developments in May 2011, the National People's Congress (NPC) set 5 GW as an official minimum PV target for 2015, with a longer-term target of 20–30 GW by 2020.</p> <p>Topping the plan only in 2012, China added 5.0 GW of panels, bringing installed capacity to 8300 MW and, in 2013, may add 6.8 GW.</p> <p>According to the European Photovoltaic Industry Association, the total installed capacity could grow from 47 to 66 GW by 2017!</p>
Wind	<p>In 2012, Chinese wind power plants generated 100.8 billion kW h of wind power, compared with 71.5 billion kW h in 2011, according to the data of the National Energy Administration. Total grid-connected installed capacity increased 31% to 62.7 GW from 47.9 GW in 2011.</p> <p>The goal is to install 100 GW of grid-connected wind farms by 2015 and to generate 190 billion kW h of power.</p> <p>Wind energy has become the Asian nation's third-biggest energy resource, following coal and hydropower, and accounts for about 2% of total electricity, according to data from China's State Electricity Regulatory Commission.</p>
Hydro	<p>By 2015, China's hydropower installations are targeted to reach around 325 GW, and to reach 430 GW (up from 380 GW) by 2020. As part of this project in July 2013, the second largest hydropower plant started the operation with one turbine of a capacity of 770,000 kW. Total capacity of the plant will be 13.86 GW when all of its 18 units go into operation in 2014.</p>

---

## 11.15 India

India is sure to be a major market for DE in the coming years given its large population and the urgent need for investment in the power sector in order to meet growing demand for power. The blackout in July 2012 leaving 700 million people without power demonstrated the inefficiency of Indian power generation and the vulnerability of centralized supply compared to decentralized generation. Recently, upcoming possibility of LNG trade with the United States might also have a catalytic effect on future DE improvements.

Indian Distributed Generation Policy by Technology and Type		
Technical	DE in general	According to Section 7 of Electricity Act: "Any generating company may establish, operate and maintain a generating station without obtaining a licence under this Act if it complies with the technical standards relating to connectivity with the grid ..."
	Large-scale cogeneration	
	Domestic cogeneration	
	PV	
	Wind	
	Hydro	To set up a hydrogenerating station, a scheme with a prescribed content shall be prepared and filed into the controlling authority for concurrence.
Financial	DE in general	<p>In India, various supports and subsidies exist to help improving DE. Foreign direct investment (<i>FDI</i>) is permitted up to 100% in the sector under the automatic route in Renewable Energy Generation and Distribution projects subject to the provisions of the Electricity Act. Undertakings engaged in generation or generation and distribution of power were offered a 10-year tax holiday for renewable energy plants if it begun to generate power before March 31, 2013. (However, they have to pay a minimum alternative tax at the rate of approximately 20%, which can be offset in future years.)</p> <p>According to the new regulations effective as of April 1, 2013, alternative incentive mechanism provides for expenditure-based incentive to business of generation, transmission, or distribution of power. As regards this incentive, all revenue and capital expenditure (except few) will be allowed as tax deduction upfront instead of claiming amortization/depreciation on the capital expenditure and there would be no tax holiday available.</p> <p>Under Ministry for Non-Conventional Energy Sources, The Indian Renewable Energy Development Agency has been set up and is a specialized financing agency to promote and finance renewable energy projects.</p> <p>In order to attract foreign investors, the Indian Government has taken several initiatives such as introducing generation-based incentives (GBI) scheme to promote projects under Independent Power Producers (<i>IPP</i>) mode (wind power INR 0.50/MW, solar power INR 12.41/kW).</p> <p>Under the domestic income-tax law, power companies have been provided with an option to claim depreciation under straight-line method. However, a company can claim either accelerated depreciation or GBI, but not both.</p>

**Indian Distributed Generation Policy by Technology and Type**

---

		<p>India aims to derive 15% of its energy requirements from renewable energy sources by the year 2020. Renewable Purchase Obligation (RPO) is one of the tools of implementing this ambitious goal. Under these rules, distribution companies, open access consumers, and captive consumers are obligated to buy a certain percentage of their power from renewable sources of energy.</p> <p>The Indian Government has given various incentives on setting up the renewable energy power project, which includes exemption from customs and excise duties on specific goods required for setting up the renewable energy projects.<sup>3</sup></p>
	Large-scale cogeneration	Tax and duty structure for CHP capital equipment is not as attractive as for other renewable energy technologies.
	Domestic cogeneration	
	On-site PV	Under the domestic income-tax law, renewable companies (solar as well as wind power) are provided with accelerated depreciation at 80%.
		In January 2010, Jawaharlal Nehru National Solar Mission (JNNSM) was launched with a mission target of 20,000 MW of solar-generating capacity by the end of the Thirteenth Five-Year Plan (2022).
	On-site wind	In 2012, the Indian Government has restricted the accelerated depreciation of 80% to windmills installed on or before March 31, 2012. Windmills installed after March 31, 2012, will be eligible for depreciation of 15% instead of 80% on written-down value method.
	Small hydro	
Others	DE in general	<p>Electricity Act of 2003 includes favorable provisions for DE<sup>11</sup> and guarantees access to all generators regardless of size. The act has moved India toward an electricity market with separate generation, transmission, and distribution of power, with increasing potential for competition. A milestone in this progress is the introduction of the <i>Availability Based Tariff (ABT)</i>, which is an intermediate step in the effort to develop a true spot market for electricity. An ABT has been introduced at all five electrical regions of the country at the interstate level.<sup>a</sup></p> <p>Section 30 of the 2003 Electricity Act is designed to facilitate on-site generation. The Bill Section 38, 2(d) of the 2003 Electricity Act makes it obligatory to provide <i>nondiscriminatory open access</i>. There is a similar obligation on the State Transmission Utility, Section 39-2(d), to provide nondiscriminatory open access.</p> <p>According to the current (12th: 2012–2017) 5-year plan of India, it is planned to add a grid interactive renewable capacity addition of about 30,000 MW, comprising of 15,000 MW wind, 10,000 MW solar, 2,100 small hydro, while the balance is planned primarily from biomass. So the share of renewables in electricity generated is expected to rise from around 6% in 2012 to 9% in 2017 and 16% in 2030.</p>
	Large-scale cogeneration	<p>CHP could be one of the beneficiaries of the deep shock that followed India's July 2012 blackout. India already leads in biomass CHP in its sugar industry but has plenty of unrealized potential for tapping waste heat for CHP.</p> <p>The IEA estimates that India could grow from its current base of less than 10 GW to almost 28 GW of CHP in 2015 and 85 GW in 2030. CHP and district heating and cooling could be implemented in smaller industrial parks, special economic zones, and other areas with a concentration of large commercial and software establishments needing secure, low-cost heat, cooling, and power, according to the agency.</p>

Indian Distributed Generation Policy by Technology and Type		
	Domestic cogeneration	
	PV	Grid-interactive solar power generation capacity stands at 1761 MW with about 557 MW installed by Q2 in 2013. With most of the CSP projects that were due to be commissioned in May 2013 delayed as the forecast for installations in 2013 looks flat compared to 2012. Only about 60% of the targeted installation goal has been achieved by Q2 in 2013 despite the commissioning deadline of Phase 1 of JNNSM ending in May.
	Wind	India has the fifth largest installed wind power capacity in the world. In 2009–2010, India's growth rate was highest among the other top four countries. As of January 31, 2013, the installed capacity of wind power in India was 19,564.95 MW. It is estimated that 6000 MW of additional wind power capacity will be installed in India by 2012. Wind power accounts for 8.5% of India's total installed power capacity, and it generates 1.6% of the country's power.
	Hydro	Hydropower makes up about 22% of the total installed capacity in India. However, the country has a total hydropower capacity of 68% yet to be developed. The utilization of hydropower potential is only 39,449 MW out of the total capacity of 145,320 MW

## 11.16 Japan

Japan has a long history of DE leadership and boasts the world's lowest energy consumed per GDP ratios. Still Japan is highly dependent on energy imports, and additional investment in DE may go a long way in addressing this. Japan's PV manufacturing infrastructure is the world's most developed, and there appears to be ever-increasing policy support for DE. There remains much room for improvement, and additional policy support will be key in realizing the potential of DE. Major drivers for DE growth will continue to be climate change and energy security. Following Fukushima catastrophe, DE became far more important than before, as a result, Japanese Government is focusing even much stronger on supporting DE.

Japanese Distributed Generation Policy by Technology and Type

**Japanese Distributed Generation Policy by Technology and Type**

---

The following subsidies and tax incentives are available:

**Subsidies for High-Efficiency Natural Gas CHP (10–3000 kW):**

The Support Programme for New Energy Users provides subsidies for businesses that introduce qualifying new energy systems such as natural gas CHP systems and fuel cells.

**The Programme for the Promotion of New Energy in Local Areas:**

This program provides subsidies for local public entities that plan to introduce qualifying new energy systems, which are close to being commercial but still have high system costs. Eligible technologies include energy efficient applications such as clean energy vehicles, natural gas-fuelled CHP systems and fuel cells, as well as renewables.

**Accelerated tax depreciation of CHP investment:**

The Taxation System for the Promotion of Investment in Energy Supply–Demand offers a 7% tax exemption for small- and medium-sized businesses or an accelerated tax depreciation of 30% of the standard acquisition value of the equipment.

**R&D on high-efficiency natural gas CHP and fuel cells:**

The Japanese government also actively supports R&D, demonstration, and commercialization of gas-engine and fuel cell CHP systems for residential use.<sup>3</sup>

Large-scale cogeneration

Domestic cogeneration

On-site PV

The 1992 net-metering policy required utilities to purchase excess power from PV systems at the retail rate the same year ambitious targets for PV were set. In 1994 the *70,000 Roofs* program was launched. Incentives included low interest loans, a comprehensive education and outreach program, and declining rebates for interconnected residential systems. Rebates were initially 50% of the installed cost for end-users but declined annually and were phased out completely in 2002. In 1997, the program was altered to also extend rebates to landlords and housing developers. The government promoted PV with print and television advertising campaigns. By the end of the program in 2002, it had exceeded its goals.<sup>12</sup> The FiT originally introduced in 1997. On June 18, 2012, a new FiT was approved, of 42 yen/kW h, about 0.406 Euro/kW h or U.S. \$0.534/kW h. The tariff covers the first 10 years of excess generation for systems less than 10 kW, and generation for 20 years for systems over 10 kW. It became effective on July 1, 2012. In April 2013, the FiT was reduced to 37.8 yen/kW h.

On-site wind

FiT in 2013 is 23.1 yen/kW h—which is 2.5 times more than the relevant German tariff—while for small wind at less than 20 kW capacity gets even higher tariffs—they are set at 57.75 yen. However, there was zero new capacity deployed under these tariffs until now

Small hydro

Others

DE in general

In 2012, Japan has published its latest Strategic Energy Plan (SEP), originally formulated in 2003 and reviewed every 3 years by conference bodies as well as various opinion polls. The latest revision includes a road map of energy-based economic growth and reformation of the energy infrastructure. The strategy is to ensure growth and encourage multifaceted international trade by taking into account the social cost and price differences between nuclear, thermal, and renewable energy generation.

### 11.17 South Korea

Like many OECD countries, South Korea is almost totally reliant on energy imports to meet domestic demand. Energy independence, reliability, and economic competitiveness will continue to be an important driver for DE for some time to come. It is clear that policy will play an important role in realizing South Korea's ambitious goals in developing DE.

Korean Distributed Generation Policy by Technology and Type

Financial	<p>DE in general</p> <p>South Korea is ranked at fifth on KPMG's Green Tax Index, which provides an indication of which countries are most active in using green tax incentives and penalties to drive sustainable corporate behavior and achieve green policy objectives. South Korea in common with the United States has a green tax system weighted toward incentives rather than penalties. South Korea leads the ranking for green innovation, which suggests that South Korea is especially active in using its tax code to encourage green research and development. At the end of 2011, the FiT was abrogated due to introduction of a RPS in 2012, where power plants over 500 MW have an obligation to buy renewable energy. (The government maintains a FiT only for existing recipients.)</p> <p>There is a research and development tax credit program, which is applied for renewable energy technologies. Import duties are reduced by 50% for all components and/equipment used in renewable energy power plants. The government also provides subsidies up to 60% to local governments for the installation of renewable energy facilities, and it offers low interest loans (5.5%–7.5%) to renewable energy projects, including a 5-year grace period followed by a 10-year payment period.<sup>3</sup></p>

(Continued)

Korean Distributed Generation Policy by Technology and Type		
	Large-scale cogeneration	Through the government's Integrated Energy Supply Policy (IESP), the most significant support for CHP uses urban planning policy to designate new developments as Integrated Energy Supply Areas (IESAs), thereby creating a captive market for DHC CHP.  Tax incentives and low-interest loans are available for businesses installing CHP equipment.  CHP plants over 100 MWe can buy natural gas directly from the Korea Gas Corporation (KOGAS) at the wholesale price. <sup>a</sup>
	Domestic cogeneration	
	On-site PV	Due to the lack of a domestic track record for solar energy during the enactment of the new law on RPS, the standard price for solar energy was fixed at 120% of the German price.
	On-site wind	Among the 11 energy sources selected by the act on RPS wind energy, water energy has its standard price calculated by the government.
	Small hydro	Among the 11 energy sources selected by the act on RPS, water energy has its standard price calculated by the government.
Others	DE in general	Under RPS, which came into force on January 1, 2013, the 13 power companies that operate plants over 500 MW will have an obligation to buy renewable energy. Percentage in 2013 is 4%, which shall be increased by 0.5% point yearly until 2016 and by 1% point after that to reach 10% by 2022.
	Large-scale cogeneration	
	Domestic cogeneration	
	PV	Under RPS, a solar installation of 220 MW has been set and gradually increasing to 1.2 GW in 2015.
	Wind	Offshore wind energy is set to grow tremendously, with a 2.5 GW offshore farm being planned on the southwest coast of the country by 2019. The project comes at a cost of U.S. \$9 billion, and will be implemented in three stages, with the first 100 MW being brought online by 2014.
	Hydro	In 2012, Korea Western Power (WP) announced their intention to build 20 tidal power plants from now to 2014, with a total capacity of 520 MW.

## 12.1 Introduction

Economic-evaluation methods facilitate comparisons among energy technology investments. Generally, the same methods can be used to compare investments in energy supply or energy efficiency. All sectors of the energy community need guidelines for making economically efficient energy-related decisions.

This chapter provides an introduction to some basic methods that are helpful in designing and sizing cost-effective systems, and in determining whether it is economically efficient to invest in specific energy efficiency or renewable energy projects. The targeted audience includes analysts, architects, engineers, designers, builders, codes and standards writers, and government policy makers—collectively referred to as the “design community.”

The focus is on microeconomic methods for measuring cost-effectiveness of individual projects or groups of projects, with explicit treatment of uncertainty. The chapter does not treat macroeconomic methods and national market-penetration models for measuring economic impacts of energy efficiency and renewable energy investments on the national economy. It provides sufficient guidance for computing the measures of economic performance for relatively simple investment choices, and it provides the fundamentals for dealing with complex investment decisions.

---

## 12.2 Making Economically Efficient Choices\*

Economic-evaluation methods can be used in a number of ways to increase the *economic efficiency* of energy-related decisions. There are methods that can be used to obtain the largest possible savings in energy costs for a given energy budget; there are methods that can be used to achieve a targeted reduction in energy costs for the lowest possible efficiency/renewable energy investment; and there are methods that can be used to determine how much it pays to spend on energy efficiency and renewable energy to lower total lifetime costs, including both *investment costs* and energy costs.

The first two ways of using economic-evaluation methods (i.e., to obtain the largest savings for a fixed budget and to obtain a targeted savings for the lowest budget) have more limited applications than the third, which aims at minimizing total costs or maximizing *net benefits* (NB) (net savings (NS)) from expenditure on energy efficiency and renewables. As an example of the first, a plant owner may budget a specific sum of money for the purpose of retrofitting the plant for energy efficiency. As an example of the second, designers may be required by state or federal building standards and/or codes to reduce the design energy loads of new buildings below some specified level. As an example of the third, engineers may be required by their clients to include, in a production plant, those energy efficiency and renewable energy features that will pay off in terms of lower overall production costs over the long run.

Note that economic efficiency is not necessarily the same as engineering thermal efficiency. For example, one furnace may be more “efficient” than another in the engineering technical sense, if it delivers more units of heat for a given quantity of fuel than another. Yet, it may not be economically efficient if the first cost of the higher output

---

\* This section is based on a treatment of these concepts provided by Marshall and Ruegg (1980a).

furnace outweighs its fuel savings. The focus in this chapter is on economic efficiency, not engineering efficiency.

Economic efficiency is conceptually illustrated in Figures 12.1 through 12.3 with an investment in energy efficiency. Figure 12.1 shows the level of energy conservation,  $Q_c$ , that maximizes NB from energy conservation—that is, the level that is most profitable over the long run. Note that it corresponds to the level of energy conservation at which the curves are most distant from one another.

Figure 12.2 shows how “marginal analysis” can be used to find the same level of conservation,  $Q_c$ , that will yield the largest NB. It depicts changes in the total benefits and cost curves (i.e., the derivatives of the curves in Figure 12.1) as the level of energy conservation is increased. The point of intersection of the marginal curves coincides with the most profitable level of energy conservation indicated in Figure 12.1. This is the point at which the cost of adding one more unit of conservation is just equal to the corresponding benefits in terms of energy savings (i.e., the point at which “marginal costs” and “marginal benefits” are equal). To the left of the point of intersection, the additional

**FIGURE 12.1**  
Maximizing net benefits.

**FIGURE 12.2**  
Equating marginal benefits and marginal costs.

**FIGURE 12.3**  
Minimizing LCC.

benefits from increasing the level of conservation by another unit are greater than the additional costs, and it pays to invest more. To the right of the point of intersection, the costs of an addition to the level of conservation exceed the benefits—and the level of total NB begins to fall, as shown in Figure 12.1. Figure 12.3 shows that the most economically efficient level of energy conservation,  $Q_c$ , is that for which the total cost curve is at a minimum.

The most economically efficient level of conservation is the same,  $Q_c$ , in Figures 12.1 through 12.3. Three different approaches to finding  $Q_c$  are illustrated: finding the maximum difference between benefits and costs; finding the point where marginal benefits equal marginal costs; and finding the lowest life-cycle costs. The graphical methods of Figures 12.1 through 12.3 are captured by the quantitative methods described in the section that follows.

### 12.3 Economic Evaluation Methods\*

There are a number of closely related, commonly used methods for evaluating economic performance. These include the *life-cycle cost* (LCC) method, levelized cost of energy (LCOE) method, net present value (NPV) or NB (net present worth) method, benefit/cost (or savings-to-investment) ratio (SIR) method, internal rate-of-return (IRR) method, overall rate-of-return (ORR) method, and discounted payback (DPB) method. All of these methods are used when the important effects can be measured in dollars. If incommensurable effects are critical to the decision, it is important that they also be taken into account. But, because only quantified effects are included in the calculations for these economic methods, unquantified effects must be treated outside the models. Brief treatments of the methods are provided; some additional methods are identified but not treated. For more comprehensive treatments, see Ruegg and Marshall (1990).

\* These methods are treated in detail in Ruegg and Marshall (1990).

### 12.3.1 Life-Cycle Cost (LCC) Method

The life-cycle costing method sums, for each investment alternative, the costs of acquisition, maintenance, repair, replacement, energy, and any other monetary costs (less than any income amounts, such as salvage value) that are affected by the investment decision. The *time value of money* must be taken into account for all amounts, and the amounts must be considered over the relevant period. All amounts are usually measured either in *present value* or annual value dollars. This is discussed later in Sections 12.5.2 and 12.5.3. At a minimum, for comparison, the investment alternatives should include a “base-case” alternative of not making the energy efficiency or renewable investment, and at least one case of an investment in a specific efficiency or renewable system. Numerous alternatives may be compared. The alternative with the lowest LCC that meets the investor’s objective and constraints is the preferred investment. This least-cost solution is analogous to the least cost presented in [Figure 12.3](#).

The following is a formula for finding the LCCs of each alternative:

$$\text{LCC}_{A1} = I_{A1} + E_{A1} + M_{A1} + R_{A1} - S_{A1} \quad (12.1)$$

where

$\text{LCC}_{A1}$  = life-cycle cost of alternative A1

$I_{A1}$  = present-value investment costs of alternative A1

$E_{A1}$  = present-value energy costs associated with alternative A1

$M_{A1}$  = present-value nonfuel operating and maintenance cost of A1

$R_{A1}$  = present-value repair and replacement costs of A1

$S_{A1}$  = present-value resale (or salvage) value less disposal cost associated with alternative A1

The LCC method is particularly useful for decisions that are made primarily on the basis of cost-effectiveness, such as whether a given energy efficiency or renewable energy investment will lower total cost (e.g., the sum of investment and operating costs). It can be used to compare alternative designs or sizes of systems, as long as the systems provide the same service. The method, if used correctly, can be used to find the overall cost-minimizing combination of energy efficiency investments and energy supply investments within a given facility. However, in general, it cannot be used to find the best investment, because totally different investments do not provide the same service.

### 12.3.2 Levelized Cost of Energy (LCOE) Method

The LCOE is similar to the LCC method, in that it considers all the costs associated with an investment alternative and takes into account the time value of money for the analysis period. However, it is generally used to compare two alternative energy supply technologies or systems, for example, two electricity production technologies that may or may not provide exactly the same service, that is, the same level of energy production. It differs from the LCC in that it usually considers taxes, but like LCC, frequently ignores financing costs.

The LCOE is the value that must be received for each unit of energy produced to ensure that all costs and a reasonable profit are made. Profit is ensured by discounting future

revenues at a discount rate that equals the rate of return that might be gained on other investments of comparable risk, that is, the opportunity cost of capital. This can be represented in the following equation:

$$\sum_{t=1}^{t=N} \frac{\text{LCOE} * Q_t}{(1+d')^t} = \sum_{t=0}^{t=N} \frac{C_t}{(1+d)^t} \quad (12.2)$$

where

N = the analysis period

$Q_t$  = the amount of energy production in period t

$C_t$  = the cost incurred in period t

$d'$  = the discount rate or opportunity cost of capital; if  $d'$  is a real discount rate (excludes inflation) then the LCOE will be in real (constant) dollar terms, while if  $d'$  is a normal discount rate, the LCOE will be in nominal (current) dollar terms

$d$  = the discount rate used to bring future costs back to their present value. If those costs are expressed in real dollars, then the discount rate  $d$  should be a real discount rate; while, if they are in nominal dollars, the discount rate should be a nominal discount rate

### 12.3.3 Net Present Value (NPV) or Net Benefits (NB) Method

The NPV method finds the excess of benefits over costs, where all amounts are discounted for their time value. (If costs exceed benefits, net losses result.)

The NPV method is also often called the “net present worth” or “NS” method. When this method is used for evaluating a cost-reducing investment, the cost savings are the benefits, and it is often called the “NS” method.

Following is a formula for finding the NPV from an investment, such as an investment in energy efficiency or renewable energy systems:

$$\text{NPV}_{A1:A2} = \sum_{t=0}^N \frac{B_t - C_t}{(1+d)^t} \quad (12.3)$$

where

$\text{NPV}_{A1:A2}$  = NB, that is, present value benefits (savings) net of present value costs for alternative A1 as compared with alternative A2

$B_t$  = benefits in year t, which may be defined to include energy savings associated with using alternative A1 instead of alternative A2

$C_t$  = costs in year t associated with alternative A1 as compared with a mutually exclusive alternative A2

$d$  = discount rate

The NPV (NB) method is useful for deciding whether to make a given investment and for designing and sizing systems. It is not appropriate for comparing investments that provide different services.

### 12.3.4 Benefit-to-Cost Ratio (BCR) or Savings-to-Investment Ratio (SIR) Method

This method divides benefits by costs or, equivalently, savings by investment. When used to evaluate energy efficiency and renewable energy systems, benefits are in terms of energy cost savings. The numerator of the SIR is usually constructed as energy savings, and net of maintenance and repair costs; and the denominator as the sum of investment costs and the present value of replacement costs less salvage value (capital cost items). However, depending on the objective, sometimes only initial investment costs are placed in the denominator and the other costs are subtracted in the numerator—or sometimes only the investor's equity capital is placed in the denominator. Like the three preceding methods, this method is based on discounted cash flows.

Unlike the three preceding methods that provided a performance measure in dollars, this method gives the measure as a dimensionless number. The higher the ratio, the more the dollar savings realized per dollar of investment. In particular, a value greater than 1 is generally required for an investment to be considered economically efficient.

Following is a commonly used formula for computing the ratio of savings-to-investment costs:

$$SIR_{A1:A2} = \frac{\sum_{t=0}^N (CS_t(1+d)^{-t})}{\sum_{t=0}^N (I_t(1+d)^{-t})} \quad (12.4)$$

where

$SIR_{A1:A2}$  = savings-to-investment ratio for alternative A1 relative to mutually exclusive alternative A2

$CS_t$  = cost savings (excluding those investment costs in the denominator) plus any positive benefits of alternative A1 as compared with mutually exclusive alternative A2

$I_t$  = additional investment costs for alternative A1 relative to A2

Note that the particular formulation of the ratio with respect to the placement of items in the numerator or denominator can affect the outcome. One should use a formulation appropriate to the decision maker's objectives.

The ratio method can be used to determine whether or not to accept or reject a given investment on economic grounds. It also can be used for design and size decisions and other choices among mutually exclusive alternatives, if applied incrementally (i.e., the investment and savings are the difference between the two mutually exclusive alternatives). A primary application of the ratio method is to set funding priorities among projects competing for a limited budget. When it is used in this way—and when project costs are “lumpy” (making it impossible to fully allocate the budget by taking projects in order according to the size of their ratios)—SIR should be supplemented with the evaluation of alternative sets of projects using the NPV or NB method.

### 12.3.5 Internal Rate-of-Return (IRR) Method

The IRR method solves for the discount rate for which dollar savings are just equal to dollar costs over the analysis period; that is, the rate for which the NPV is zero. This discount

rate is the rate of return on the investment. It is compared to the investor's minimum acceptable rate of return to determine whether the investment is desirable. Unlike the preceding three techniques, the IRR does not call for the inclusion of a prespecified discount rate in the computation, but, rather, solves for a discount rate.

The rate of return is typically calculated by a process of trial and error, by which various compound rates of interest are used to discount cash flows until a rate is found for which the NPV of the investment is zero. The approach is the following: compute NPV using Equation 12.3, except substitute a trial interest rate for the discount rate,  $d$ , in the equation. A positive NPV means that the IRR is greater than the trial rate; a negative NPV means that the IRR is less than the trial rate. Based on the information, try another rate. By a series of iterations, find the rate at which NPV equals zero.

Computer algorithms, graphical techniques, and—for simple cases—discount-factor tabular approaches are often used to facilitate IRR solutions (Ruegg and Marshall, 1990, pp. 71–72). Expressing economic performance as a rate of return can be desirable for ease in comparing the returns on a variety of investment opportunities, because returns are often expressed in terms of annual rates of return. The IRR method is useful for accepting or rejecting individual investments or for allocating a budget. For designing or sizing projects, the IRR method, like the SIR, must be applied incrementally. It is not recommended for selecting between mutually exclusive investments with significantly different lifetimes (e.g., a project with a high annual return of 35% for 20 years is a much better investment than a project with the same 35% annual return for only 2 years).

IRR is a widely used method, but it is often misused, largely due to shortcomings that include the possibility of

- No solution (the sum of all nondiscounted returns within the analysis period are less than the investment costs)
- Multiple solution values (some costs occur later than some of the returns)
- Failure to give a measure of overall return associated with the project over the analysis period (returns occurring before the end of the analysis are implicitly assumed to be reinvested at the same rate of return as the calculated IRR. This may or may not be possible).

### 12.3.6 Overall Rate-of-Return (ORR) Method

The ORR method corrects for the last two shortcomings expressed earlier for the IRR. Like the IRR, the ORR expresses economic performance in terms of an annual rate of return over the analysis period. But unlike the IRR, the ORR requires, as input, an explicit reinvestment rate on interim receipts and produces a unique solution value.\* The explicit reinvestment rate makes it possible to express net cash flows (excluding investment costs) in terms of their future value at the end of the analysis period. The ORR is then easily computed with a closed-form solution as shown in Equation 12.5.

\* As shown in Equation 12.5, the reinvestment rate is also used to bring all investments back to their present value. Alternatively, investments after time zero can be discounted by the overall growth rate. In this case, a unique solution is not guaranteed, and the ORR must be found iteratively (Stermole and Stermole, 2000).

$$ORR_{A1:A2} = \left[ \frac{\left[ \sum_{t=0}^N (B_t - C_t)(1+r)^{N-t} \right]}{\sum_{t=0}^N \left[ \frac{I_t}{(1+r)^t} \right]} \right]^{1/N} - 1 \quad (12.5)$$

where

$ORR_{A1:A2}$  = overall rate of return on a given investment alternative A1 relative to a mutually exclusive alternative A2 over a designated study period

$B_t$  = benefits from a given alternative relative to a mutually exclusive alternative A2 over time period  $t$

$C_t$  = costs (excluding that part of investment costs on which the return is to be maximized) associated with a given alternative relative to a mutually exclusive alternative A2 over time  $t$

$r$  = the reinvestment rate at which net returns can be reinvested, usually set equal to the discount rate

$N$  = the length of the study period

$I_t$  = investment costs in time  $t$  on which the return is to be maximized

The ORR is recommended as a substitute for the IRR, because it avoids some of the limitations and problems of the IRR. It can be used for deciding whether or not to fund a given project, for designing or sizing projects (if it is used incrementally), and for budget-allocation decisions.

### 12.3.7 Discounted Payback (DPB) Method

This evaluation method measures the elapsed time between the time of an initial investment and the point in time at which accumulated discounted savings or benefits—net of other accumulated discounted costs—are sufficient to offset the initial investment, taking into account the time value of money. (If costs and savings are not discounted, the technique is called “simple payback.”) For the investor who requires a rapid return of investment funds, the shorter the length of time until the investment pays off, the more desirable is the investment.

To determine the *DPB* period, find the minimum value of  $Y$  (year in which payback occurs) such that the following equality is satisfied.

$$\sum_{t=1}^Y \frac{B_t - C'_t}{(1+d)^t} = I_0 \quad (12.6)$$

where

$B_t$  = benefits associated in period  $t$  with one alternative as compared with a mutually exclusive alternative

$C'_t$  = costs in period  $t$  (not including initial investment costs) associated with an alternative as compared with a mutually exclusive alternative in period  $t$

$I_0$  = initial investment costs of an alternative as compared with a mutually exclusive alternative, where the initial investment cost comprises total investment costs

DPB is often—correctly—used as a supplementary measure when project life is uncertain. It is used to identify feasible projects when the investor's time horizon is constrained. It is used as a supplementary measure in the face of uncertainty to indicate how long capital is at risk. It is a rough guide for accept/reject decisions. It is also overused and misused. Because it indicates the time at which the investment just breaks even, it is not a reliable guide for choosing the most profitable investment alternative, as savings or benefits after the payback time could be significant.

### 12.3.8 Other Economic-Evaluation Methods

A variety of other methods have been used to evaluate the economic performance of energy systems, but these tend to be hybrids of those presented here. One of these is the required revenue method, which computes a measure of the before-tax revenue in present or annual value dollars required to cover the costs on an after-tax basis of an energy system (Ruegg and Short, 1988, pp. 22–23). Mathematical programming methods have also been used to evaluate the optimal size or design of projects, as well as other mathematical and statistical techniques.

---

## 12.4 Risk Assessment

Many of the inputs to the evaluation methods mentioned earlier will be highly uncertain at the time an investment decision must be made. To make the most informed decision possible, an investor should employ these methods within a framework that explicitly accounts for risk and uncertainty.

*Risk assessment* provides decision makers with information about the “risk exposure” inherent in a given decision—that is, the probability that the outcome will be different from the “best-guess” estimate. Risk assessment is also concerned with the “risk attitude” of the decision maker, which describes his/her willingness to take a chance on an investment of uncertain outcome. Risk assessment techniques are typically used in conjunction with the evaluation methods outlined earlier; and not as stand-alone evaluation techniques.

The risk assessment techniques range from simple and partial to complex and comprehensive. Though none takes the risk out of making decisions, the techniques—if used correctly—can help the decision maker make more informed choices in the face of uncertainty.

This chapter provides an overview of the following probability-based risk assessment techniques:

- Expected value (EV) analysis
- Mean-variance criterion (MVC) and coefficient of variation (CV)
- Risk-adjusted discount rate (RADR) technique
- Certainty equivalent (CE) technique
- Monte Carlo simulation
- Decision analysis
- Real options analysis (ROA)
- Sensitivity analysis

There are other techniques that are used to assess the risks and uncertainty (e.g., CAP\_M and break-even analysis), but those are not treated here.

### 12.4.1 Expected Value (EV) Analysis

EV analysis provides a simple way of taking into account uncertainty about input values, but it does not provide an explicit measure of risk in the outcome. It is helpful in explaining and illustrating risk attitudes.

*How to calculate EV:* An “expected value” is the sum of the products of the dollar value of alternative outcomes,  $a_i$  ( $i = 1, \dots, n$ ), and their probabilities of occurrence,  $p_i$ . The EV of the decision is calculated as follows:

$$EV = a_1p_1 + a_2p_2 + \dots + a_np_n \quad (12.7)$$

*Example of EV analysis:* The following simplified example illustrates the combining of EV analysis and NPV analysis to support a purchase decision.

Assume that a not-for-profit organization must decide whether to buy a given piece of energy-saving equipment. Assume that the unit purchase price of the equipment is \$100,000, the yearly operating cost is \$5,000 (obtained by a fixed-price contract), and both costs are known with certainty. The annual energy cost savings, on the other hand, are uncertain, but can be estimated in probabilistic terms as shown in Table 12.1 in the columns headed  $a_1$ ,  $p_1$ ,  $a_2$ , and  $p_2$ . The present-value calculations are also given in Table 12.1.

If the equipment decision was based only on NPV, calculated with the “best-guess” energy savings (column  $a_1$ ), the equipment purchase would be found to be uneconomic with a NPV of \$ – 4812. But if the possibility of greater energy savings is taken into account by using the EV of savings rather than the best guess, the conclusion is that, over repeated applications, the equipment is expected to be *cost-effective*. The expected NPV of the energy-saving equipment is \$25,000 per unit.

*Advantages and disadvantages of the EV technique:* An advantage of the technique is that it predicts a value that tends to be closer to the actual value than a simple “best-guess” estimate over repeated instances of the same event, provided, of course, that the input probabilities can be estimated with some accuracy.

A disadvantage of the EV technique is that it expresses the outcome as a single-value measure, such that there is no explicit measure of risk. Another is that the estimated outcome

**TABLE 12.1**

Expected Value (EV) Example

Year	Equipment Purchase \$1000	Operating Costs \$1000	Energy Savings					PV \$1000
			$a_1$ \$1000	$p_1$	$a_2$ \$1000	$p_2$	PV <sup>a</sup> Factor	
0	–100	—	—	—	—	—	1	–100

3		–5	30	0.7	60	0.3	0.794	27.0
4		–5	30	0.6	60	0.4	0.735	27.2
5		–5	30	0.8	60	0.2	0.681	21.1
								25.0

Note: Expected NPV.

<sup>a</sup> Present-value calculations are based on a discount rate of 8%.

<sup>b</sup> Probabilities sum to 1.0 in a given year.

is predicated on many replications of the event, with the EV, in effect, a weighted average of the outcome over many like events. But the EV is unlikely to occur for a single instance of an event. This is analogous to a single coin toss: the outcome will be either heads or tails, not the probabilistic-based weighted average of both.

*EV and risk attitude:* EVs are useful in explaining risk attitude. Risk attitude may be thought of as a decision maker's preference between taking a chance on an uncertain money pay-out of known probability versus accepting a sure money amount. Suppose, for example, a person were given a choice between accepting the outcome of a fair coin toss where heads means winning \$10,000 and tails means losing \$5000 and accepting a certain cash amount of \$2000. EV analysis can be used to evaluate and compare the choices. In this case, the EV of the coin toss is \$2500, which is \$500 more than the certain money amount. The "risk-neutral" decision maker will prefer the coin toss because of its higher EV. The decision maker who prefers the \$2000 certain amount is demonstrating a "risk-averse" attitude. On the other hand, if the certain amount were raised to \$3000 and the first decision maker still preferred the coin toss, he or she would be demonstrating a "risk-taking" attitude. Such trade-offs can be used to derive a "utility function" that represents a decision maker's risk attitude.

The risk attitude of a given decision maker is typically a function of the amount at risk. Many people who are risk averse when faced with the possibility of significant loss, become risk neutral—or even risk taking, when potential losses are small. Because decision makers vary substantially in their risk attitudes, there is a need to assess not only risk exposure (i.e., the degree of risk inherent in the decision) but also the risk attitude of the decision maker.

#### 12.4.2 Mean-Variance Criterion (MVC) and Coefficient of Variation (CV)

These techniques can be useful in choosing among risky alternatives, if the mean outcomes and standard deviations (variation from the mean) can be calculated.

Consider a choice between two projects—one with higher mean NB and a lower standard deviation than the other. This situation is illustrated in Figure 12.4. In this case, the project whose probability distribution is labeled B can be said to have stochastic dominance over the project labeled A. Project B is preferable to Project A, both on grounds that its output is likely to be higher and that it entails less risk of loss. But what if Project A, the alternative with higher risk, has the higher mean NB, as illustrated in Figure 12.5? If this were the case, the MVC would provide inconclusive results.

When there is no stochastic dominance of one project over the other(s), it is helpful to compute the CV to determine the relative risk of the alternative projects. The CV indicates

**FIGURE 12.4**  
Stochastic dominance as demonstrated by mean-variance criterion.

**FIGURE 12.5**

Inconclusive results from mean-variance criterion.

which alternative has the lower risk per unit of project output. Risk-averse decision makers will prefer the alternative with the lower CV, other things being equal. The CV is calculated as follows:

$$CV = \frac{\sigma}{\mu} \quad (12.8)$$

where

CV = coefficient of variation

$\sigma$  = standard deviation

$\mu$  = mean

The principal advantage of these techniques is that they provide quick, easy-to-calculate indications of the returns and risk exposure of one project relative to another. The principal disadvantage is that the MVC does not provide a clear indication of preference when the alternative with the higher mean output has the higher risk, or vice versa.

### 12.4.3 Risk-Adjusted Discount Rate (RADR) Technique

The RADR technique takes account of risk through the discount rate. If a project's benefit stream is riskier than that of the average project in the decision maker's portfolio, a higher-than-normal discount rate is used; if the benefit stream is less risky, a lower-than-normal discount rate is used. If costs are the source of the higher-than-average uncertainty, a lower-than-normal discount rate is used and vice versa. The greater the variability in benefits or costs, the greater the adjustment in the discount rate.

The RADR is calculated as follows:

$$RADR = RFR + NRA + XRA \quad (12.9)$$

where

RADR = risk-adjusted discount rate

RFR = risk-free discount rate, generally set equal to the treasury bill rate

NRA = "normal" risk adjustment to account for the average level of risk encountered in the decision maker's operations

XRA = extra risk adjustment to account for risk greater or less than normal risk

TABLE 12.2

RADR Example

Year	Costs (\$M)	Revenue (\$M)	PV Costs <sup>a</sup> (\$M)	PV Revenue <sup>a</sup> (\$M)	NPV (\$M)
0	80	—	80	—	–80
1	5	20	4	17	13
2	5	20	4	14	10
3	5	20	4	12	8
4	5	20	3	10	7
5	5	20	3	9	6
6	5	20	3	7	4
7	5	20	2	6	4
Total NPV					–28

<sup>a</sup> Costs are discounted with a discount rate of 12%; revenue with a discount rate of 18%.

An example of using the RADR technique is the following: A company is considering an investment in a new type of alternative energy system with high payoff potential and high risk on the benefits side. The projected cost and revenue streams and the discounted present values are shown in Table 12.2. The treasury bill rate, taken as the risk-free rate, is 8%. The company uses a normal risk adjustment of 5% to account for the average level of risk encountered in its operations. This investment is judged to be twice as risky as the company's average investment, so an additional risk adjustment of 5% is added to the risk-adjusted discount rate. Hence, the RADR is 18%. With this RADR, the NPV of the investment is estimated to be a loss of \$28 million. On the basis of this uncertainty analysis, the company would be advised not to accept the project.

Advantages of the RADR technique are that it provides a way to account for both *risk exposure* and *risk attitude*. Moreover, RADR does not require any additional steps for calculating NPV once a value of the RADR is established. The disadvantage is that it provides only an approximate adjustment. The value of the RADR is typically a rough estimate based on sorting investments into risk categories and adding a “fudge factor” to account for the decision maker's risk attitude. It generally is not a fine-tuned measure of the inherent risk associated with variation in cash flows. Further, it typically is biased toward investments with short payoffs because it applies a constant RADR over the entire analysis period, even though risk may vary over time.

#### 12.4.4 Certainty Equivalent (CE) Technique

The CE technique adjusts investment cash flows by a factor that will convert the measure of economic worth to a “CE” amount—the amount a decision maker will find equally acceptable to a given investment with an uncertain outcome. Central to the technique is the derivation of the certainty equivalent factor (CEF), which is used to adjust net cash flows for uncertainty.

Risk exposure can be built into the CEF by establishing categories of risky investments for the decision maker's organization and linking the CEF to the CV of the returns—greater variation translating into smaller CEF values. The procedure is as follows:

1. Divide the organization's portfolio of projects into risk categories. Examples of investment risk categories for a private utility company might be the following: low-risk investments—expansion of existing energy systems and equipment

replacement; moderate-risk investments—adoption of new, conventional energy systems; and high-risk investments—investment in new alternative energy systems.

2. Estimate the CVs (see Section 12.4.2) for each investment-risk category (e.g., on the basis of historical risk-return data).
3. Assign CEFs by year, according to the coefficients of variation, with the highest-risk projects being given the lowest CEFs. If the objectives are to reflect only risk exposure, set the CEFs such that a risk-neutral decision maker will be indifferent between receiving the estimated certain amount and the uncertain investment. If the objective is to reflect risk attitude as well as risk exposure, set the CEFs such that the decision maker with his or her own risk preference will be indifferent.

To apply the technique, proceed with the following steps:

4. Select the measure of economic performance to be used—such as the measure of NPV (i.e., NB).
5. Estimate the net cash flows and decide in which investment-risk category the project in question fits.
6. Multiply the yearly net cash flow amounts by the appropriate CEFs.
7. Discount the adjusted yearly net cash flow amounts with an RFR (an RFR is used because the risk adjustment is accomplished by the CEFs).
8. Proceed with the remainder of the analysis in the conventional way.

In summary, the CE NPV is calculated as follows:

$$NPV_{CE} = \sum_{t=0}^N \left[ \frac{CEF_t(B_t - C_t)}{(1 + RFD)^t} \right], \quad (12.10)$$

where

$NPV_{CE}$  = NPV adjusted for uncertainty by the CE technique

$B_t$  = estimated benefits in time period  $t$

$C_t$  = estimated costs in time period  $t$

RFD = risk-free discount rate

Table 12.3 illustrates the use of this technique for adjusting NPV calculations for an investment in a new, high-risk alternative energy system. The CEF is set at 0.76 and is assumed to be constant with respect to time.

A principal advantage of the CE Technique is that it can be used to account for both risk exposure and risk attitude. Another is that it separates the adjustment of risk from discounting and makes it possible to make more precise risk adjustments over time. A major disadvantage is that the estimation of CEF is only approximate.

#### 12.4.5 Monte Carlo Simulation

Monte Carlo simulation entails the iterative calculation of the measure of economic worth from probability functions of the input variables. The results are expressed as a probability

**TABLE 12.3**

CE Example (Investment-Risk Category;  
High-Risk—New-Alternative Energy System)

Yearly Net Cash Flow (\$M)		CV	CEF	RFD Discount Factors <sup>a</sup>	NPV (\$M)
1	−100	0.22	0.76	0.94	−71
2	−100	0.22	0.76	0.89	−68
3	20	0.22	0.76	0.84	13
4	30	0.22	0.76	0.79	18

6	65	0.22	0.76	0.7	35
7	65	0.22	0.76	0.67	33
8	65	0.22	0.76	0.63	31
9	50	0.22	0.76	0.59	22
10	50	0.22	0.76	0.56	21
<i>Total NPV</i>					60

<sup>a</sup> The RFD is assumed equal to 6%.

density function and as a cumulative distribution function. The technique, thereby, enables explicit measures of risk exposure to be calculated. One of the economic-evaluation methods treated earlier is used to calculate economic worth; a computer is employed to sample repeatedly—hundreds of times—from the probability distributions and make the calculations. Monte Carlo simulation can be performed by the following steps:

1. Express variable inputs as probability functions. Where there are interdependencies among input values, multiple probability density functions, tied to one another, may be needed.
2. For each input for which there is a probability function, draw randomly an input value; for each input for which there is only a single value, take that value for calculations.
3. Use the input values to calculate the economic measure of worth and record the results.
4. If inputs are interdependent, such that input X is a function of input Y, first draw the value of Y, then draw randomly from the X values that correspond to the value of Y.
5. Repeat the process many times until the number of results is sufficient to construct a probability density function and a cumulative distribution function.
6. Construct the probability density function and cumulative distribution function for the economic measure of worth, and perform statistical analysis of the variability.

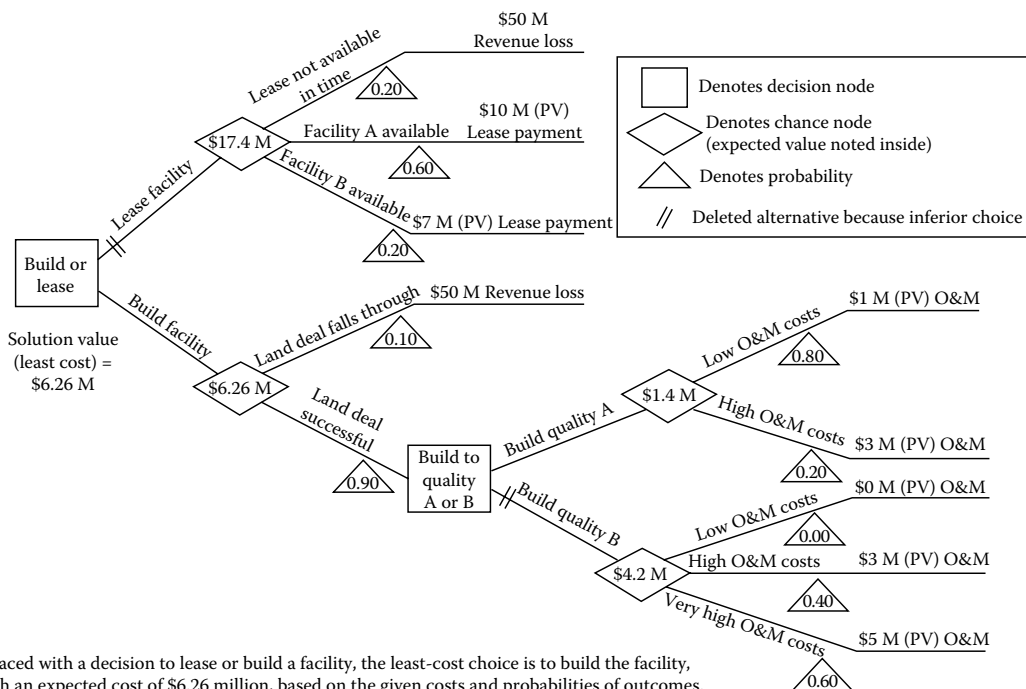

The strong advantage of the technique is that it expresses the results in probabilistic terms, thereby providing explicit assessment of risk exposure. A disadvantage is that it does not explicitly treat risk attitude; however, by providing a clear measure of risk exposure, it facilitates the implicit incorporation of risk attitude in the decision. The necessity of expressing inputs in probabilistic terms and the extensive calculations are also often considered disadvantages.

### 12.4.6 Decision Analysis

Decision analysis is a versatile technique that enables both risk exposure and risk attitude to be taken into account in the economic assessment. It diagrams possible choices, costs, benefits, and probabilities for a given decision problem in “decision trees,” which are useful in understanding the possible choices and outcomes.

Although it is not possible to capture the richness of this technique in a brief overview, a simple decision tree, shown in Figure 12.6, is discussed to give a sense of how the technique is used. The decision problem is whether to lease or build a facility. The decision must be made now, based on uncertain data. The decision tree helps to structure and analyze the problem. The tree is constructed left to right and analyzed right to left. The tree starts with a box representing a decision juncture or node—in this case, whether to lease or build a facility. The line segments branching from the box represent the two alternative paths: the upper one the lease decision and the lower one the build decision. Each has a cost associated with it that is based on the expected cost to be incurred along the path. In this example, the minimum expected cost of \$6.26 million is associated with the option to build a facility.

An advantage of this technique is that it helps to understand the problem and to compare alternative solutions. Another advantage is that, in addition to treating risk exposure, it can also accommodate risk attitude by converting benefits and costs to utility values (not addressed here). A disadvantage is that the technique, as typically applied, does not provide an explicit measure of the variability of the outcome.

Faced with a decision to lease or build a facility, the least-cost choice is to build the facility, with an expected cost of \$6.26 million, based on the given costs and probabilities of outcomes.

**FIGURE 12.6**  
Decision tree: build versus lease.

### 12.4.7 Real Options Analysis (ROA)

ROA is an adaptation of financial options valuation techniques\* to real asset investment decisions. ROA is a method used to analyze decisions in which the decision maker has one or more options regarding the timing or sequencing of an investment. It explicitly assumes that the investment is partially or completely *irreversible*, that there exists leeway or *flexibility* about the timing of the investment, and that it is subject to *uncertainty* over future payoffs. Real options can involve options (and combinations) to: defer, sequence, contract, shut down temporarily, switch uses, abandon, or expand the investment. This is in contrast to the NPV method that implies the decision is a “now or never” choice.

The value of an investment with an option is said to equal the value of the investment using the traditional NPV method (that implicitly assumes no flexibility or option) plus the value of the option. The analysis begins by construction of a decision tree with the option decision embedded in it. There are two basic methods to solve for the option value: the risk-adjusted replicating portfolio (RARP) approach and the risk-neutral probability (RNP) approach. The RARP discounts the expected project cash flows at a RADR, while the RNP approach discounts CE cash flows at a risk-free rate. In other words, the RARP approach takes the cash flows essentially as is, and adjusts the discount rate per time period to reflect that fact that the risk changes as one moves through the decision tree (e.g., risk declines with time as more information becomes available). In the RNP approach, the cash flows themselves are essentially adjusted for risk and discounted at a risk-free rate.

Copeland and Antikarov provide an overall four-step approach for ROA<sup>†</sup>:

1. Step 1—Compute a base-case traditional NPV (e.g., without flexibility).
2. Step 2—Model the uncertainty using (binominal) event trees (still without flexibility; e.g., without options)—although uncertainty is incorporated, the “expected” value of Step 2 should equal that calculated in Step 1.
3. Step 3—Create a decision tree incorporating decision nodes for options, as well as other (nondecision and nooption decisions) nodes.
4. Step 4—Conduct an ROA by valuing the payoffs, working backward in time, node by node, using the RARP or RNP approach to calculate the ROA value of the investment.

### 12.4.8 Sensitivity Analysis

Sensitivity analysis is a technique for taking into account uncertainty that does not require estimates of probabilities. It tests the sensitivity of economic performance to alternative values of key factors about which there is uncertainty. Although sensitivity analysis does not provide a single answer in economic terms, it does show decision makers how the

\* Financial options valuation is credited to Fisher Black and Myron Scholes who demonstrated mathematically that the value of a European call option—an option, but not the obligation, to purchase a financial asset for a given price (i.e., the exercise or strike price) on a particular date (i.e., the expiry date) in the future—depends on the current price of the stock, the volatility of the stock’s price, the expiry date, the exercise price, and the risk-free interest rate. (See Black and Scholes, 1973.)

<sup>†</sup> See Dixit and Pindyck (1994), which is considered the “bible” of real options, and Copeland and Antikarov (2001) which offers more practical spreadsheet methods. Ibid, pp. 220 and 239–240.

**FIGURE 12.7**

Sensitivity of present-value energy savings to time horizons, discount rates, and energy price escalation rates.

economic viability of a renewable energy or efficiency project changes as fuel prices, discount rates, time horizons, and other critical factors vary.

Figure 12.7 illustrates the sensitivity of fuel savings realized by a solar energy heating system to three critical factors: time horizons (0–25 years), discount rates ( $D$  equals 0%, 5%, 10%, and 15%), and energy escalation rates ( $E$  equals 0%, 5%, 10%, and 15%). The present value of savings is based on yearly fuel savings valued initially at \$1000.

Note that, other things being equal, the present value of savings increase with time—but less with higher discount rates and more with higher escalation rates. The huge impact of fuel price escalation is most apparent when comparing the top line of the graph ( $D = 0.10$ ,  $E = 0.15$ ) with the line next to the bottom ( $D = 0.10$ ,  $E = 0$ ). The present value of savings at the end of 25 years is approximately \$50,000 with a fuel escalation rate of 15%, and only about \$8000 with no escalation, other things being equal. Whereas the quantity of energy saved is the same, the dollar value varies widely, depending on the escalation rate.

This example graphically illustrates a situation frequently encountered in the economic justification of energy efficiency and renewable energy projects: The major savings in energy costs, and thus the bulk of the benefits, accrue in the later years of the project and are highly sensitive to both the assumed rate of fuel-cost escalation and the discount rate. If the two rates are set equal, they will be offsetting as shown by the straight line labeled  $D = 0$   $E = 0$  and  $D = 0.10$   $E = 0.10$ .

## 12.5 Building Blocks of Evaluation

Beyond the formula for the basic evaluation methods and risk assessment techniques, the practitioner needs to know some of the “nuts-and-bolts” of carrying out an economic analysis. He or she needs to know how to structure the evaluation process; how to choose a method of evaluation; how to estimate dollar costs and benefits; how to perform discounting operations; how to select an analysis period; how to choose a discount rate; how

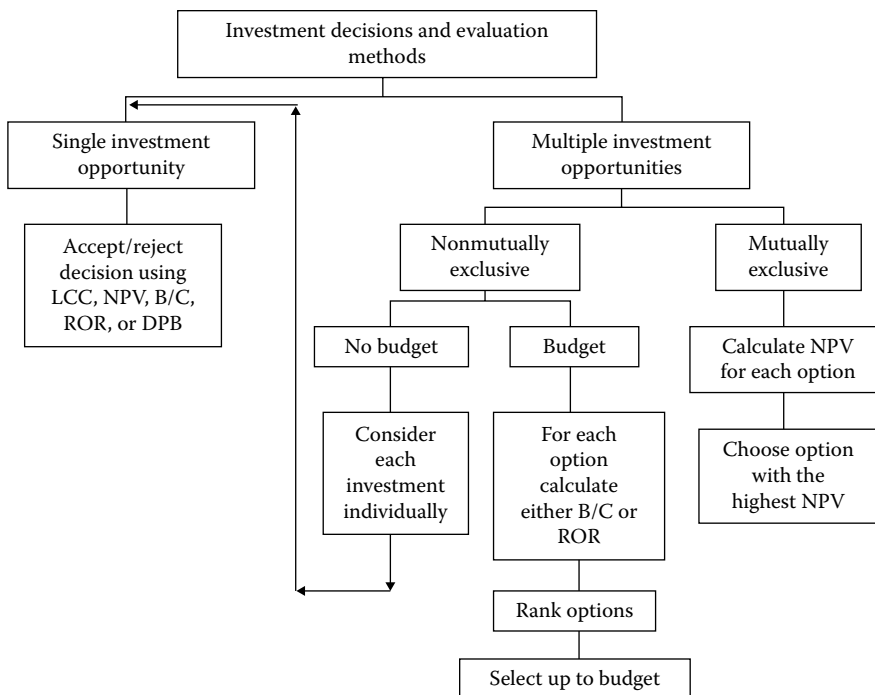

to adjust for inflation; how to take into account taxes and financing; how to treat residual values; and how to reflect assumptions and constraints, among other things. This section provides brief guidelines for these topics.

### 12.5.1 Structuring the Evaluation Process and Selecting a Method of Evaluation

A good starting point for the evaluation process is to define the problem and the objective. Identify any constraints to the solution and possible alternatives. Consider if the best solution is obvious, or if economic analysis and risk assessment are needed to help make the decision. Select an appropriate method of evaluation and a risk assessment technique. Compile the necessary data and determine what assumptions are to be made. Apply appropriate formula(s) to compute a measure of economic performance under risk. Compare alternatives and make the decision, taking into account any incommensurable effects that are not included in the dollar benefits and costs. Take into account the risk attitude of the decision maker, if it is relevant.

Although the six evaluation methods given earlier are similar, they are also sufficiently different, in that they are not always equally suitable for evaluating all types of energy investment decisions. For some types of decisions, the choice of method is more critical than for others. Figure 12.8 categorizes different investment types and the most suitable evaluation methods for each. If only a single investment is being considered, the “accept/reject” decision can often be made by any one of several techniques, provided the correct criterion is used.

**FIGURE 12.8**  
Investment decisions and evaluation methods.

*Accept/reject criteria:*

LCC technique—LCC must be lower as a result of the energy efficiency or renewable energy investment than without it.

- NPV (NB) technique—NPV must be positive as a result of the investment.
- B/C (SIR) technique—B/C (SIR) must be greater than 1.
- IRR technique—the IRR must be greater than the investor's minimum acceptable rate of return.
- DPB technique—the number of years to achieve DPB must be less than the project life or the investor's time horizon, and there are no cash flows after payback is achieved that would reverse payback.

If multiple investment opportunities are available, but only one investment can be made (i.e., they are mutually exclusive), any of the methods (except DPB) will usually work, provided they are used correctly. However, the NPV method is usually recommended for this purpose, because it is less likely to be misapplied. The NPV of each investment is calculated and the investment with the highest present value is the most economic. This is true even if the investments require significantly different initial investments, have significantly different times at which the returns occur, or have different useful lifetimes. Examples of mutually exclusive investments include different system sizes (e.g., three different photovoltaic array sizes are being considered for a single rooftop), different system configurations (e.g., different turbines are being considered for the same wind farm), and so forth.

If the investments are not mutually exclusive, then (as shown in [Figure 12.8](#)) one must consider whether there is an overall budget limitation that would restrict the number of economic investments that might be undertaken. If there is no budget (i.e., no limitation on the investment funds available), then there is really no comparison to be performed and the investor simply makes an “accept/reject” decision for each investment individually as described earlier.

If funds are not available to undertake all of the investments (i.e., there is a budget), then the easiest approach is to rank the alternatives, with the best having the highest benefit-to-cost ratio or rate of return. (The investment with the highest NPV will not necessarily be the one with the highest rank, because present value does not show return per unit investment.) Once ranked, those investments at the top of the priority list are selected until the budget is exhausted.

In the case where a fast turnaround on investment funds is required, DPB is recommended. The other methods, although more comprehensive and accurate for measuring an investment's lifetime profitability, do not indicate the time required for recouping the investment funds.

### 12.5.2 Discounting

Some or all investment costs in energy efficiency or renewable energy systems are incurred near the beginning of the project and are treated as “first costs.” The benefits, on the other hand, typically accrue over the life span of the project in the form of yearly energy saved or produced. To compare benefits and costs that accrue at different points in time, it is necessary to put all cash flows on a time-equivalent basis. The method for converting cash flows to a time-equivalent basis is often called “discounting.”

The value of money is time-dependent for two reasons: First, inflation or deflation can change the buying power of the dollar; and second, money can be invested over time to yield a return over and above inflation. For these two reasons, a given dollar amount today will be worth more than that same dollar amount a year later. For example, suppose a person were able to earn a maximum of 10% interest per annum risk-free. He or she would require \$1.10 a year from now to be willing to forego having \$1 today. If the person were indifferent between \$1 today and \$1.10 a year from now, then the 10% rate of interest would indicate that person's time preference for money. The higher the time preference, the higher the rate of interest required to make future cash flows equal to a given value today. The rate of interest for which an investor feels adequately compensated for trading money now for money in the future is the appropriate rate to use for converting present sums to future equivalent sums and future sums to present equivalent sums (i.e., the rate for discounting cash flows for that particular investor). This rate is often called the "discount rate."

To evaluate correctly the economic efficiency of an energy efficiency or renewable energy investment, it is necessary to convert the various expenditures and savings that accrue over time to a lump-sum, time-equivalent value in some base year (usually the present), or to annual values. The remainder of this section illustrates how to discount various types of cash flows.

Discounting is illustrated by Figure 12.9 in a problem of installing, maintaining, and operating a heat pump, as compared to an alternative heating/cooling system. The life-cycle cost calculations are shown for two reference times. The first is the present, and it is therefore called a present value. The second is based on a yearly time scale and is called an annual value. These two reference points are the most common in economic evaluations of investments. When the evaluation methods are derived properly, each time basis will give the same relative ranking of investment priorities.

**FIGURE 12.9**

Determining present-value LCCs: heat pump example. *Note:* <sup>a</sup>P, present value; A, annual value; F, future value. <sup>b</sup>UPW, uniform present worth factor; SPW, single present worth factor; UPW\*, uniform present worth factor with energy escalation. Purchase and installation costs are \$1500 incurred initially. (From Ruegg, R.T. and Marshall, H.E., *Building Economics: Theory and Practice*, Chapman & Hall, New York, 1990.)

The assumptions for the heat pump problem—which are given only for the sake of illustration and not to suggest actual prices—are as follows:

1. The residential heat pump (not including the ducting) costs \$1500 to purchase and install.
2. The heat pump has a useful life of 15 years.
3. The system has annual maintenance costs of \$50 every year during its useful life, fixed by contractual agreement.
4. A compressor replacement is required in the eighth year at a cost of \$400.
5. The yearly electricity cost for heating and cooling is \$425, evaluated at the outset, and increased at a rate of 7% per annum due to rising electricity prices.
6. The discount rate (a nominal rate that includes an inflation adjustment) is 10%.
7. No salvage value is expected at the end of 15 years.

The LCCs in the sample problem are derived only for the heat pump and not for alternative heating/cooling systems. Hence, no attempt is made to compare alternative systems in this discounting example. To do so would require similar calculations of life-cycle costs for other types of heating/cooling systems. Total costs of a heat pump system include costs of purchase and installation, maintenance, replacements, and electricity for operation. Using the present as the base-time reference point, we need to convert each of these costs to the present before summing them. If we assume that the purchase and installation costs occur at the base reference point (the present), the \$1500 is already in present value terms.

Figure 12.9 illustrates how to convert the other cash flows to present values. The first task is to convert the stream of annual maintenance costs to present value. The maintenance costs, as shown in the cash flow diagram of Figure 12.9, are \$50 per year, measured in current dollars (i.e., dollars of the years in which they occur). The triangle indicates the value to be found. Here we follow the practice of compounding interest at the end of each year. The present refers to the beginning of year one.

The discounting operation for calculating the present value of maintenance costs (last column of Figure 12.9) is to multiply the annual maintenance costs times the uniform present worth (UPW) factor. The UPW is a multiplicative factor computed from the formula given in Table 12.4, or taken from a look-up table of factors that have been published in many economics textbooks. UPW factors make it easy to calculate the present values of a uniform series of annual values. For a discount rate of 10% and a time period of 15 years, the UPW factor is 7.606. Multiplying this factor by \$50 gives a present value maintenance cost equal to \$380. Note that the \$380 present value of \$50 per year incurred in each of 15 years is much less than simply adding \$50 for 15 years (i.e., \$750). Discounting is required to achieve correct statements of costs and benefits over time.

The second step is to convert the one-time future cost of compressor replacement, \$400, to its present value. The operation for calculating the present value of compressor replacement is to multiply the *future value* of the compressor replacement times the single-payment present worth (SPW) factor, which can be calculated from the formula in Table 12.4, or taken from a discount factor look-up table. For a discount rate of 10% and a time period of 15 years, the SPW factor is 0.4665. Multiplying this factor by \$400 gives a present-value cost of the compressor replacement of \$187, as shown in the last column of Figure 12.9.

**TABLE 12.4**

Discount Formulas

Standard Nomenclature	Use When	Standard Notation	Algebraic Form
Single compound amount	Given P; to find F	(SCA, d%, N)	$F = P(1 + d)^N$
Single present worth	Given F; to find P	(SPW, d%, N)	$P = F \frac{1}{(1 + d)^N}$
Uniform compound amount	Given A; to find F	(UCA, d%, N)	$F = A \frac{(1 + d)^N - 1}{d}$
Uniform sinking fund	Given F; to find A	(USF, d%, N)	$A = F \frac{d}{(1 + d)^N - 1}$
Uniform capital recovery	Given P; to find A	(UCR, d%, N)	$A = P \frac{d(1 + d)^N}{(1 + d)^N - 1}$
Uniform present worth	Given A; to find P	(UPW, d%, N)	$P = A \frac{(1 + d)^N - 1}{d(1 + d)^N}$
Uniform present worth modified	Given A escalating at a rate e; to find P	(UPW*, d%, e, N)	$P = A \frac{(1 + e) \left[ 1 - \left( \frac{1 + e}{1 + d} \right)^N \right]}{d - e}$

*Note:* P, a present sum of money; F, a future sum of money, equivalent to P at the end of N periods of time at a discount rate of d; N, number of interest periods; A, an end-of-period payment (or receipt) in a uniform series of payments (or receipts) over N periods at discount rate d, usually annually; e, a rate of escalation in A in each of N periods.

Again, note that discounting makes a significant difference in the measure of costs. Failing to discount the \$400 would result in an overestimate of cost, in this case of \$213.

The third step is to convert the annual electricity costs for heating and cooling to present value. A year's electricity costs, evaluated at the time of installation of the heat pump, are assumed to be \$425. Electricity prices, for purposes of illustration, are assumed to increase at a rate of 7% per annum. This is reflected in Table 12.4 by multiplying \$425 times  $(1.07)^t$  where  $t = 1, 2, \dots, 15$ . The electricity cost at the end of the fourth year, for example, is  $\$425(1.07)^4 = \$55$ .

The discounting operation for finding the present value of all electricity costs (shown in Figure 12.9) is to multiply the initial, yearly electricity costs times the appropriate UPW\* factor. (An asterisk following UPW denotes that a term for price escalation is included.) The UPW or UPW\* discount formulas in Table 12.4 can also be used to obtain present values from annual costs or multiplicative discount factors from look-up tables can be used. For a period of 15 years, a discount rate of 10%, and an escalation rate of 7%, the UPW\* factor is 12.1092. Multiplying the factor by \$425 gives a present value of electricity costs of \$5146. Note, once again, that failing to discount (i.e., simply adding annual electricity expenses in current prices) would overestimate costs by \$1229 (\$6376–\$5146). Discounting with a UPW factor that does not incorporate energy price escalation would underestimate costs by \$1913 (\$5146–\$3233).

The final operation described in Figure 12.9 is to sum purchase and installation cost and the present values of maintenance, compressor replacement, and electricity costs. Total LCCs of the heat pump in present value terms are \$7213. This is one of the amounts that a designer would need for comparing the cost-effectiveness of heat pumps to alternative heating/cooling systems.

Only one discounting operation is required for converting the present value costs of the heat pump to annual value terms. The total present value amount is converted to the total

annual value simply by multiplying it by the uniform capital recovery (UCR) factor—in this case the UCR for 10% and 15 years. The UCR factor, calculated with the UCR formula given in Table 12.4, is 0.13147. Multiplying this factor by the total present value of \$7213 gives the cost of the heat pump as \$948 in annual value terms. The two figures—\$7213 and \$948 per year—are time-equivalent values, made consistent through the discounting.

Figure 12.9 provides a model for the designer who must calculate present values from all kinds of benefit or cost streams. Most distributions of values occurring in future years can be handled with the SPW, the UPW, or the UPW\* factors.

### 12.5.3 Discount Rate

Of the various factors affecting the NB of energy efficiency and renewable energy investments, the discount rate is one of the most dramatic. A project that appears economic at one discount rate will often appear uneconomic at another rate. For example, a project that yields NS at a 6% discount rate might yield net losses if evaluated with a 7% rate.

As the discount rate is increased, the present value of any future stream of costs or benefits is going to become smaller. High discount rates tend to favor projects with quick payoffs over projects with benefits deferred further in the future.

The discount rate should be set equal to the rate of return available on the next-best investment opportunity of similar risk to the project in question—that is, it should indicate the opportunity cost of the investor.

The discount rate may be formulated as a “real rate” exclusive of general price inflation or as a “nominal rate” inclusive of inflation. The former should be used to discount cash flows that are stated in *constant dollars*. The latter should be used to discount cash flows stated in *current dollars*.

### 12.5.4 Inflation

Inflation is a rise in the general price level. Because future price changes are unknown, it is frequently assumed that prices will increase at the rate of inflation. Under this assumption, it is generally easier to conduct all economic evaluations in constant dollars and to discount those values using “real” discount rates. For example, converting the constant dollar annual maintenance costs in Figure 12.9 to a present value can be easily done by multiplying by a UPW factor (calculated using a real discount rate) because the maintenance costs do not change over time. However, some cash flows are more easily expressed in current dollars—for example, equal loan payments, tax depreciation, etc. These can be converted to present values using a nominal discount rate.

### 12.5.5 Analysis Period

The analysis period is the length of time over which costs and benefits are considered in an economic evaluation. The analysis period need not be the same as either the “useful life” or the “economic life,” two common concepts of investment life. The useful life is the period over which the investment has some value; that is, the investment continues to conserve or provide energy during this period. Economic life is the period during which the investment in question is the least-cost way of meeting the requirement. Often, economic life is shorter than useful life.

The selection of an analysis period will depend on the objectives and perspective of the decision maker. A speculative investor who plans to develop a project for immediate sale, for example, may view the relevant time horizon as that short period of ownership from planning and acquisition of property to the first sale of the project. Although the useful life of a solar domestic hot water heating system, for example, might be 20 years, a speculative home builder might operate on the basis of a 2-year time horizon, if the property is expected to change hands within that period. Only if the speculator expects to gain the benefit of those energy savings through a higher selling price for the building, will the higher first cost of the solar energy investment likely be economic.

If an analyst is performing an economic analysis for a particular client, that client's time horizon should serve as the analysis period. If an analyst is performing an analysis in support of public investment or a policy decision, the life of the system or building is typically the appropriate analysis period.

When considering multiple investment options, it is best with some evaluation methods (such as LCC, IRR, and ORR) to use the same analysis period. With others like NPV and BCR, different analysis periods can be used. If an investment's useful life is shorter than the analysis period, it may be necessary to consider reinvesting in that option at the end of its useful life. If an investment's useful life is longer than the analysis period, a salvage value may need to be estimated.

### **12.5.6 Taxes and Subsidies**

Taxes and subsidies should be taken into account in economic evaluations, because they may affect the economic viability of an investment, the return to the investor, and the optimal size of the investment. Taxes, which may have positive and negative effects, include—but are not limited to—income taxes, sales taxes, property taxes, excise taxes, capital gain taxes, depreciation recapture taxes, tax deductions, and tax credits.

Subsidies are inducements for a particular type of behavior or action. They include grants—cash subsidies of specified amounts; government cost sharing; loan-interest reductions; and tax-related subsidies. Income tax credits for efficiency or renewable energy expenditures provide a subsidy by allowing specific deductions from the investor's tax liability. Property tax exemptions eliminate the property taxes that would otherwise add to annual costs. Income tax deductions for energy efficiency or renewable energy expenses reduce annual tax costs. The imposition of higher taxes on nonrenewable energy sources raises their prices and encourages efficiency and renewable energy investments.

It is important to distinguish between a before-tax cash flow and an after-tax cash flow. For example, fuel costs are a before-tax cash flow (they can be expensed), while a production tax credit for electricity from wind is an after-tax cash flow.

### **12.5.7 Financing**

Financing of an energy investment can alter the economic viability of that investment. This is especially true for energy efficiency and renewable energy investments that generally have large initial investment costs with returns spread out over time. Ignoring financing costs when comparing these investments against conventional sources of energy can bias the evaluation against the energy efficiency and renewable energy investments.

Financing is generally described in terms of the amount financed, the loan period, and the interest rate. Unless specified otherwise, a uniform payment schedule is usually

assumed. Generally, financing improves the economic effectiveness of an investment if the after-tax nominal interest rate is less than the investor's nominal discount rate.

Financing essentially reduces the initial outlay in favor of additional future outlays over time—usually equal payments for a fixed number of years. These cash flows can be treated like any other: The equity portion of the capital cost occurs at the start of the first year, and the loan payments occur monthly or annually. The only other major consideration is the tax deductibility of the interest portion of the loan payments.

### 12.5.8 Residual Values

Residual values may arise from salvage (net of disposal costs) at the end of the life of systems and components, from reuse values when the purpose is changed, and from remaining value when assets are sold prior to the end of their lives. The present value of residuals can generally be expected to decrease, other things equal, as (1) the discount rate rises, (2) the equipment or building deteriorates, and (3) the time horizon lengthens.

To estimate the residual value of energy efficiency or renewable energy systems and components, it is helpful to consider the amount that can be added to the selling price of a project or building because of those systems. It might be assumed that a building buyer will be willing to pay an additional amount equal to the capitalized value of energy savings over the remaining life of the efficiency or renewable investment. If the analysis period is the same as the useful life, there will be no residual value.

---

## 12.6 Economic Analysis Software for Renewable Energy Investments

Over the last three to four decades, a large number of models for the economic analysis of renewable energy systems have been developed. In the early years, the emphasis was on simpler models for the analysis of solar hot water and space heating. In the last decade, the emphasis has shifted to models of renewable electric technologies as those technologies have become more and more cost competitive. At the same time due to the complexities of the electric system, the models have become more and more sophisticated with respect to both system performance and system economics and financing. The need for reliable power and the variability of wind and solar are dealt with in many models by performance projections down to the hourly level. Similarly, the complex ownership and regulation of power plants and electric utilities has led to increasingly sophisticated financing and ownership structures in today's models. We will examine these intricacies as we briefly review a handful of the more prominent models used in the United States with an emphasis on the economic measures used, the technologies treated, and the different areas of emphasis of the different models.

*System advisor model* (available at <https://sam.nrel.gov/>) SAM is probably the most sophisticated of the tools available today for the analysis of renewable energy technologies in the electric sector. Developed by the National Renewable Energy Laboratory (NREL), "SAM makes performance predictions and cost of energy estimates for grid-connected power projects based on installation and operating costs and system design parameters that you specify as inputs to the model." (Gilman and Dobos 2012). It calculates the performance for each of the 8760 hours of the year which can be viewed at the hourly level or

through more aggregated measures like capacity factors and seasonal or annual output. The technologies it can evaluate include

- Photovoltaic systems (flat plate and concentrating)
- Parabolic trough concentrating solar power systems
- Power tower concentrating solar power systems
- Linear Fresnel concentrating solar power systems
- Dish-stirling concentrating solar power systems
- Conventional fossil-fuel thermal systems
- Solar water heating for residential or commercial buildings\*
- Large and small wind power projects
- Geothermal power and coproduction
- Biomass power

SAM can evaluate the economics of these systems from the perspective of different owners and developer perspectives to include

- Residential rooftop
- Commercial rooftop
- Utility scale (power purchase agreement)
  - Single owner
  - Leveraged partnership flip
  - All equity partnership flip
  - Sale leaseback

SAM calculates the following measures based on the cash flows for the ownership, financing, and other descriptors input by the user:

- Payback period (buildings only)
- Revenue with and without renewable energy system
- LCOE
- NPV
- Power purchase agreement price (electricity sales price)
- IRR

In making these financial calculations, SAM can account for a wide range of incentives including

- Investment-based incentives
- Capacity-based incentives
- Production-based incentives

---

\* This is the only non-electric-production technology that can be evaluated with SAM.

- Investment tax credits
- Production tax credits
- Depreciation (MACRS, straight-line, custom)

*Cost of Renewable Energy Spreadsheet Tool* (CREST is available at <https://financere.nrel.gov/finance/content/crest-cost-energy-models>) CREST was developed for NREL by Sustainable Energy Advantage. It is distinguished from SAM primarily in that it is easier to use, is spreadsheet based, and has fewer technical performance, financing, and economic-metric details and options. It calculates the first year cost of energy or the LCOE for photovoltaics, concentrating solar power, wind, and geothermal electricity technologies, as well as anaerobic digestion technologies. It can account for different cost-based incentives and several ownership structures.

*HOMER* (available at: <http://homerenergy.com/index.html>) HOMER can be used to design and analyze hybrid power systems, that can include storage, conventional generators and combined heat and power systems along with photovoltaics, wind, hydropower, and biomass. HOMER was also originally developed at NREL and is now supported by HOMER Energy. It is distinguished from NREL's SAM and CREST models described earlier primarily in that it can be used for grid and off-grid applications of hybrid and distributed energy systems. To analyze these systems, HOMER's performance calculations are made on an hourly basis for every hour of a year and show the changing mix over time of contributing generators from the hybrid system.

*RETScreen* (available from the Canadian government at: <http://www.etscreen.net/ang/home.php>): RETScreen is actually two separate programs—RETScreen 4, an Excel spreadsheet program (available at: <http://www.etscreen.net/ang/version4.php>), and RETScreen Plus, a Windows-based performance measurement and verification program. We focus here on the economic analysis part, RETScreen 4. It differs from the NREL suite of models described earlier primarily in that it addresses both electric and nonelectric renewable energy technologies as well as efficiency and cogeneration projects. It includes a large database of international resource and weather data for analyzing systems in almost all global locations, although it makes annual performance approximations, not hourly estimates. It calculates the standard set of economic metrics, for example, IRR, NPV, payback, through cash flow analysis that considers financing and tax provisions.

---

## 12.7 Summary

There are multiple methods for evaluating economic performance and multiple techniques of risk analysis that can be selected and combined to improve decisions in energy efficiency and renewable energy investments. Economic performance can be stated in a variety of ways, depending on the problem and preferences of the decision maker: as NPV, as LCCs, as the cost of energy, as a rate of return, as years to payback, or as a ratio. To reflect the reality that most decisions are made under conditions of uncertainty, risk assessment techniques can be used to reflect the risk exposure of the project and the risk attitude of the decision maker. Rather than expressing results in single, deterministic terms, they can be expressed in probabilistic terms, thereby revealing the likelihood

that the outcome will differ from the best-guess answer. These methods and techniques can be used to decide whether or not to invest in a given energy efficiency or renewable energy system; to determine which system design or size is economically efficient; to find the combination of components and systems that are expected to be cost-effective; to estimate how long before a project will break even; and to decide which energy-related investments are likely to provide the highest rate of return to the investor. The methods support the goal of achieving economic efficiency—which may differ from engineering technical efficiency. There are many models available today that can assist in evaluating the economic and financial viability of an investment in renewable energy.

---

## 12.8 Defining Terms

*Analysis period*—Length of time over which costs and benefits are considered in an economic evaluation.

*Benefit/cost (B/C) or saving-to-investment (SIR) ratio*—A method of measuring the economic performance of alternatives by dividing present-value benefits (savings) by present-value costs.

*Constant dollars*—Values expressed in terms of the general purchasing power of the dollar in a base year. Constant dollars do not reflect price inflation or deflation.

*Cost-effective investment*—The least-cost alternative for achieving a given level of performance.

*Current dollars*—Values expressed in terms of actual prices of each year (i.e., current dollars reflect price inflation or deflation).

*Discount rate*—Based on the opportunity cost of capital, this minimum acceptable rate of return is used to convert benefits and costs occurring at different times to their equivalent values at a common time.

*Discounted payback period*—The time required for the discounted annual net benefits derived from an investment to pay back the initial investment.

*Discounting*—A technique for converting cash flows that occur over time to equivalent amounts at a common point in time using the opportunity cost for capital.

*Economic efficiency optimization*—Maximizing net benefits or minimizing costs for a given level of benefits (i.e., “getting the most for your money”).

*Economic life*—That period of time over which an investment is considered to be the least-cost alternative for meeting a particular objective.

*Future value (worth)*—The value of a dollar amount at some point in the future, taking into account the opportunity cost of capital.

*Internal rate of return*—The discount rate that equates total discounted benefits with total discounted costs.

*Investment costs*—The sum of the planning, design, and construction costs necessary to obtain or develop an asset.

*Levelized cost of energy*—The before-tax revenue required per unit of energy to cover all costs plus a profit/return on investment equal to the discount rate used to levelize the costs.

*Life-cycle cost*—The total of all relevant costs associated with an asset or project over the analysis period.

*Net benefits*—Benefits minus costs.

*Present value (worth)*—Past, present, or future cash flows all expressed as a lump sum amount as of the present time, taking into account the time value of money.

*Real options analysis*—Method used to analyze investment decisions in which the decision maker has one or more options regarding the timing or sequencing of investment.

*Risk assessment*—As applied to economic decisions, the body of theory and practice that helps decision makers assess their risk exposures and risk attitudes in order to increase the probability that they will make economic choices that are best for them.

*Risk attitude*—The willingness of decision makers to take chances on investments with uncertain outcomes. Risk attitudes may be classified as risk averse, risk neutral, and risk taking.

*Risk exposure*—The probability that a project's economic outcome will be less favorable than what is considered economically desirable.

*Sensitivity analysis*—A non-probability-based technique for reflecting uncertainty that entails testing the outcome of an investment by altering one or more system parameters from the initially assumed values.

*Time value of money*—The amount that people are willing to pay for having money today rather than some time in the future.

*Uncertainty*—As used in the context of this chapter, a lack of knowledge about the values of inputs required for an economic analysis.

### 13.1 Introduction

Air pollution causes considerable damage to human health, flora and fauna, and materials. The damage costs are external costs, to the extent that they are not included in the prices of goods, that is, they are external to the market. The external costs can be internalized via taxes, tradable permits, or other environmental regulations. Here we use the term *damage costs*, to avoid possible ambiguities about the extent to which the damage costs are already internalized.

Since 1990, there has been much progress in the analysis of damage costs, thanks to several major projects to evaluate the external costs of energy in Europe (ExternE 1995, 1998, 2005, 2008) and also in the United States (ORNL/RFF 1994, Rowe et al. 1995, Abt 2004, NRC 2010). This chapter, by key participants of the ExternE project series, presents an overview of the methodology and the results.

The quantification of damage costs has many important applications:

- Guidance for environmental regulations (e.g., determining the optimal level of the limit for the emission of a pollutant)
- Finding the socially optimal level of a pollution tax
- Identifying technologies with the lowest social cost (e.g., coal, nuclear, or wind for the production of electricity?)
- Evaluating the benefits of improving the pollution abatement of an existing installation such as a waste incinerator
- Optimizing the dispatching of power plants
- “Green accounting,” that is, including corrections for environmental damage in the traditional accounts of GDP

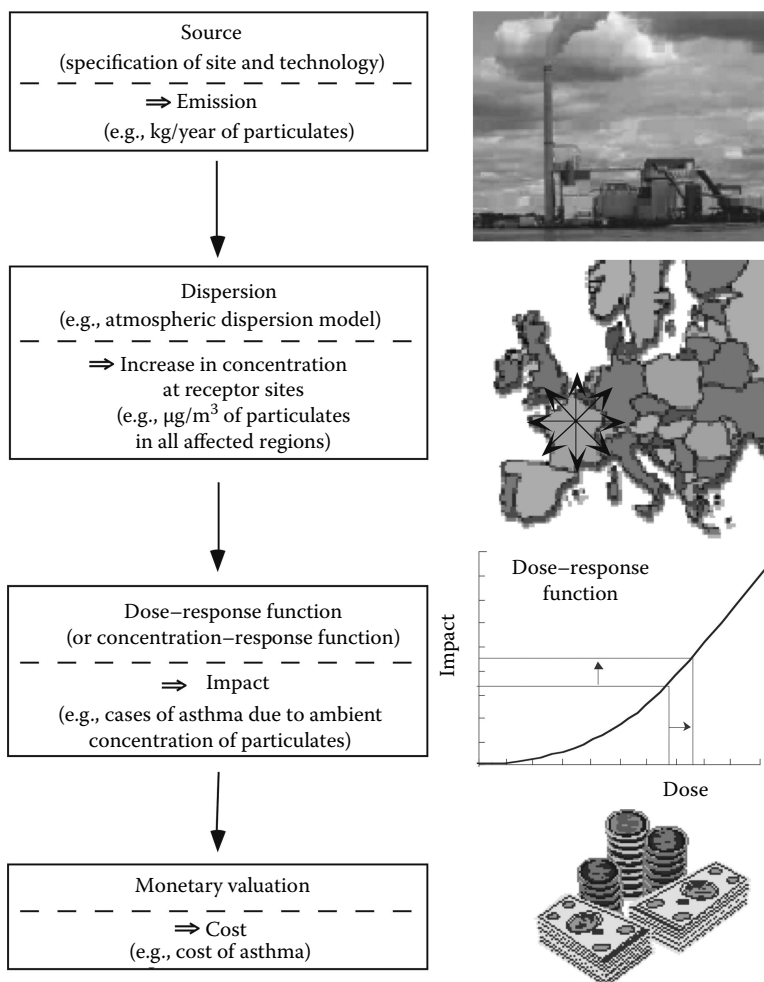

---

### 13.2 Methodology

#### 13.2.1 Impact Pathway Analysis (IPA)

To calculate the damage costs, one needs to carry out an impact pathway analysis (IPA), tracing the passage of a pollutant from where it is emitted to the affected receptors (population, crops, forests, buildings, etc.). The principal steps of an IPA can be grouped as follows, as shown in [Figure 13.1](#),

1. *Emission*: Specification of the relevant technologies and pollutants, for example, kg of  $\text{NO}_x$  per  $\text{GWh}_e$  emitted by a power plant
2. *Dispersion*: Calculation of increased pollutant concentrations in all affected regions, for example, incremental concentration of ozone, using models of atmospheric dispersion and chemistry for ozone formation due to  $\text{NO}_x$  (this step is also called environmental fate analysis, especially when it involves more complex pathways that pass through the food chain)

**FIGURE 13.1**

Impact pathway analysis (IPA). Another term for dose-response function is exposure-response function (ERF). (From Spadaro, J.V., Quantifying the damages of airborne pollution: Impact models, sensitivity analyses and applications, PhD doctoral thesis, Ecole des Mines de Paris, Paris, France, 1999.)

3. *Impact:* Calculation of the dose from the increased concentration and calculation of impacts (damage in physical units) from this dose, using dose-response functions (also known as exposure-response functions [ERFs]), for example, cases of asthma due to this increase in ozone
4. *Cost:* Monetary valuation of these impacts, for example, multiplication by the cost of a case of asthma

The impacts and costs are summed over all receptors of concern. The work involves a multidisciplinary system analysis, with inputs from engineers, dispersion modelers, epidemiologists, ecologists, and economists. The result of an IPA is the damage cost per kg of emitted pollutant, as shown in Figure 13.2.

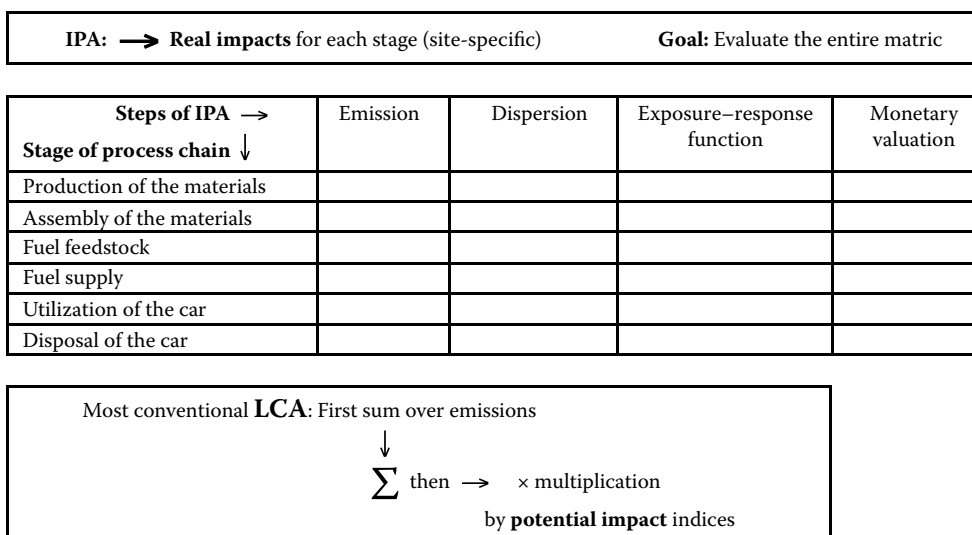

**FIGURE 13.2**

Typical damage costs in €<sub>2000</sub>/kg of pollutant for sources in the EU27, according to ExternE (2008). The error bars show 68% confidence intervals. *Note:* h, physical stack height of source; PM<sub>co</sub>, coarse particles (between 2.5 and 10 µm; aerodynamic size in microns).

### 13.2.2 Life Cycle Assessment (LCA)

For many environmental choices one needs to look not only at a particular source of pollutants, but has to take into account an entire process chain by means of a life cycle assessment (LCA). For example, a comparison of power generation technologies involves an analysis of the entire fuel chain, as sketched in Figure 13.3. Whether an IPA of a single source or an LCA of an entire process or product chain is required, depends on the policy choice in question. For finding the optimal limit for the emission of NO<sub>x</sub> from an incinerator, an IPA is sufficient, but the choice between coal, nuclear, and wind for electric power requires an LCA.

In principle, the damages and costs for each pollution source in the life cycle should be evaluated by a site-specific IPA. But in practice, most LCA studies have taken the shortcut of first summing the emissions over all stages and then multiplying the result by site-independent indices of *potential impact*. Also, most practitioners of LCA reject the concept of monetary valuation. By contrast, ExternE and analogous work in the United States are based on a realistic IPA assessment of the impacts and damage costs.

**FIGURE 13.3**

Relation between impact pathway analysis (IPA) and current practice of most LCA, illustrated for the example of electricity production with fossil fuel. (From Spadaro, J.V., Quantifying the damages of airborne pollution: Impact models, sensitivity analyses and applications, PhD doctoral thesis, Ecole des Mines de Paris, Paris, France, 1999; Spadaro, J.V. and Rabl, A., *Int. J. Life Cycle Assess.*, 4(4), 229, 1999.)

### 13.2.3 Atmospheric Dispersion and Chemistry

The principal greenhouse gases, CO<sub>2</sub>, CH<sub>4</sub>, and N<sub>2</sub>O, stay in the atmosphere long enough to mix uniformly over the entire globe. For most other air pollutants, in particular PM<sub>10</sub>,\* NO<sub>x</sub>, and SO<sub>2</sub>, atmospheric dispersion is significant over hundreds to thousands of km, so both local and regional effects are important. One needs, therefore, a combination of local and regional dispersion models to account for all significant damages. For the local range (<50 km from the source), Gaussian plume models can be used.

At the regional scale, one needs to take into account the chemical reactions that lead to the transformation of primary pollutants (i.e., the pollutants as they are emitted) to secondary pollutants, for example, the creation of sulfates from SO<sub>2</sub>.

Whereas, only the inhalation dose matters for the classical air pollutants (PM<sub>10</sub>, NO<sub>x</sub>, SO<sub>2</sub>, and O<sub>3</sub>), certain micropollutants (toxic metals and persistent organic pollutants) affect us also through food and drink. A relatively simple model for the passage of such pollutants through the food chain has been developed by Spadaro and Rabl (2004). A general finding of such calculations is that the dose from ingestion can be about two orders of magnitude larger than that from inhalation. However, for electric power technologies, the emitted quantities of these micropollutants are so small that they make at most a small contribution to the total damage cost (even for the dirtiest fuels, coal, and heavy oil).

\* Usually PM (particulate matter) has a subscript, indicating the largest size in μm, of the particles that are included in the measured PM concentration. The most common measures are PM<sub>10</sub> and PM<sub>2.5</sub>.

### 13.2.4 Exposure–Response Functions (ERFs)

The dose–response function, also known as exposure–response function (ERF), relates the pollution exposure that affects a receptor (e.g., population) to the physical impact on this receptor (e.g., incremental number of hospitalizations). A damage can be quantified only if the corresponding ERF is known. Such functions are known for the most important impacts on human health, building materials, and crops, caused by the most important air pollutants such as primary and secondary (i.e., nitrates, sulfates) particles, ozone, CO, SO<sub>2</sub>, NO<sub>x</sub>, benzene, dioxins, As, Cd, Cr, Hg, Ni, and Pb.

### 13.2.5 Monetary Valuation

The goal of the monetary valuation of damages is to account for all costs, market and non-market. For example, the valuation of an asthma attack has to include not only the cost of the medical treatment but also the willingness-to-pay (WTP) to avoid the remaining suffering. If the WTP for a nonmarket good has been determined correctly, it is like a price, consistent with prices paid for market goods. Economists have developed several tools for determining nonmarket costs; of these tools, contingent valuation (CV) has enjoyed increasing popularity (Mitchell and Carson 1989). The basic idea of a CV is to ask people how much they would be willing to pay for a certain good if they could buy it. Countless CV studies have been carried out and can be used for the assessment of damage costs.

As it turns out, damage costs of air pollution are dominated by nonmarket goods, especially the valuation of mortality. The single most important parameter is the so-called *value of statistical life* (VSL). This term often evokes hostile reactions from people who think that economists try to measure the value of life. The value of life is limitless (to save an individual in danger no means are spared). Really VSL is the *willingness to pay for avoiding the risk of an anonymous premature death*. A better term is *value of prevented fatality* (VPF).

### 13.2.6 Health Impacts

In monetary terms, the health impacts contribute the largest part of the damage costs. The most important cost comes from chronic mortality due to particulate matter (PM), calculated on the basis of data obtained by Pope et al. (2002) (this term, chosen by analogy with acute and chronic morbidity impacts, indicates that the total or long-term effects of pollution on mortality have been included, by contrast to acute mortality impacts that are observed within a few days of exposure to pollution). Table 13.1 shows the most important pollutants and impacts on health. Primary pollutants are the pollutants as they are emitted, secondary pollutants are created in the environment by chemical transformation of certain primary pollutants. For instance, SO<sub>2</sub> is transformed to sulfate aerosols, and the assessments by ExternE, Abt (2004), and NRC (2010) assume that their health impacts are like those of PM.

### 13.2.7 Global Warming

Estimating the cost of global warming is difficult because of the large number of different impacts in all countries of the world that should be taken into account. Furthermore, as these impacts will occur in future decades and centuries one needs to estimate how these impacts and costs will evolve into the distant future (IPCC 2007). On top of the scientific uncertainties, there are controversial ethical issues related to the valuation of mortality in developing countries (where most of the impacts will occur) and the choice of the discount rate for intergenerational costs.

**TABLE 13.1**

## Air Pollutants and Their Effects on Health

Primary Pollutants	Secondary Pollutants	Impacts
Particulate matter (PM <sub>10</sub> , PM <sub>2.5</sub> )		Mortality, cardiopulmonary morbidity, (cerebrovascular hospital admissions, congestive heart failure, chronic bronchitis, chronic cough in children, lower respiratory symptoms, cough in asthmatics)
SO <sub>2</sub>		Mortality, cardiopulmonary morbidity (hospitalization, consultation of doctor, asthma, sick leave, restricted activity)
SO <sub>2</sub>	Sulfates	Assumed to be like PM
NO <sub>x</sub>		Morbidity
NO <sub>x</sub>	Nitrates	Assumed to be like PM
NO <sub>x</sub> + VOC	Ozone	Mortality, morbidity (respiratory hospital admissions, restricted activity days, asthma attacks, symptom days)
CO		Mortality (congestive heart failure), morbidity (cardiovascular)
PAH (diesel soot, benzene, 1,3-butadiene, dioxins)		Cancers
As, Cd, Cr <sup>VI</sup> , Ni		Cancers, other morbidity
Hg, Pb		Morbidity (neurotoxic), mortality

Many studies have been published with estimates of the cost per tonne of CO<sub>2</sub>. Tol (2005) carried out a comprehensive review of studies of climate change costs. Combining the over 100 estimates for the marginal damage cost of CO<sub>2</sub> to form an overall probability density function, he finds that the distribution is strongly right-skewed, with a median of \$3.8/t<sub>CO<sub>2</sub></sub>, a mean of \$25.4/t<sub>CO<sub>2</sub></sub>, and upper bound of the 95% confidence interval of \$95/t<sub>CO<sub>2</sub></sub>. According to Tol, under standard assumptions of time discounting, equity weighting, and risk aversion, the marginal damage cost is unlikely to exceed \$14/t<sub>CO<sub>2</sub></sub> and is probably even smaller. This value is significantly lower than the \$85/t<sub>CO<sub>2</sub></sub>\* reported by the widely publicized Stern Review (Stern et al. 2006). The discrepancy can to a large extent be explained by the very low value of the intergenerational discount rate employed by Stern et al., in contrast to the conventional social discount rate used by most other studies.

The conventional social discount rate has two components: the growth rate of the economy and the so-called pure rate of time preference (basically the impatience of people to consume now rather than in the future). We have shown that inclusion of the pure rate of time preference in the intergenerational discount rate leads to an inconsistency in any cost-benefit analysis of abatement options for climate change: the moneys assumed for future cost-benefit trade-offs will not be there (Rabl 1996, Rabl et al. 2014). Since the discount rate of the Stern Review is very close to taking the pure rate of time preference as zero, we believe that its damage cost estimate is closer to the truth than estimates obtained with the conventional discount rate, in particular the value of 21 €/t<sub>CO<sub>2</sub>eq</sub> used by the current phase of Externe (2008).†

\* 65 €/t<sub>CO<sub>2</sub></sub> at the exchange rate of \$1.3/€ during 2012.

† The subscript “eq” indicates that the result can also be used for other greenhouse gases if their masses are multiplied by their global warming potential (GWP).

### 13.3 Assumptions and Models of ExternE

#### 13.3.1 Assumptions

The key assumptions for the calculations of ExternE are summarized in Table 13.2. They have been implemented in the EcoSense software that has been used to calculate the damage costs of ExternE. The atmospheric modeling is based on source–receptor (SR) matrices that have been provided specifically for ExternE by EMEP, the official modeling organization for transboundary pollution in Europe (<http://www.emep.int/>). The grid cell size is approximately 50 km × 50 km for the model of the European region, that is, the continent plus adjacent areas.

For PM, the emissions are provided in terms of PM<sub>2.5</sub> and PM<sub>co</sub> (= PM fraction between 2.5 and 10 µm) rather than PM<sub>10</sub>, and so are the SR matrices and the damage costs. Damage costs for PM<sub>10</sub> can be calculated if one knows the respective fractions are  $f_{2.5}$  and  $f_{co}$  of PM<sub>2.5</sub> and PM<sub>co</sub> in the PM<sub>10</sub>.

$$\text{€/kg}_{\text{PM10}} = f_{2.5} \text{ €/kg}_{\text{PM2.5}} + f_{co} \text{ €/kg}_{\text{PMco}}. \quad (13.1)$$

**TABLE 13.2**

Key Assumptions for the Calculations of ExternE

Atmospheric dispersion models	
Local range	Gaussian plume models ISC (for elevated sources) and ROADPOL (for ground level sources).
Regional range (Europe)	Source–receptor (SR) matrices calculated by EMEP were used for ExternE (2008), without any local modeling. SR matrices were calculated for primary and secondary pollutants, including O <sub>3</sub> .
Impacts on health	
Form of ERFs	Straight line for all health impacts, without threshold for PM (primary and secondary) and with threshold for O <sub>3</sub> .
Chronic mortality	The ERF for life expectancy loss is derived from increase in age-specific mortality due to PM <sub>2.5</sub> (Pope et al. 2002), by integrating over age distribution.
Acute mortality	For ozone, assuming 0.75 YOLL per death.
Nitrate and sulfate aerosols	The ERFs for PM <sub>2.5</sub> and PM <sub>10</sub> are applied to nitrates and sulfates on the basis of mass and size range, without distinction of composition or other characteristics.
	Sulfates are assumed to be entirely PM <sub>2.5</sub> whereas for nitrates the PM <sub>2.5</sub> and PM <sub>co</sub> fractions are calculated by EMEP.
Radionuclides	Linear ERFs without threshold: 0.05 Fatal cancers/person-Sv; 0.12 Nonfatal cancers/person-Sv; 0.01 Severe effects hereditary/person-Sv.
Micropollutants	Cancers due to As, Cd, Cr, Ni, dioxins, benzene, butadiene, and formaldehyde. Neurotoxic impacts of Hg and Pb.
Impacts on plants	ERFs for crop loss due to SO <sub>2</sub> and ozone.
Impacts on buildings and materials	Corrosion and erosion due to SO <sub>2</sub> and soiling due to particles.
Monetary valuation	
Accidents	Value of prevented fatality (VPF) = 1.5 M€
Loss of life expectancy	Proportional to loss of life expectancy, with value of life year (VOLY) = €40,000 for chronic, and €60,000 for acute mortality.
Cancers	0.48 M€ per nonfatal cancer, 1.12 M€ per fatal cancer.
Discount rate	3% until 2030, 2% thereafter.

For example, what is the damage cost of PM<sub>10</sub> emissions from low stacks in the EU27 if they have a composition 60% PM<sub>2.5</sub> and 40% PM<sub>co</sub>? Inserting the respective numbers from Figure 13.2 into Equation 13.1 we obtain  $0.6 \times 26.1 \text{ €/kg}_{\text{PM}_{2.5}} + 0.4 \times 1.5 \text{ €/kg}_{\text{PM}_{\text{co}}} = 16.3 \text{ €/kg}_{\text{PM}_{10}}$ .

### 13.3.2 ERFs and Unit Costs

The ERF slopes and unit costs of ExternE (2008) are listed in Table 13.3 (Preiss et al. 2008). The entries in the ERF column include the fraction of the total population that is affected by the respective pollutant and endpoint, thus they are applied directly to the general population.

As EMEP provides SR matrices for PM<sub>2.5</sub> and PM<sub>co</sub> but not for PM<sub>10</sub>, one has to decide how to apply the ERFs for PM<sub>10</sub>. For that one would need to know how much of the impact of the

**TABLE 13.3**

Exposure–Response Function Slopes and Unit Costs, Assumed by ExternE (2008)

Pollutant	Endpoint	ERF Slope	Unit Cost	Exposure Cost	
		(cases/year) per (person·µg/m <sup>3</sup> )	€ <sub>2000</sub> /case	(€/year) per (person·µg/m <sup>3</sup> )	% of Total
PM <sub>2.5</sub>	Chronic mortality, YOLL	6.51E-04	40,000 <sup>a</sup>	26.04	79.4%
	Net restricted activity days (netRAD)	9.59E-03	130	1.25	3.8%
	Work loss days (WLD)	1.39E-02	295	4.10	12.5%
	Minor restricted activity days (MRAD)	3.69E-02	38	1.40	4.3%
	<b>Total</b>			<b>32.79</b>	<b>100%</b>
PM <sub>10</sub>	Infant mortality, deaths	6.84E-08	3,000,000	0.205	3.4%
	New cases of chronic bronchitis	1.86E-05	200,000	3.710	62.2%
	Respiratory hospital admissions	7.03E-06	2,000	0.014	0.2%
	Cardiac hospital admissions	4.34E-06	2,000	0.009	0.1%
	Medication/bronchodilator use, children	4.03E-04	1	0.000	0.0%
	Medication/bronchodilator use, adults	3.27E-03	1	0.003	0.1%
	LRS, children, days	2.08E-02	38	0.792	13.3%
	LRS, adults, days	3.24E-02	38	1.230	20.6%
	<b>Total</b>			<b>5.963</b>	<b>100%</b>
O <sub>3</sub> , SOMO35	Acute mortality, YOLL	2.23E-06	60,000 <sup>b</sup>	0.134	15.1%
	Respiratory hospital admissions	1.98E-06	2,000	0.004	0.4%
	Minor restricted activity days (MRAD)	7.36E-03	38	0.280	31.7%
	Medication use/ bronchodilator use	2.62E-03	1	0.003	0.3%
	LRS excluding cough, days	1.79E-03	38	0.068	7.7%
	Cough days	1.04E-02	38	0.396	44.8%
	<b>Total</b>			<b>0.885</b>	<b>100%</b>

Note: YOLL, years of life lost; LRS, lower respiratory symptoms; SOMO35, sum of ozone means over 35 ppb (Equation 13.3).

<sup>a</sup> Value of life year lost due to chronic exposure (discounted because of delay between exposure and death).

<sup>b</sup> Value of life year lost due to acute exposure (not discounted).

PM<sub>10</sub> ERFs is due to PM<sub>2.5</sub> and how much due to PM<sub>co</sub>. Such information is not available, and so the following somewhat literal interpretation has been used by ExternE (2008) for applying the ERFs for PM<sub>10</sub>: both PM<sub>2.5</sub> and PM<sub>co</sub> being by their definition also PM<sub>10</sub>, the PM<sub>10</sub> exposure costs are applied to both PM<sub>2.5</sub> and PM<sub>co</sub>. To calculate the damage cost of PM<sub>2.5</sub>, the concentration of PM<sub>2.5</sub> is multiplied by each of the exposure costs for PM<sub>2.5</sub> and for PM<sub>10</sub>, and the resulting terms are summed; thus the PM<sub>2.5</sub> concentrations are multiplied by (32.79 + 5.963) (€/year) per (person µg/m<sup>3</sup>). For the damage cost of PM<sub>co</sub>, the concentration of PM<sub>co</sub> is multiplied by the exposure costs for PM<sub>10</sub>; thus the PM<sub>co</sub> concentrations are multiplied by 5.963 (€/year) per (person µg/m<sup>3</sup>). This procedure, documented in Preiss et al. (2008), can be summarized as follows:

$$\begin{aligned}\text{Cost per PM}_{2.5} \text{ exposure} &= (32.79 + 5.963) \text{ (€/year)/(person } \mu\text{g/m}^3\text{)} \\ &= 38.753 \text{ (€/year)/(person } \mu\text{g/m}^3\text{)}\end{aligned}\quad (13.2a)$$

and

$$\text{Cost per PM}_{co} \text{ exposure} = 5.963 \text{ (€/year)/(person } \mu\text{g/m}^3\text{)}. \quad (13.2b)$$

For O<sub>3</sub>, ExternE (2008) assumes a hockey stick ERF with zero impact below a threshold of 35 ppb and linear increase above. This is implemented by stating the ERF slope in terms of SOMO35, the sum of ozone means over 35 ppb. More explicitly SOMO35 is defined as the sum of the differences between maximum daily 8 h moving average concentrations greater than 35 ppb (= 70 µg/m<sup>3</sup>) and 35 ppb:

$$\text{SOMO35} = \sum_{i=1}^{365} \text{Max}[0, c_i - 35\text{ppb}] \quad (13.3)$$

where  $c_i$  is the maximum daily 8 h running mean ozone concentration in ppb and the summation is over all days per calendar year. SOMO35 has a dimension of ppb·days (or (µg/m<sup>3</sup>)·days).

Multiplying the ERF slope by the unit cost, one obtains the exposure cost, that is, the incremental cost per 1/(µg/m<sup>3</sup>) per person per year, to be multiplied by the population in the grid cells of EcoSense and by the concentration increase per kg of emitted pollutant to calculate the cost per kg of pollutant. In the uniform world model (UWM), the incremental cost per 1/(µg/m<sup>3</sup>) per person per year is multiplied by the regional population density and divided by the depletion velocity  $v_{\text{dep}}$ , see the example in Section 13.3.4.

### 13.3.3 Damage Costs of ExternE (2008)

Figure 13.2 shows the damage costs calculated by ExternE (2008) for typical emissions in the EU27. The error bars indicate the uncertainties, as 68% confidence intervals (corresponding to one geometric standard deviation), as estimated by Spadaro and Rabl (2008).

Not shown in Figure 13.2 are the greenhouse gases. The cost per tonne of CO<sub>2</sub> depends on when it is emitted. The value used by ExternE (2008), 21 €/t<sub>CO<sub>2</sub>eq</sub> for emissions in 2010.

### 13.3.4 UWM: A Simple Model for Damage Cost Estimation

A simple and convenient tool for the development of typical values is the UWM, first presented by Curtiss and Rabl (1996) and further developed, with detailed validation studies, by Spadaro (1999), Spadaro and Rabl (2002), and Rabl et al. (2014). The UWM is a product of a few factors; it is simple and transparent, showing at a glance the role of the most important parameters of the IPA. It is exact for tall stacks in the limit where the distribution of

either the sources or the receptors is uniform and the key atmospheric parameters do not vary with location. In practice, the agreement with detailed models is usually within a factor of two for stack heights above 50 m. For policy applications, one needs typical values and the UWM is more relevant than a detailed analysis for a specific site.

The UWM for the damage cost rate  $\dot{D}_{uni}$  in €/year of a particular impact due to the emission rate  $\dot{m}$  of a primary pollutant is

$$\dot{D}_{uni} = p S_{ERF} \dot{m} \rho / v_{dep} \quad (13.4)$$

where

$p$  = unit cost per case (*price*) (€/case)

$S_{ERF}$  = ERF slope ([cases/year]/[person·(μg/m<sup>3</sup>)])

$\dot{m}$  = emission rate of pollutant (kg/year)

$\rho$  = average (land and water) population density (person/km<sup>2</sup>) within 1,000 km of source

$v_{dep}$  = depletion velocity of pollutant (m/s)

The latter quantity accounts for the removal rate of the pollutant from the atmosphere, due to dry and wet deposition. For secondary pollutants, the equation has the same form, but with an effective depletion velocity that includes the transformation rate of the primary into the secondary pollutant. With this model it is easy to transfer the results from one region to another (if ERF and depletion velocity are the same): simply rescale the result in proportion to receptor density and unit cost.

### Example 13.1

Use the UWM to estimate the contribution of chronic mortality to the cost of PM<sub>2.5</sub> if the regional population density  $\rho = 100$  persons/km<sup>2</sup> and the depletion velocity  $v_{dep} = 0.005$  m/s.

#### Solution

Inserting the entries for chronic mortality in Table 13.3 and an emission rate of  $\dot{m} = 1$  kg/year into Equation 13.4, we find an impact rate of

$$\begin{aligned} \dot{D}_{uni} &= \frac{40,000 \text{ €}}{\text{YOLL}} \times \frac{6.51\text{E-}04 \text{ YOLL/year}}{\text{person} \cdot (\mu\text{g/m}^3)} \times \frac{10^{-4} \text{ persons}}{\text{m}^2} \times \frac{1 \text{ kg}}{365.25 \times 24 \times 3600 \text{ s}} \times \frac{10^9 \mu\text{g/kg}}{0.005 \text{ m/s}} \\ &= 16.50 \text{ €/year.} \end{aligned}$$

Since both emission rate and impact rate are stated per year, the cost per kg is 16.50 €/kg.

## 13.4 Results for Electricity Production

### 13.4.1 General Remarks

Since the 1990s, several assessments of fuel chains have been carried out, both in the United States (Levy et al. 1999, 2009, Abt 2004, NRC 2010) and the EU (ExternE 1995, 1998, 2008, Rabl et al. 2004). They all use an IPA, generally based on the same literature, although with somewhat different interpretations. The focus in all these studies is on greenhouse gases and the classical air pollutants. Here we summarize key results for the United States and EU27.

To put the damage costs in perspective, we show in Table 13.4 the average selling price of electricity in the United States and in France, for industrial and for residential consumers.

**TABLE 13.4**

Average Selling Price of Electricity in the United States and in France around 2010 for Industrial and for Residential Consumers

	Residential	Industrial
United States, ¢/kWh	11.0	6.7
France, ¢cent/kWh	11.0	6.0

### 13.4.2 Damage Costs of Power in the EU27

The emissions inventory of ExternE (2008) for coal and natural gas plants is summarized in Table 13.5. It is based on the ecoinvent database (Frischknecht et al. 2007) and distinguishes four LCA stages: construction of the power plant, operation of the power plant (for fossil plants combustion of the fuel), dismantling of the power plant, and fuel (for fossil plants production and transport of the fuel).

In Figures 13.4 and 13.5 we show selected results, with two entries for nuclear and wind, respectively. For wind, the first entry is for a system to supply base load power, consisting of wind turbine plus natural gas combined cycle (NGCC). The second entry is for wind turbines alone, assuming that sufficient storage is available; this entry does not include any costs for storage. The first entry for nuclear is taken directly from the data CD of ExternE (2008), for the second entry we have added the estimate of Rabl and Rabl (2013) for the cost of a catastrophic accident and waste storage. The choice between the two estimates for nuclear power involves problematic subjective judgments: is the future accident risk for reactors under consideration as bad as the worldwide average in the past, and is the cost of waste management fully internalized by the payments to a reserve fund that are currently paid by the nuclear industry?

The arrows in Figure 13.4 indicate the total cost where it exceeds the scale of the graph. For photovoltaics (PV), there has been a dramatic decrease of the private cost since 2011 and we do not try to estimate the current cost per kWh. The private cost of nuclear was estimated by EdF (Electricité de France), the world's largest nuclear utility company which in the past has been able to build nuclear power plants for impressively low cost, thanks to

**TABLE 13.5**

Typical Emissions by Coal and Gas Power Plants in the EU-27, in g/kWh<sub>e</sub>

	Hard Coal, Condensing Power Plant			Natural Gas Combined Cycle		
	Upstream	Plant	Total	Upstream	Plant	Total
CO <sub>2</sub>	30.9	730.2	761.1	46.9	355.5	402.4
CH <sub>4</sub>	2.2	0.0	2.2	1.0	0.0	1.0

The results can be found in the data CD distributed with the CASES book edited by Markandya, A., Bigano, A., and Porchia, R. in 2010: *The Social Cost of Electricity: Scenarios and Policy Implications*, Edward Elgar Publishing Ltd., Cheltenham, U.K.

<sup>a</sup> Assuming GWP of 25 for CH<sub>4</sub>.

**FIGURE 13.4**

Selected results for the costs, both external and private, of current power technologies in the EU27. The arrows indicate the estimated total cost. For the second version of nuclear, the estimate of Rabl and Rabl (2013) for accident and waste has been added. For wind, the first version is for a combination wind + NGCC for base load (without private costs), the second version is for wind with storage (but without costs for the latter). (Data of ExternE, 2008, with this reference we cite the methodology and results of the latest phases of ExternE: NEEDS (2004–2008) and CASES (2006–2008). The results can be found in the data CD distributed with the CASES book edited by Markandya, A., Bigano, A., and Porchia, R., in 2010: *The Social Cost of Electricity: Scenarios and Policy Implications*, Edward Elgar Publishing Ltd., Cheltenham, U.K.)

**FIGURE 13.5**

Breakdown of damage costs of Figure 13.4 by stages of fuel chain. (Data of ExternE, 2008, with this reference we cite the methodology and results of the latest phases of ExternE: NEEDS (2004–2008) and CASES (2006–2008). The results can be found in the data CD distributed with the CASES book edited by Markandya, A., Bigano, A., and Porchia, R., in 2010: *The Social Cost of Electricity: Scenarios and Policy Implications*, Edward Elgar Publishing Ltd., Cheltenham, U.K.)

strong efficiencies and economies of scale and efficient centralized management. But even in France the cost of nuclear power has been increasing, driven by safety measures implemented in response to Chernobyl and Fukushima. It is interesting to compare the private cost in Figure 13.4 with the levelized energy cost of 11 ¢/kWh<sub>e</sub> estimated for new nuclear plants in the United States by EIA (2012) ([http://www.eia.gov/forecasts/aeo/electricity\\_generation.cfm](http://www.eia.gov/forecasts/aeo/electricity_generation.cfm)).

Generally, the damage costs are largest for fossil fuels without CO<sub>2</sub> capture. Since carbon capture and sequestration (CCS) is a new technology that has not yet been tested in full-scale plants, the cost estimates are extremely uncertain and we do not show them in these figures. The health and environmental costs of fossil plants with CCS can readily be estimated from Figure 13.4. The greenhouse gas emissions are reduced by a factor of about 5–7. Unfortunately, CCS is energy-intensive and increases the fuel input by about 10%–20%. Since the combustion process and the quantity of classical pollutants per tonne of input fuel are unchanged, CCS increases the health and non-greenhouse gas environmental impacts of the fossil plants in Figure 13.4 by a factor of 1.1–1.2. In Sections 13.4.4 and 13.4.5, we provide further detail on the nuclear and renewable technologies.

### 13.4.3 Damage Costs of Power in the United States

The externality study by NRC (2010) uses a methodology very similar to ExternE. In Table 13.6, we show the emissions and damage costs of coal and gas-fired power plants; they do not include upstream emissions. Both emission per kWh and damage cost per kg vary widely, and the indicated range includes all values from the 5th percentile to the 95th percentile (in these distributions all plants are weighted equally, by contrast to the results shown in Figure 13.6). The mean of the SO<sub>2</sub> and PM<sub>10</sub> emissions from coal plants is an order of magnitude higher than in the EU as shown by a comparison with Table 13.5. The NO<sub>x</sub> emissions are about three times higher. Gas is much cleaner, but even here the emissions are significantly higher than in the EU. We had some trouble interpreting the PM data in NRC (2010) because different contributors used different definitions for PM<sub>10</sub>; whereas, the emissions data seem to be specified with the usual definition of PM<sub>10</sub>, the impacts seem to be reported according to the awkwardly unconventional definition given in the footnote on p. 313 of their Appendix C where PM<sub>10</sub> is defined as PM between 2.5 and 10 µm, a quantity designated PM<sub>co</sub> in ExternE and in this chapter.

**TABLE 13.6**

Emissions and Damage Costs for Coal and Gas Power Plants

Pollutant	g/kWh, Coal Mean (Range)	\$/kg, Coal Mean (Range)	g/kWh, Natural Gas Mean (Range)	\$/kg, Natural Gas Mean (Range)
SO <sub>2</sub>	5.44 (0.68–14.97)	6.39 (1.98–12.13)	0.02 (0.00–0.07)	14.33 (1.98–48.51)
NO <sub>x</sub>	1.86 (0.59–4.08)	1.76 (0.75–3.09)	1.04 (0.02–2.49)	2.43 (0.51–5.40)
PM <sub>2.5</sub>	0.27 (0.04–0.82)	10.47 (2.87–28.67)	0.05 (0.00–0.13)	35.28 (2.87–176.41)
PM <sub>co</sub>	0.06 (0.05–0.95)	0.51 (0.15–1.43)	0.00 (0.00–0.15)	1.87 (0.19–8.60)

*Source:* Data of NRC, Hidden costs of energy: Unpriced consequences of energy production and use, National Research Council of the National Academies, Washington, DC, 2010, Available from National Academies Press, [http://www.nap.edu/catalog.php?record\\_id=12794](http://www.nap.edu/catalog.php?record_id=12794).

*Note:* The range covers the distribution from 5% to 95%; it indicates geographical variability, not uncertainty. These data and Figure 13.6 include only the power plants, without upstream emissions.

**FIGURE 13.6**

Results of NRC (2010) for damage costs of electric power in the United States, in ¢/kWh. For illustrative purposes the study indicates climate damage with a hypothetical \$30/t<sub>CO<sub>2</sub>eq</sub>.

Finally, Figure 13.6 shows the average damage cost of coal and gas power plants in the United States, weighted according to their production. For the cost of greenhouse gases, NRC (2010) does not want to make a definitive choice but uses \$30/t<sub>CO<sub>2</sub>eq</sub> as a hypothetical value for the purpose of illustration (25 €/t<sub>CO<sub>2</sub>eq</sub> at an exchange rate of \$1.3/€).<sup>\*</sup> The damage costs in Table 13.6 and Figure 13.6 include only the power plant emissions, not upstream or downstream impacts. As for nuclear power, NRC only reviews the studies by ORNL/RFF (1994) and Externe (1995) without trying a new assessment. No damage cost estimates are provided for renewable energy sources. Like in Europe the damage costs for fossil fuel power plants are very significant compared to the market price (see Table 13.4).

NRC also has some interesting data on combustion products of coal power plants. The total production of coal wastes is about 120 million tonnes/year, of which 43% is utilized, mostly for construction materials. The quantity of combustion products is 0.06 kg/kWh of electricity from coal.

### 13.4.4 Nuclear Fuel Chain

#### 13.4.4.1 Normal Operation

Several assessments of the nuclear fuel cycle have been published since 1990, including Externe (1995), ORNL/RFF (1994), Ontario Hydro (1993), and Externe (2008). All of these are based on IPA and LCA, and they all agree that the damage cost due to radionuclides from normal operation is very small. The only significant radiological contribution to the damage cost comes from human health, in particular cancers and hereditary effects. Some studies find significant non-radiological contributions if isotope separation is done in countries where much of the electricity comes from fossil fuels, especially coal. But even those studies find that the total external costs from the normal operation of the nuclear fuel chain are small compared to fossil fuels.

To illustrate how small the radiological doses from normal operation are, Rabl et al. (2014) look at the dose per person that would result if the nuclear technology of France of the 1990s were used to provide electricity at a rate equal to the entire electricity production

<sup>\*</sup> The NRC report uses the same “tons” for both short tons (= 907 kg) and metric tonnes. Since the climate change literature is based on tonnes, we believe that NRC means tonnes for CO<sub>2</sub>, by contrast to results for other pollutants which are presumably in short tons because they are calculated with the APEEP model which works with short tons (Nick Muller, personal communication, May 21, 2013).

of the world in 2010 (20,000 TWh/year) for the next 100 years. Such a scenario would increase the dose rate by only about 0.15% beyond the background, which is generally around 2.5 mSv/year, almost entirely due to natural sources (radon and cosmic radiation) and medical x-rays. New nuclear plants have significantly lower emissions than what we assumed for this scenario, and in any case uranium-based fission reactors are only a stop-gap until cleaner technologies come on line.

However small the impacts of the normal operation may be, there remains concern about the three problematic aspects of nuclear power: waste management, catastrophic accidents, and the link to proliferation and terrorism. The latter defies quantification in terms of costs. The risks from nuclear waste evoke fear because of the long lives of some of the radionuclides. However, those risks can be rendered negligible if one chooses permanently safeguarded retrievable storage, the option currently planned for France. Even with sealed *leave alone* storage such had been planned at Yucca Mountain in the United States, the impacts of a leak would be limited to the local zone because any groundwater would not move far, and the resulting damage costs would be small, by contrast to emissions from a major nuclear accident which can disperse widely through air or ocean.

#### 13.4.4.2 Nuclear Accidents

Usually the cost of a large nuclear accident has been estimated by combining probabilistic safety assessments (PSAs) of nuclear reactors, to determine the probability of an accident, with programs to evaluate the health and economic consequences of an accident. Such calculations have been carried out by ORNL/RFF (1994), Externe (1995), and Dreicer et al. (1995), and the costs per kWh were found to be quite small because of the low probability estimated by PSAs based on engineering fault tree analysis.

But is the probability of severe accidents really so low? Since they are rare occurrences, historical data do not provide much guidance. There have been only two severe accidents with significant release of core material: Chernobyl and Fukushima. They are rated seven, the highest number on the scale of accident severity which is logarithmic. The accident of Three Mile Island rates only five on this scale. Each time one learns and improves the safety. No one builds Chernobyl-type reactors anymore, and the protection against earthquakes and floods will be improved after Fukushima. But what unexpected risks remain lurking in the background? Fear of another catastrophic accident where operators and designers have underestimated risk is why many people are calling for an end to nuclear power and even the shutdown of all existing nuclear plants, arguing that energy efficiency and renewables are clean and cost-effective alternatives.

It would not be wise to retire nuclear plants precipitously, if the alternatives entail total (private + damage) costs that are even higher. Rabl and Rabl (2013) have compared the damage costs of nuclear with those of the alternatives. Unlike the earlier assessments with complex and opaque computer calculations, they present a very simple and transparent calculation based on the actual track record of nuclear power plants. It is summarized in [Table 13.7](#) for nuclear and [Table 13.8](#) for the cleanest alternative; for detailed justification of the assumptions and parameters we refer to their paper. For their central estimate they assume impacts comparable to Chernobyl and Fukushima. The release of radioactive material and the ensuing health impacts of Chernobyl were much worse than for Fukushima. The total worldwide cancer deaths due to Chernobyl have been estimated as 24,000 by Garwin (2005) and as 16,000 (95% uncertainty interval 6,700–38,000) by Cardis et al. (2006). For Fukushima, Ten Hoeve and Jacobson (2012) put the total expected death toll at 130 (uncertainty range of 15–1100), based on detailed modeling of dispersion and doses.

**TABLE 13.7**

Assumptions and Results for the External Costs of Nuclear Power

Cost Elements	Parameter <sup>a</sup>	Units	Central	Low	High
Fatal cancers	10,000				
Cost per cancer	5	M€/cancer			
Discount factor for cancers <sup>b</sup>	0.38				
<i>Cost of cancers</i>		G€	18.8	10	50
Lost reactors, 1 GW each	6				
Cost per reactor	5	G€/reactor			
<i>Cost of reactors</i>		G€	30	20	40
<i>Cost of cleanup</i>		G€	30	20	200
Displaced persons	500,000				
Cost per displaced person	0.5	M€/person			
<i>Cost of displaced persons</i>		G€	250	100	1000
Area lost for agricultural production	1,000	km <sup>2</sup>			
Yield, cereals, 5 tonnes/ha per year	500	tonnes/km <sup>2</sup> /year			
Price, cereals 150 €/tonne	150	€/tonne			
Loss €/km <sup>2</sup> /year	75,000	€/km <sup>2</sup> /year			
Loss duration	100	Years			
<i>Cost of lost agriculture</i>		G€	7.5	5	50
Lost power production	90	TWh			
Value per kWh	0.2	€/kWh			
<i>Cost of lost power</i>		G€	18	10	50
<i>Total cost of accident, if now</i>		G€	354	165	1390
Years without accident			25	40	15
Discount rate	0.05				
Discount factor <sup>c</sup>			0.56	0.43	0.69

Note: All but the last 3 lines is for a catastrophic accident. T, tera; G, giga; M, mega; k, kilo.

<sup>a</sup> The parameter values are used only for the central estimate.

<sup>b</sup> To account for delay between accident and occurrence of cancer.

<sup>c</sup> To account for an accident occurring between now and 25 (or 15 or 40) years from now.

<sup>d</sup> Cost if now × discount factor/(years without accident × TWh/year).

<sup>e</sup> Damage cost of nuclear estimated by Externe (2008).

Rabl and Rabl also include an item for the cost of waste management. To account for the general tendency to underestimate future costs, Rabl and Rabl take 0.2 €cent/kWh as a damage cost of providing a permanent nuclear waste disposal site even though much of that is already internalized because plant operators are required to put sufficient money into a waste management fund. Since the 0.2 €cent/kWh for the cost of waste management in Table 13.7 is not a damage cost but an estimate of insufficient payment by utilities for future waste management, we label it external cost. By contrast, the cost of an accident and the 0.21 €cent/kWh for pollution from normal operation are damage costs.

Of course, any assessment of the external costs of nuclear is controversial, in particular with regard to accidents, proliferation, terrorism, and waste management. Subjective

**TABLE 13.8**

Calculations of Rabl and Rabl (2013) for the Damage Costs of Producing Base Load Power by Wind Turbines with NGCC Plants as Cleanest Fossil Backup

Cost Elements	Units	Central	Low	High
Cost of GHG <sup>a</sup>	€/t <sub>CO<sub>2</sub>eq</sub>	21	7	63
Fraction of base load power provided by wind		0.34	0.38	0.27
Damage cost of wind turbines	€cent/kWh	0	0	0
GHG emissions from NGCC <sup>a</sup>	kg/kWh	0.43	0.43	0.43
Cost of GHG emissions from NGCC <sup>a</sup>	€cent/kWh	0.90	0.3	2.7
Cost of classical air pollutants from NGCC <sup>a</sup>	€cent/kWh	0.50	0.17	1.49
Fraction of base load power provided by NGCC		0.66	0.62	0.73
NGCC contribution due to GHG costs <sup>a</sup>	€cent/kWh	0.59	0.19	1.97
NGCC contribution due to classical air pollutants <sup>a</sup>	€cent/kWh	0.33	0.10	1.09
Total damage cost <sup>a</sup>	€cent/kWh	0.92	0.29	3.05

Note: GHG, greenhouse gases.

<sup>a</sup> These numbers have been modified slightly to be consistent with ExternE (2008).

choices are inevitable and any specific assumption can and will be criticized. Rabl and Rabl offer their assessment as basis for discussion because it is better to base decisions on an explicit analysis rather than vague impressions.

Table 13.7 shows what such assumptions imply for the central estimate of the accident cost. The cost per kWh is obtained by dividing the cost of an accident by the number of years between accidents and the annual electricity production of the countries considered here (EU, United States, Canada, Japan, South Korea, and Taiwan); in addition it is multiplied by a discount factor to account for an accident occurring between now and 25 years from now. The values listed in the parameter columns are used only for the central results. The last two columns indicate lower and upper bounds; they are rough estimates of plausible ranges about the central values. For comparison, note that the accident database of Hirschberg et al. (2004) shows an estimate of G\$ 339<sub>1996</sub> (approximately 360 G€<sub>2010</sub>) for the cost of Chernobyl; it is within the range shown in Table 13.7.

The historical accident probability assumed for Table 13.7 is about an order of magnitude higher than what has been estimated by the standard PSAs with detailed fault tree modeling for the majority of reactors that have been built. That is the main reason why the accident cost in Table 13.7 is so much higher than the estimates by ORNL/RFF (1994), ExternE (1995), and Dreicer et al. (1995). Thus any estimate of the external costs of nuclear power involves problematic subjective judgments: is the future risk for reactors under consideration as bad as the worldwide average in the past, and is the cost of waste management fully internalized by the payments to a reserve fund that are currently paid by the nuclear industry? If one believes that waste management is fully internalized and that the future accident risk is as estimated by PSAs, the bottom line in Table 13.7 would be three times smaller, about 0.25 €cent/kWh.

### 13.4.5 Renewable Energy Technologies

Among renewable electricity sources there is a wide variety of technologies such as hydro, wind, biomass, and various forms of direct solar energy utilization, in particular PV and solar thermal power plants. Hydro, wind, and solar have special appeal, being not only inexhaustible but generally with little environmental impact or health risk. Of course, detailed studies are needed to check whether the impacts of these technologies are really benign.

For electricity from biomass, the main technologies that have been considered are combustion with steam turbine or gasification with gas turbine. There are significant health impacts from the air pollution emitted by the power plant and by the machinery needed for the production and transport of the fuel. The net greenhouse gas emissions from the biomass itself are zero, but there are emissions from the associated machines and vehicles, as well as chemical inputs (fertilizers, pesticides). Combustion with steam turbine is not the most efficient way of using biomass because temperature and pressure of the produced steam, and thus the power plant efficiency, are relatively low. In addition such plants are usually too small to maximize economies and efficiencies of scale. A better alternative is to add wood chips to coal in conventional coal-fired power plants (up to 5% of the total fuel can be added in this form), as already practiced in some power plants.

For hydro, PV, and wind there are of course no emissions from power generation. There are upstream emissions from the production of the materials, although the corresponding damage costs are small. However, one must not overlook the variability of wind or insolation and the corresponding variability in the amount of electricity they supply. To achieve a reliable power supply, backup capacity must be available, especially if solar and wind provide a high fraction of the total electricity production. Of course, energy storage would be an attractive solution, but for most applications storage of the required magnitude and duration is still too expensive or the potential sites (for the most cost-effective option, pumped hydro) are too limited. Without sufficient storage the backup capacity requirement of wind and solar implies that part of the replaced electricity will come from fossil fuels, with the attendant costs for health and environment.

Rabl and Rabl (2013) calculate the damage costs of producing base load power by wind turbines with NGCC plants as cleanest fossil backup. Their results are shown in [Table 13.8](#), although slightly modified to make them consistent with the numbers of ExternE (2008). The fraction of base load power provided by wind is around 34%, a number for very good wind sites. Rabl and Rabl make this calculation in the context of proposals for premature retirement of existing nuclear plants and note that the damage cost of a wind plus NGCC base load plant, 0.92 ¢cent/kWh in [Table 13.8](#), is higher than the damage cost of nuclear with the costs of accident and waste management, 0.79 ¢cent/kWh for the central estimate shown in [Table 13.7](#); however, the uncertainty ranges are large.

Amenity impacts of renewables are highly dependent on local conditions, in particular the population near the site. The impacts of hydro are so variable that specific results cannot be taken as general guidelines. The impacts can range from beneficial (for instance due to flood control or recreational facilities) to extremely harmful if large populations are displaced without compensation or if a dam breaks. The decomposition of submerged vegetation in new reservoirs can cause significant emissions of greenhouse gases. Such emissions are highly variable with site; Gagnon and van de Vate (1997) indicate 15 g<sub>CO<sub>2</sub>eq</sub>/kWh as typical value for cold climates, and possibly much higher values in tropical zones.

---

## 13.5 Waste Treatment and Energy Recovery

### 13.5.1 Assumptions

Despite all the efforts to increase the recycling of waste, there remains much waste that is not suitable for recycling or biotreatment, and it has to be either sent to landfill or incinerated (pyrolysis could be a cleaner alternative to incineration which can produce fuels, but

TABLE 13.9

Assumptions for the Emissions from Incineration of MSW

Pollutant	mg/Nm <sup>3</sup>	g/t <sub>waste</sub>	€/kg <sub>pollutant</sub>	€/t <sub>waste</sub>
PM <sub>10</sub>	10	51.5	7.6	0.39
SO <sub>2</sub>	50	258	6.2	1.60
NO <sub>2</sub>	200	1,030	5.4	5.52
CO <sub>2</sub>		807,000	0.021	16.95
As (2.8% of 0.5 mg/Nm <sup>3</sup> )	0.014	0.072	529.6	0.04
Cd (81.2% of 0.05 mg/Nm <sup>3</sup> )	0.0406	0.21	83.7	0.02
Cr <sup>VI</sup> (6.5% of 0.2 × 0.5 mg/Nm <sup>3</sup> ) <sup>a</sup>	0.0065	0.033	66.3	0.00
Hg (0.05 mg/Nm <sup>3</sup> )	0.05	0.26	8,000	2.06
Ni (33.8% of 0.5 mg/Nm <sup>3</sup> )	0.169	0.87	2.3	0.00
Pb (22% of 0.5 mg/Nm <sup>3</sup> )	0.11	0.57	278.3	0.16
Dioxins	1.00E-07	5.15E-07	37,000,000	0.02

Note: They are taken as the limit values of the flue gas concentrations, in Directive EC (2000), assuming 5150 Nm<sup>3</sup>/t<sub>waste</sub>. For metals other than Hg the directive specifies only certain sums: 0.5 mg/Nm<sup>3</sup> for the sum of As + Co + Cr + Cu + Mn + Ni + Pb + Sn + Sb + V, and 0.05 mg/Nm<sup>3</sup> for the sum of Cd + Tl; % within these sums based on ETSU (1996). The last two columns show the damage costs per kg of pollutant assumed for this chapter and the resulting cost per t<sub>waste</sub> of the direct incinerator emissions.

<sup>a</sup> Assuming that 20% of Cr from incinerators is Cr<sup>VI</sup>.

so far it is not widely used). Waste can be an important source of energy, and so we present results of an assessment of the damage costs of waste treatment and the benefits of energy recovery, for the principal technologies for municipal solid waste, namely incineration and landfill. These results are based on the paper by Rabl et al. (2008), recently updated in the book by Rabl et al. (2014); like the rest of this chapter they are based on ExternE (2008).

For incinerators we assume the emission limits of Directive EC (2000), as summarized in Table 13.9. This table also shows our assumptions for the damage cost per kg of pollutant and the implications for the cost per tonne of waste due to emissions from the incinerator.

The principal emissions to air from landfill are CH<sub>4</sub> and CO<sub>2</sub>. Figure 13.7 shows the total greenhouse gas emissions of a municipal solid waste landfill versus time. CH<sub>4</sub> is expressed as equivalent CO<sub>2</sub>, using a global warming potential (GWP) of 25. Note that a modern landfill is divided into a large number of individual compartments; they are filled one after another and sealed when full. The data of ADEME (2003) are plotted in Figure 13.7, where the time is measured from the date that a compartment is sealed. In practice, it is impossible to capture all of the CH<sub>4</sub>, and capture rates around 70% are commonly assumed (although measured data seem to be difficult to find). Here we assume a capture rate of 70% for the first 40 years, on average, after closure of a compartment; after 40 years we assume that all the remaining CH<sub>4</sub> escapes to the atmosphere. This last assumption reflects uncertainty in the way that sites will be managed around the time of closure is approached. One possibility is that regulators will simply sign off a site as *inert* after a certain period of time. Another is that regulators would require operators to provide evidence, such as data on emission rates, to show that a site is inert. The latter would provide a higher level of environmental protection.

### 13.5.2 Recovery of Energy and Materials

The damage costs and the comparison between landfill and incineration turn out to be extremely sensitive to assumptions about energy recovery. For that reason we consider a fairly large number of options, for typical installations in France, according to ADEME (2000). In Section 13.5.3, we indicate the options with labels where the letters E and H refer

**FIGURE 13.7**

Greenhouse gas emissions from a municipal solid waste landfill versus time,  $t_{\text{CO}_2\text{eq}}/t_{\text{waste}}$  if 70% of the  $\text{CH}_4$  is captured. (Based on ADEME, Outil de calcul des émissions dans l'air de  $\text{CH}_4$ ,  $\text{CO}_2$ ,  $\text{SO}_x$ ,  $\text{NO}_x$  issues des centres de stockage de déchets ménagers et assimilés (Tool for calculation of emissions of  $\text{CH}_4$ ,  $\text{CO}_2$ ,  $\text{SO}_x$ ,  $\text{NO}_x$  from municipal and similar solid waste), Agence Française de l'Environnement et de la Maîtrise de l'Energie, Paris, France, 2003.)

to heat and electricity and the letters c, g, n, and o to the fuel (coal, gas, nuclear, and oil, respectively) displaced by energy recovery. For example, (E = c&o, H = c&o) designates a system where heat and electricity are produced, each displacing a fuel mixture of coal and oil, 50% of each. The following options are considered for incineration:

- Recovery of heat and electricity (E = ..., H = ...)
- Recovery of electricity only (E = ...)
- Recovery of heat only (H = ...)

The following options are considered for landfill:

- No energy recovery
- Recovery of electricity, by motor (reciprocating engine) (E = ...)
- Recovery of electricity, by turbine (E = ...)
- Recovery of heat (H = ...)

For each of these options we consider several suboptions:

- The recovered electricity displaces coal and oil-fired power plants, 50% each (E = c&o)
- The recovered electricity displaces nuclear power plants (E = n)
- The recovered heat displaces gas and oil-fired heating systems, 50% each (H = g&o)
- The recovered heat displaces only oil-fired heating systems (H = o)

For recovery of electricity we assume a year-round demand, so all the electricity is used. Likewise for recovery of heat we assume a year-round demand (industrial process heat loads or certain district heating systems with year-round demand, e.g., Paris and Vienna), so that little of the heat is wasted. Year-round demand is essential for good recovery rates because the supply of waste tends to be fairly constant. For other load distributions the results can be estimated by rescaling the numbers for energy recovery (see Figure 13.8).

**FIGURE 13.8**

Some detailed results, by stage and pollutant. Trace = dioxins and toxic metals. Benefits from energy recovery can be quite different for different countries. The direct incinerator emissions are based on the actual data for France in 2011.

**TABLE 13.10**

Assumptions for Energy Recovery

kWh/t <sub>waste</sub>	Electricity	Heat
Part load heat and electricity	202	607
Base load electricity only	270	0
Base load heat	0	1,850

Aluminum	1.5	0.539	0.80

Source: Based on Rabl, A. et al., *Waste Manag. Res.*, 26, 147, 2008.

Note that for the purpose of this analysis the benefit of recovered electricity is essentially zero if it displaces nuclear because the damage costs of nuclear are very small compared to those of oil or coal; thus this option is almost equivalent to no electricity production at all as far as damage costs are concerned. Our assumptions for energy recovery rates, to be taken through to the next section, are shown in Table 13.10. The avoided emissions are based on the Large Combustion Plant Directive (EC 2001).

Recovery of materials is practical only for incinerators, not for landfills. Our assumptions for recovery rates and avoided damage costs are listed in Table 13.11; the avoided damage costs are based on the LCA inventory of Delucchi (2003).

### 13.5.3 Results for Damage Cost per Tonne of Waste

The real emissions are likely to be lower than the limit values of EC (2000). In Table 13.12, we compare the incinerator emissions and damage costs for limit values and with those for the actual emissions in France, based on the data kindly provided to us by Olivier Guichardaz of Dechets-Infos. For most of the pollutants the emissions have been greatly reduced. CO<sub>2</sub>, by contrast, has increased slightly since the composition of waste has been changing with recycling.

A summary of the total damage cost for all the options, assuming the actual emissions in France in 2011, is shown in Figure 13.9. More detailed results for some of the options can be found in Figure 13.8, showing the contribution of each stage and of the major pollutants (dioxins and toxic metals are shown as *trace*). The damage costs of waste transport are negligible, as illustrated in Figure 13.8 with an arbitrary choice of 100 km roundtrip by a 16 tonne truck for which they amount to 0.45 €/t<sub>waste</sub>. By far, the most important contributions come from direct emissions (of the landfill or incinerator) and energy recovery.

TABLE 13.12

Comparison of Incinerator Emissions and Damage Costs for Limit Values and Actual Emissions in France

Pollutant	Limit Values EC (2000)		Actual Emissions, France 2011		Ratio Actual/Limit
	g/t <sub>waste</sub>	€/t <sub>waste</sub>	g/t <sub>waste</sub>	€/t <sub>waste</sub>	
PM <sub>10</sub>	51.5	0.39	7.3	0.06	0.14
SO <sub>2</sub>	257.5	1.60	54.3	0.34	0.21
NO <sub>2</sub>	1,030	5.52	600	3.22	0.58

Total		26.76		22.22	0.83

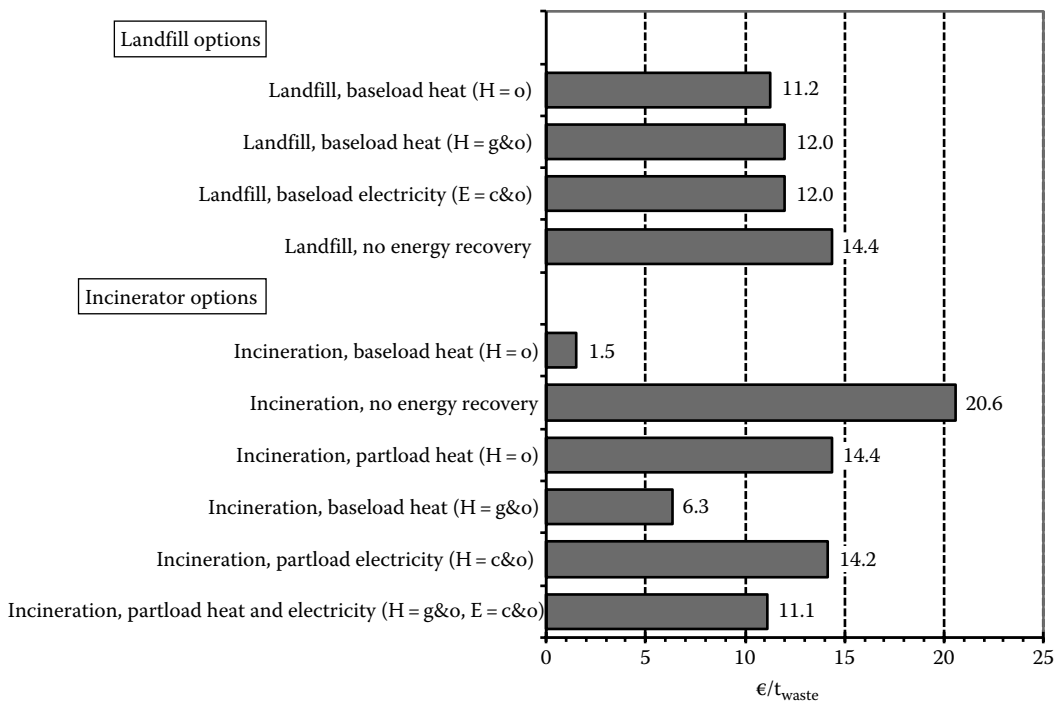

FIGURE 13.9

Results for total damage cost for waste treatment options. If electricity displaces nuclear, damage costs are essentially the same as for the case without energy recovery. Benefits from energy recovery can be quite different for different countries. Amenity costs are not included; they are very site-specific and could make a contribution on the order of 1 €/t<sub>waste</sub>. The direct incinerator emissions are based on the actual data for France in 2011. For comparison, the private costs of landfill are around 50 €/t<sub>waste</sub>, those of incineration around 100 €/t<sub>waste</sub>.

Materials recovery is relevant for incineration only and brings a relatively small benefit. For incineration energy recovery can be crucial and can reduce the total damage cost to  $1.5 \text{ €/t}_{\text{waste}}$ .

For the direct emissions of the incinerator, the total is  $22.22 \text{ €/t}_{\text{waste}}$ , most of that being due to  $\text{NO}_x$  and  $\text{CO}_2$ . Toxic metals and dioxins, shown in Figure 13.8 as *trace*, contribute about 2% of the total ( $0.46 \text{ €/t}_{\text{waste}}$ ), mostly because of Hg and Pb. The contribution of dioxins is negligible, only  $0.003 \text{ €/t}_{\text{waste}}$ , thanks to the low emission limit of the Waste Incineration Directive (EC 2000).

For landfill, the cost is dominated by  $\text{CH}_4$  emissions because only about 70% of the  $\text{CH}_4$  can be captured. Energy recovery from a landfill is not very significant (and because of  $\text{NO}_x$  from the electricity production, this option increases the damage cost if the electricity displaces nuclear). By contrast, energy recovery is crucial for the damage cost of incineration. Under favorable conditions (all heat produced by incinerator displaces coal and oil), the total damage cost could even be negative in some situations, that is, a net benefit. By contrast to most other countries, in France recovery of electricity does not bring significant benefits, because it is base load power and all the base load power is produced by nuclear. In any case, electricity production brings far lower benefits than heat because of the poor conversion efficiency of incinerator heat (due to its low temperature) compared to central station power plants.

---

### 13.6 Conclusions

The damage costs are worst for coal, oil, and lignite. If internalized by a pollution tax, they would significantly increase the market price of electricity. Natural gas is much cleaner, with damage costs intermediate between coal and the renewables. Nuclear has low damage costs. Even if the cost of catastrophic accidents is included, with a pessimistic assessment based on the historical record, its damage cost is lower for baseload than for wind with NGCC as backup. For the fossil fuels, the largest contribution to the damage cost comes from greenhouse gases, here valued at  $21 \text{ €/t}_{\text{CO}_2\text{eq}}$ . However, as explained in Section 13.2.6, we believe that this is an underestimate, the true cost being closer to the  $65 \text{ €/t}_{\text{CO}_2\text{eq}}$  of the Stern Review (Stern et al. 2006). That implies a much larger damage cost for the fossil fuel chains. For waste treatment, energy recovery can bring important benefits, especially for waste incineration where it can greatly reduce the damage costs.

The uncertainties of damage costs are large, about a factor of 3 in either direction, according to Spadaro and Rabl (2008). The reader may wonder whether it is meaningful to use them as basis for decisions. The first reply is that even a threefold uncertainty is better than infinite uncertainty without analysis. Second, in many cases the benefits are either so much larger or so much smaller than the costs that the implication for a decision is clear even in the face of uncertainty. Third, if in the other cases the decisions are made without a significant bias in favor of either costs or benefits, some of the resulting decisions will err on the side of costs, others on the side of benefits. Rabl et al. (2005) have examined the consequences of such unbiased errors and found a very reassuring result: the extra social cost incurred because of uncertain damage costs is remarkably small, less than 10%–20% in most cases even if the damage costs are in error by a factor of 3. But without any knowledge of the damage costs, the extra social cost (compared to the minimal social cost that one would incur with perfect knowledge) could be very large.

---

## Glossary

CBA	Cost-benefit analysis
CCS	carbon capture and sequestration
CO <sub>2eq</sub>	Quantity of a greenhouse gas expressed as equivalent quantity of CO <sub>2</sub> , using the GWP of the gas
CV	Contingent valuation
Discount rate	Rate $r$ that allows comparison of monetary values incurred at different times, defined such that an amount $P_n$ in year $n$ has the same utility as an amount $P_0 = P_n (1 + r)^{-n}$ in year 0.
ERF	Exposure–response function
EU27	European Union with 27 member states
External costs	Costs that arise when the social or economic activities of one group of people have an impact on another for which the first group does not fully account, for example, when a polluter does not compensate others for the damage imposed on them.
GDP	gross domestic product
GWP	Global warming potential
IPA	Impact pathway analysis
LCA	Life cycle assessment
N	Nitrogen
NGCC	natural gas combined cycle
NO <sub>x</sub>	Unspecified mixture of NO and NO <sub>2</sub>
O <sub>3</sub>	Ozone
PAH	Polycyclic aromatic hydrocarbons
PM <sub>d</sub>	Particulate matter with aerodynamic diameter smaller than $d$ $\mu\text{m}$
PV	photovoltaics
PSA	probabilistic safety assessment
S	Sulfur
S <sub>ERF</sub>	Slope of exposure–response function [cases/(person·year· $\mu\text{g}/\text{m}^3$ )]
UWM	Uniform world model (for simplified estimation of damage costs)
V <sub>dep</sub>	Depletion velocity (m/s)
VOC	Volatile organic compounds
VOLY	Value of a life year
VPF	value of prevented fatality = VSL
VSL	Value of statistical life
WTP	Willingness-to-pay
YOLL	Years of life lost (reduction of life expectancy)

## 14.1 Distributed Generation Technologies

### 14.1.1 Introduction

Distributed generation (DG) can be defined as a source of electric power connected to a distribution network or a customer site, representing an innovative and efficient way to both generate and deliver electricity, since it generates electricity right where it is going to be used. Nowadays, technological improvements allow power generation systems to be built in smaller sizes with high efficiency, low cost, and minimal environmental impact.

DG can serve as a supplement to electricity generated by huge power plants and delivered through the electric grid. However, located at a customer's site, DG can also be used to manage energy service needs or help meet increasingly rigorous requirements for power quality (PQ) and reliability. DG has the potential to provide site-specific reliability improvement, as well as transmission and distribution (T&D) benefits including: shorter and less extensive outages, lower reserve margin requirements, improved PQ, reduced lines losses, reactive power control, mitigation of T&D congestion, and increased system capacity with reduced T&D investment.

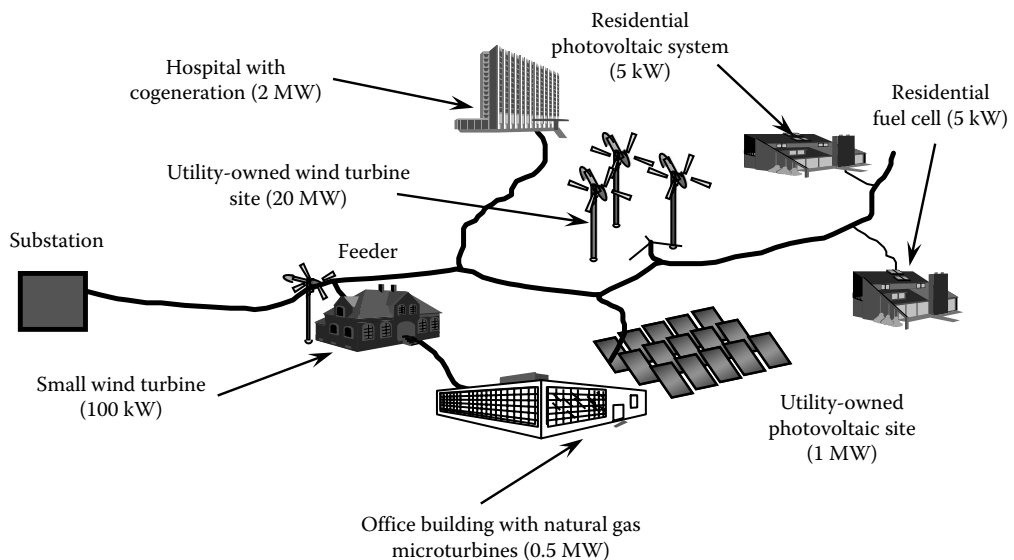

DG also provides economic benefits because its technologies are modular and provide location flexibility and redundancy as well as short lead times. Economic benefits can also be gained by using DG technologies for peak-shaving purposes, for combined heat and power (CHP) (cogeneration), and for standby power applications. In addition, many DG technologies provide environmental benefits including reduced land requirements, lower or no greenhouse gas emissions, and lower environmental compliance costs.

DG technologies can be divided in two different kinds, according to their availability: firm and intermittent power. The firm power technologies are those that enable the power control of DG units that can be managed as a function of the load requirements. Firm DG plants can be utilized as backup, working only in situations of grid unavailability, in periods of high consumption (when the electricity is more expensive), working continuously or dispatched to meet the variable load in an optimal manner. The intermittent power technologies do not allow the management of the produced energy by themselves having a random generation character. Examples of this kind of technologies are wind power or solar power that only produces energy when the wind or the sun is available. These technologies can be installed aggregated with energy storage, which by filtering the energy generation fluctuation enables the management of the delivered energy by the combined system.

In DG applications, traditional technologies can be used, such as internal combustion engines (ICEs), gas turbines, and in large installations steam turbines and combined cycle turbines. Other kinds of technologies such as microturbines, Stirling engines, fuel cells or renewable energies, including solar power, geothermal power, or wind power, can also be utilized (Figure 14.1).

### 14.1.2 Internal Combustion Engines

ICEs were one of the first technologies that used fossil fuels for electricity generation. Developed more than a century ago, ICEs are the most common of all DG technologies. They are available from sizes of a few kW for residential backup generation to generators on the order of 10 MW.

**FIGURE 14.1**  
Power system with multiple energy sources.

An ICE uses the thermal energy of fuel combustion to move a piston inside a cylinder, converting the linear motion of the piston to rotary motion of a crankshaft and uses that rotation to turn an AC electric generator. ICEs are also called reciprocating engines because of the reciprocating linear motion of the pistons. ICEs can be fuelled with gasoline, natural gas, diesel fuel, heavy oil, biodiesel, or biogas.

The two main types of ICEs used for DG applications are

1. Four cycle-spark-ignited engines (Otto cycle), which use an electrical spark introduced into the cylinder. This explosion engine, or ignition by spark, that uses the Otto cycle, was invented by Nikolaus August Otto, in 1867. Fast-burning fuels, such as gasoline and natural gas, are commonly used in these engines. Biofuels such as alcohols and biogas may also be used.
2. Compression-ignited (diesel cycle) engines, in which the combustion is initiated by compression. This engine was developed by Rudolph Diesel, in 1892, in which the compression of the fuel–air mixture inside the piston cylinder raises it to a temperature where it spontaneously ignites work best with slow-burning fuels, such as diesel. Biofuels, such as biodiesel and vegetable oils, may also be used.

DG engines have efficiencies that range from 25% to 45% (Table 14.1). In general, diesel engines are more efficient than Otto engines because they operate at higher compression ratios. Engine manufacturers are targeting lower fuel consumption and shaft efficiencies up to 50%–55% in large engines (>1 MW). Efficiencies of Otto engines using natural gas are expected to improve and approach those of diesel engines.

ICE generators for distributed power applications, commonly called gensets, are found universally in sizes from less than 5 kW to over 10 MW. Gensets are frequently used as a backup power supply in residential, commercial, and industrial applications. When used in combination with a 1–5 min UPS (uninterruptible power supply), the system is able to

**TABLE 14.1**

## Internal Combustion Engines Overview

Commercially Available	Yes
Size range	5 kW–10 MW
Fuel	Natural gas, diesel, heavy fuel, biogas
Efficiency	25%–45%
Environmental	Emission controls required for NOx and CO
Other features	Cogeneration (some models)
Commercial status	Widely available

supply seamless power during a utility outage. In addition, large ICE generators may be used as base load generation, grid support, or peak-shaving devices. ICE generators have start-up times ranging between 0.5 and 15 min, and a high tolerance for frequent starts and stops. The smaller engines, available in sizes as small as a few kW, are intended for much dispersed applications, such as individual homes and small businesses to cope with power outages.

### 14.1.3 Gas Turbines

Gas turbines are an electricity production technology used very often in the last decades. The first studies of gas utilization to actuate turbines started at the end of the nineteenth century. However, the first efficient gas turbines started to operate in 1930. A gas turbine consists of a compressor, a combustion chamber, and a turbine coupled to the generator. The turbines with only one axis have all the pieces associated with a continuous axis, all rotating at the same speed. This kind of architecture is used when variations in the turbine speed are not foreseeable. The rotor that drives the generator can be mechanically separated from the rotor driven by the combustion of gases, with more flexibility in the operation speed.

Unlike ICEs, the gas turbines work in continuous process and not in a repetition of a sequence of different operations. However, the operation can be viewed as a set of four stages similar to the four strokes of the ICEs (Figure 14.2).

1. A compressor drives a rotor that directs the work fluid (air) to the combustion chamber, where the air is compressed, increasing the pressure up to 10 bar and the temperature to 300°C.
2. The compressed air is mixed with the burning fuel, achieving temperatures of 1250°C. This combustion occurs with controlled conditions to maximize the fuel efficiency and minimize the emissions.
3. The air at high pressure is passed through the turbine, which converts the air energy into mechanical energy. Part of this energy is transmitted to the compressor and the remainder is used for electricity generation through a generator.
4. The exhaust gases are released to the atmosphere, or may be used for generation of process heat, or to increase the electricity generated as described in the following text.

**FIGURE 14.2**

Combustion turbine. (1) Air intake section; (2) compression section; (3) combustion section; (4) turbine section; (5) exhaust section; and (6) exhaust diffuser. (From Siemens, Combustion turbine, 2015, <http://www.energy.siemens.com/hq/en/fossil-power-generation/>, accessed October 12, 2015. With permission.)

Since gas turbines produce a large volume of exhaust gases at high temperatures, the energy of these gases can be utilized for steam production for industrial processes (cogeneration) or for electricity production through combined cycle. In a combined cycle, the gas turbine is used as the first cycle, where the exhaust gases of the gas turbine are used to produce steam in a heat recovery steam generator. This steam is then used to drive a steam turbine, increasing the electrical global efficiency of the system to values up to 60%.

In the Cheng cycle, the steam is injected in the expansion chamber of the gas turbine (superheated steam injection). In the expansion chamber, the steam is mixed with the gases of the combustion, which expands and produces additional work increasing the electrical efficiency.

The conversion of mechanical energy into electricity is made almost always through synchronous generators. In DG applications, the rotation speed of the turbines can be higher than the generator synchronous speed which requires a gearbox, reducing the conversion efficiency by about 3%. The generator also works like an auxiliary engine to start the turbine.

Natural gas is the fuel that enables the best efficiency to be reached in gas turbines. However, gas turbines can work with other fuels, such as fuel oil, diesel, propane, J-5 (used in aeronautics), kerosene, methane, and biogas. The heavy oil utilization decreases the efficiency and the power of the turbine by 5%–8%. Since heavy oil is less expensive, it can decrease the electricity production costs, but the emissions are higher than with other fuels.

The gas turbine generators are available in a wide power range, corresponding at three types of generators:

1. Microturbines (20–500 kW)
2. Medium turbines (500–10,000 kW)
3. Large turbines (more than 10 MW)

**TABLE 14.2**

General Characteristics of Gas Turbines

Commercial Availability	High
Size range	500 kW–250 MW
Fuel	Natural gas, biogas, oil derivatives
Efficiency	25%–45%
Environmental emissions	Very low when controls are used, high noise

These generators use gas turbines with the same working principle, but with different configurations and operation characteristics. The large turbines are not normally considered DG. Table 14.2 shows the general characteristics of gas turbines.

#### 14.1.4 Microturbines

Microturbines are small combustion turbines that produce between 25 and 500 kW of power. Microturbines were derived from turbocharger technologies found in large trucks or in the turbines found in aircraft auxiliary power units. Only the largest class of gas turbine generators, those made for central station utility applications, are designed specifically for electric power production. Microturbines have undergone significant innovations, enabling the energy production with high quality and reliability, with low greenhouse gas emissions, and with moderate costs, thus becoming a competitive technology.

Microturbines have the same working principle as the gas turbines, with various modifications in the system configuration. In these turbines the rotor rotates at a very high speed (up to 100,000 rpm) and one of the innovations consists in the adoption of a unique shaft, on which the compressor, the turbine, and the generator are assembled (Figure 14.3).

**FIGURE 14.3**

Microturbine. (From Capstone, Microturbine, 2005, <http://www.capstoneturbine.com/>, accessed October 12, 2005. With permission.)

These systems eliminate the gearbox, reducing the cost and increasing the reliability, but with a reduced overall efficiency. Another innovation is the utilization of air bearings, avoiding the need of a fluid for refrigeration and lubrication, because the unique used element is the air. The air can be continuously renovated and will never be contaminated by the materials wastage and by the combustion products.

One of the key characteristics of the microturbines is the heat recovery, that utilizes the thermal energy of the exhaust gases (at high temperatures), for preheating the air supply to the compressor. The mechanical energy is converted to electrical energy by a permanent magnet AC generator, which includes a low inertia rotor rotating at the turbine speed.

Because of the high rotor speed, the AC output has a frequency of approximately 2 kHz. To connect the microturbine generator with a 50 or 60 Hz grid, the microturbine voltage output must be connected to an AC–DC–AC converter. In this converter, the microturbine voltage output is rectified, filtered, and converted to an AC voltage through an inverter system synchronized with the 50 or 60 Hz supply.

Microturbines can also operate with a wide variety of fuels, such as natural gas (at high or low pressure), propane, diesel, gasoline, biogas (methane), or kerosene. The electrical efficiency of microturbines is between 20% and 35%, with heat recovery utilization. If the heat recovery does not exist, this value can decrease to 15%. In cogeneration systems, the global efficiency can reach 85% (Table 14.3).

Microturbine generators can be divided into two general classes:

- Heat recovery microturbines recover heat from the exhaust gas to boost the temperature of the air stream supplied to the combustion and increase the efficiency. Further exhaust heat recovery can be used in a cogeneration configuration.
- Microturbines without heat recovery (or simple cycle) have lower efficiencies, but also have lower capital costs.

Other applications of microturbine technology include the following:

- Core power conversion element of vehicles, such as buses, trucks, helicopters, and so on. Automotive companies are interested in microturbines to provide a light-weight and efficient fuel-based energy source for hybrid electric vehicles.
- Standby power, PQ, peak shaving, and cogeneration applications. Some types of microturbines are well-suited for small commercial building establishments, such as restaurants, hotels, small offices, retail stores, and many others.
- Utilization of by-products of processes in oil-processing, gas-transferring, petroleum production, industrial waste utilization for the purpose of optimizing the use of natural gas, associated gas, biogas, landfill gas, and others.

**TABLE 14.3**

Microturbines Overview

Commercial Availability	Yes (Only a Few Manufacturers)
Size range	30–1000 kW
Fuel	Natural gas, hydrogen, propane, diesel
Efficiency	20%–35% (recuperated)
Environmental emissions	Low (<9–50 ppm) NO <sub>x</sub>
Other features	Cogeneration (50°C–80°C water)
Commercial status	Medium volume production

The development of microturbines is ongoing in a variety of areas:

- Heat recovery/cogeneration
- Use of waste heat for absorption cooling
- Increase of the efficiency
- Fuel flexibility
- Vehicles
- Hybrid systems (e.g., fuel cell/microturbine, flywheel/microturbine)

#### 14.1.5 Stirling Engines

Stirling engines (Figure 14.4), invented in 1816 by Robert Stirling, are a class of reciprocating piston engines and are classed as external combustion engines. They constitute an efficient thermodynamic machine, for the direct conversion of heat into mechanical work, with a theoretical efficiency of 40%. Stirling engines were commonly used prior to beginning of the twentieth century. As steam engines improved and the competing compact Otto cycle engine was invented, Stirling engines lost favor. The developments in DG and concentrated solar thermal power have revived interest in Stirling engines. The principles of Stirling engines are described in Chapter 42 and will not be covered here.

The operation is reversible, that is, by supplying thermal energy, mechanical energy is produced, and by supplying mechanical energy, thermal energy is produced. Stirling

**FIGURE 14.4**

Stirling engine. (From Urieli, I., Stirling engines, 2005, <http://www.ohio.edu/people/urieli/stirling/engines/engines.html>, accessed October 12, 2005.)

**TABLE 14.4****Stirling Engines Overview**

<b>Commercially Available</b>	<b>On a Limited Scale</b>
Size range	<1 to 25 kW
Fuel	Fuel flexibility—fossil or renewable heat is possible
Efficiency	12%–30%
Environmental	Potential for low emissions
Other features	Cogeneration (some models)
Commercial status	Availability for specialized applications

engines can be fuelled by any source of heat (fossil fuel or renewable) and some models have possibilities to perform cogeneration. The continuous combustion process in a Stirling engine, which is easier to optimize and control, results in lower emissions compared to the intermittent explosions of fuel–air mixtures in internal combustion Otto and diesel engines.

Usually, Stirling engines are found in sizes from 1 to 25 kW (Table 14.4) and are produced in small quantities for specialized applications. Large 25 kW Stirling engines have an electrical efficiency of approximately 30%. The primary challenges faced by Stirling engines over the last two decades have been their long-term durability/reliability and their relatively high cost.

Stirling engines are ideally suited for solar thermal power. Using a gas as an operating fluid, there is no practical limit placed on the solar unit's upper temperature due to its operating fluid. Maximum temperature would be limited only by the materials used in its construction.

Stirling engine developments have been directed at a wide range of applications, including

- Small scale—Residential or portable power generation.
- Solar dish applications—Heat reflected from concentrating dish reflectors is used to drive the Stirling engine.
- Vehicles—Auto manufacturers have investigated utilizing Stirling engines in vehicles to improve the fuel economy.
- Refrigeration—Stirling engines are being developed to provide cooling for applications such as microprocessors and superconductors.
- Aircrafts—Stirling engines could provide a quieter-operating engine for small aircraft.
- Space—Power generation units aboard space ships and vehicles.

#### 14.1.6 Fuel Cells

Fuel cells are a technology for power generation that is quiet and highly efficient with no moving parts. Fuel cells generate electricity through an electrochemical process in which the energy stored in a fuel is converted directly into DC electricity and thermal energy. The chemical energy typically comes from hydrogen contained in various types of fuels (hydrocarbon fuels, such as natural gas, methanol, ethanol, biogas, etc.), including pure hydrogen.

Several hundred phosphoric acid fuel cells (PAFCs) demonstration and test plants have been built in the mid-1990s to early twenty-first century, mostly with 200 kW capacity, appropriate for DG applications in many commercial buildings to provide premium PQ for demanding loads. The operating temperature is about 200°C, which is suitable for cogeneration applications in buildings and in small industrial plants. They do not offer opportunity of self-reforming and they require precious platinum for their catalyst. PAFCs' efficiency and peak output capability deteriorate by about 2% per year.

One of the most promising developments is the design of hybrid systems. Solid oxide fuel cells (SOFCs) have high efficiency, particularly in a combined cycle operation mode, in which they can surpass conventional combined cycle gas turbine plants. High efficiencies under part load operation also result in high overall efficiency.

For applications in industrial heat-power cogeneration and public electricity supply, high-temperature fuel cells, such as SOFCs and molten-carbonate fuel cells (MCFCs) are most suitable. Both systems permit the use of a wide range of fuels. Such fuel cell systems compete in the lower rating range with gas turbines and motor cogeneration plants, and in the upper rating range with combined gas and steam turbine power plants. Conventional plants have a clear advantage in terms of practical experience and in terms of comparatively low capital costs compared with fuel cell plants. High-temperature fuel cells are likely to gain market penetration due to a decrease in specific need for primary fuels and also due to a sharp decrease of specific pollutant emissions, when compared with conventional generation. This last factor is a key advantage in DG applications in urban areas.

A detailed description of the fuel cells technology is given in Chapter 53.

#### **14.1.7 Solar Photovoltaic**

Photovoltaic (PV) cells, or solar cells, convert sunlight directly into electricity. PV technology has several applications, including

- Off grid/remote
- Grid attached residential and commercial buildings
- Remote communication systems
- Central power plants (above 1 MW)

Traditionally, PV has been used in remote areas where the grid is not available; such systems store electricity in batteries for use when the sun is not shining and are called stand-alone power systems. PV-generated power is less expensive than conventional power where the load is small and the area is too difficult to serve by electric utilities. However, solar power is now appearing more in urban areas due to the decreasing costs of PV panels and due to policy mechanisms to promote PV generation. Here, the surplus or all the generated electricity is injected into the grid. These are called grid-connected solar systems.

Distributed PV systems that provide electricity at the point of use have reached widespread commercialization. Chief among these distributed applications are PV power systems for individual buildings. Interest in the building integration of PVs, where

**FIGURE 14.5**  
Building-integrated photovoltaics in a façade and in a roof.

the PV elements actually become an integral part of the building, often serving as the façade or exterior weather skin, is growing worldwide. PV specialists and innovative designers in Europe, Japan, and the United States are now exploring creative ways of incorporating solar electricity into their work. A building-integrated photovoltaics (BIPV) system consists of integrating PVs modules into the building envelope, such as the roof or the façade (Figure 14.5). By simultaneously serving as building envelope material and power generator, BIPV systems can provide savings in materials and in electricity costs.

PVs can be integrated into many different assemblies within a building envelope:

- Incorporated into the façade of a building, complementing or replacing traditional glass
- Incorporated in the external layers of the wall of a building façade
- Use in roofing systems providing a direct replacement for different types of roofing material
- Incorporated in skylight systems in which part of the solar light is transmitted to the inside of the building and the other part is converted into electricity.

PV is the most modular and operationally simple of the clean distributed power technologies, with benefits that include the ability to provide power during summer peak periods, distribution congestion benefits, environmental benefits, and reduced fuel price risk.

A detailed description of the PV technology is given in Chapter 44.

#### **14.1.8 Wind Power**

Wind energy became a significant research area in the 1970s during the energy crisis and the resulting search for potential renewable energy sources. Modern wind turbine technology has made significant advances over the last 25 years. Today, wind power technology is available as a mature, environmentally sound, and convenient alternative. Generally, individual wind turbines are grouped into wind farms containing several turbines. Many wind farms are MW scale, ranging from a MW to tens of MW. Wind turbines

**FIGURE 14.6**  
Building-integrated wind power.

may be connected directly to utility distribution systems and the larger wind farms are often connected to transmission lines.

The small-scale wind farms and individual units are typically defined as distributed generation. Residential systems (1–15 kW) are available (Figure 14.6). However, they have low efficiency and are generally not suitable for urban or small-lot suburban homes due to space requirements and reduced wind velocity in urban environments. Single small turbines, below 50 kW, are also available and used in telecommunications stations, or for water pumping.

A detailed description of the wind power technology is given in Chapter 37.

### 14.1.9 Cogeneration

CHP, also known as cogeneration, is an efficient, clean, and reliable approach to producing both electricity and usable thermal energy (heating and/or cooling) at high efficiency and near the point of use, from a single fuel source. Since CHP is highly efficient, it reduces traditional air pollutants and carbon dioxide emissions, the leading greenhouse gas associated with climate change, as well.

CHP can use a variety of technologies to meet an energy user's needs. The range of technologies available allows the design of cogeneration facilities to meet specific onsite heat and electrical requirements. CHP systems consist of a number of individual components—prime mover, generator, heat recovery, and electrical interconnection—configured into an integrated system. The type of equipment that drives the overall system (i.e., the prime mover) typically identifies the CHP system.

Typical CHP prime movers include

- Combustion turbines
- Reciprocating engines
- Boilers with steam turbines
- Microturbines
- Fuel cells

CHP may be used in a variety of applications ranging from small 10 kW systems to very large utility-scale applications approaching 1000 MW. The first step in assessing which CHP application is right for a particular facility is to identify whether there is

**FIGURE 14.7**  
Trigeneration technology.

coincident demand of electrical and thermal energy at the host site. The CHP project will be most economically viable when the system provides the maximum amount of energy that can be used. Therefore, CHP project development begins with an analysis of site electrical and thermal load profiles. Based on these profiles, the type of CHP technology which most closely matches the facility's power and demand will be chosen.

In developed countries, about 10% of all electricity is generated in CHP plants, leading to huge primary energy savings and reduction of emissions. CHP in some industries, such as the pulp and paper, uses biomass byproduct as fuel input.

Trigeneration can provide even greater efficiency than cogeneration. Trigeneration is the conversion of a single fuel source into three useful energy products: electricity, steam or hot water, and chilled water (Figure 14.7). Trigeneration converts and distributes up to 90% of the energy contained in the fuel burned in a turbine or engine into usable energy. Introducing an absorption chiller into a cogeneration system means that the site is able to increase the operational hours of the plant with an increased utilization of heat, particularly in summer periods. Trigeneration has been applied with very positive results in buildings, such as hotels and hospitals, which feature a large space conditioning load during most of the year.

A detailed description of cogeneration technologies is given in Chapter 32.

#### 14.1.10 Conclusions

The utilization of DG technologies enables the creation of a power system with multiple energy sources, allowing the integration of conventional central power plants with dispersed DG fossil fuel-based generation, as well as with dispersed DG renewable generation. It is anticipated that DG growth and its large-scale application may lead to an improvement in reliability, to improved security of supply, to the decrease of power costs, and to the minimization of environmental impacts. In Figure 14.8 and Table 14.5, a characterization of the most important DG technologies is presented showing typical parameters associated with each technology.

**FIGURE 14.8**  
DG technologies comparative efficiency range.

## 14.2 Integration of Distributed Generation and Smart Grids

### 14.2.1 Introduction

Connecting a distributed power system to the electrical grid has potential impacts on the safety and reliability of the grid, which is one of the most significant barriers to the installation of DG technologies. Electric utilities have understandably always placed a high priority on the safety and reliability of their electrical systems. Faced with the interconnection of potentially large number of distributed generators, utilities have perceived DG as a threat. This has led some utilities to place overly conservative restrictions on interconnected systems, causing added costs that may make an installation economically unfeasible. Several techniques may reduce adverse network impacts allowing DG connection, but those techniques can be project specific and may be expensive, and adversely affect project economics.

Connection of DG fundamentally affects the operation of distribution networks with changes and impacts such as

- Voltage fluctuations
- Increased fault levels
- Degraded protection
- Bidirectional power flow
- Altered transient stability

To reduce the impact in the power grid, several requirements are needed. Typical requirements include equipment that prevents power from being fed to the grid when the grid

is de-energized, manual disconnects and PQ requirements such as limits on the inter-connected system's effects on "flicker," harmonic distortion, and other types of waveform disturbance. Systems may also be required to automatically shut down in the event of electrical failures, to provide an isolation transformer for the system, as well as to provide liability insurance.

Interconnection requirements for large DG installations (~10 MW) are well understood because they are very similar to the interconnections required for central power stations. Interconnection requirements for smaller installations are more difficult because the utility must balance the desire for a safe interconnection with the plant owner's desire to have a "quick and easy" interconnection design to get the DG up and running. Interconnection complexity generally increases with project size and is technology dependent.

The grid interconnection is important for three main reasons:

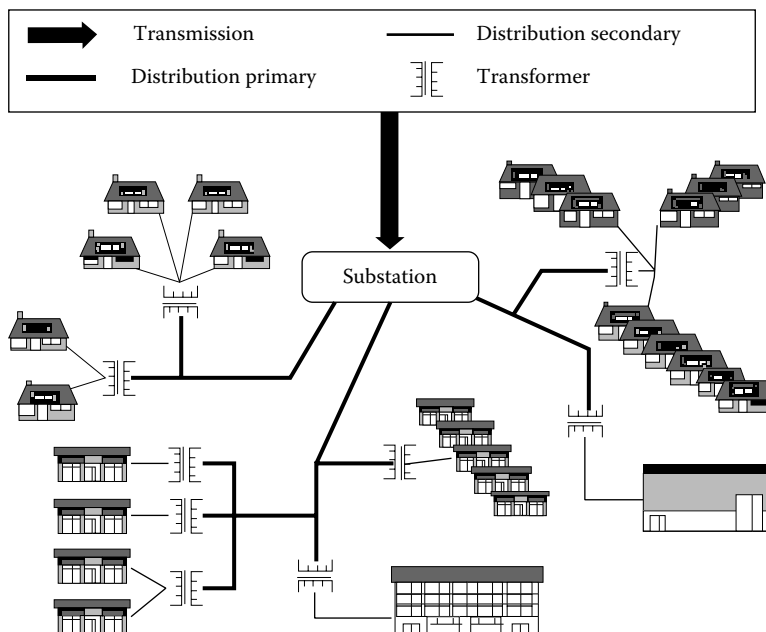

1. The number of small generators seeking interconnection to the grid has been increasing.
2. DG advocates contend that the current interconnection requirements and processes are effectively increasing costs unfairly and pricing DG out of the market.
3. Distribution companies are concerned that DG will negatively impact the safety and reliability of the grid and unfairly increase the distribution companies' costs.

#### 14.2.2 Power Distribution

Electric grid is broadly divided into two systems: the transmission system that transfers bulk power at high voltages, from power plants to utility-owned substations and a few very large customers, and the distribution system that delivers power at medium and low voltages from the substation to the majority of customers.

The utility distribution systems can be categorized as either radial or networked. Power system design is a trade-off between complexity and cost in order to maximize economy and reliability. As a result, the general structure of the power delivery system has a networked nature at the transmission level and a more radial nature at the distribution level.

Radial distribution refers to a system where the power lines extend from a common substation to the customer loads coming off at single nodes along the line (Figure 14.9). In these distribution systems, power can only flow in one direction: from the substation

**FIGURE 14.9**

Radial distribution system. (From California Energy Commission, *California Interconnection Guidebook: A Guide to Interconnecting Customer-Owned Electric Generation Equipment to the Electric Utility Distribution System Using California's Electric Rule 21*, California Energy Commission, Sacramento, CA, 2003, [http://www.energy.ca.gov/reports/2003-11-13\\_500-03-083F.PDF](http://www.energy.ca.gov/reports/2003-11-13_500-03-083F.PDF). With permission.)

to a load. While there can be many radial distribution lines emanating from a substation, each load is typically served by only one line. A disruption to that feed or substation will typically affect all customer loads on that line. A radial system generally offers a less reliable power source than a networked system because it lacks redundancy. However, the radial system and its protection equipment are less complex and less expensive than the networked system. The introduction of an energy source such as DG within the radial distribution system will affect the load distribution in the system, and may even cause reverse power flow if it is large relative to the load. Introduction of a sufficiently large power source within the radial distribution normally requires some modification to the protection system.

Networked distribution refers to a system where numerous separate lines form a grid so that customer loads can tap off of multiple independent feeds, which are then tied to a common bus on the secondary side of the transformers (Figure 14.10). These can be separate lines from a common substation or they can be from independent substations.

**FIGURE 14.10**

Networked distribution system. (From California Energy Commission, *California Interconnection Guidebook: A Guide to Interconnecting Customer-Owned Electric Generation Equipment to the Electric Utility Distribution System Using California's Electric Rule 21*, California Energy Commission, Sacramento, CA, 2003, [http://www.energy.ca.gov/reports/2003-11-13\\_500-03-083F.PDF](http://www.energy.ca.gov/reports/2003-11-13_500-03-083F.PDF). With permission.)

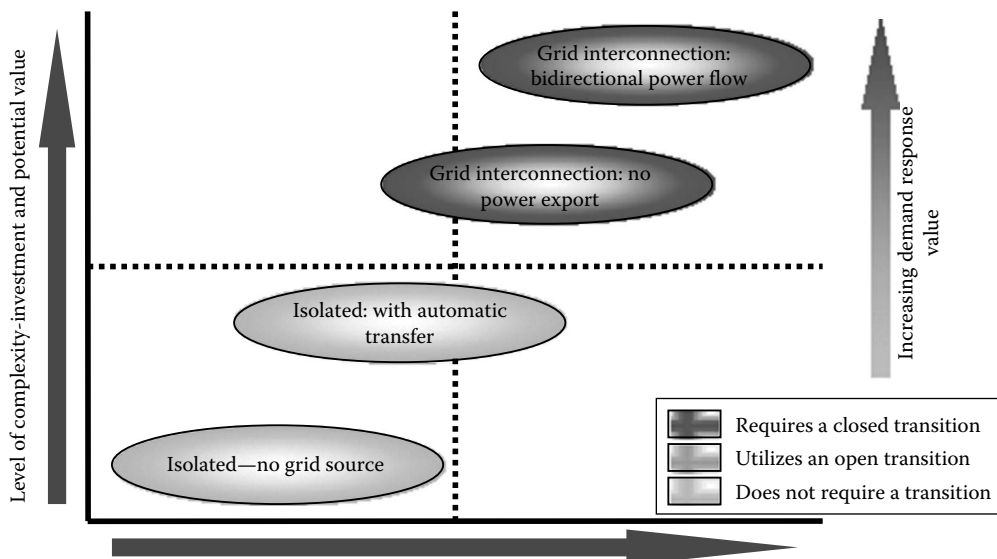

The networked system offers reliability advantages over the radial system because it provides multiple power sources for loads. This multipath design is sometimes referred to as a “looped” system. These systems use network protectors, which quickly isolate faults to protect the grid and shift customer loads onto the remaining feeds. Understandably, utilities are reluctant to allow the interconnection of anything that they feel will endanger the integrity or safety of this system. System protection in a networked distribution system is more complex and expensive than in the radial distribution system, due to the extra intelligence needed for reliable, effective protection. Since the networked system is specifically designed to deliver energy from multiple transformers to loads, it is capable of dealing with reverse power flow.

### 14.2.3 Types of Grid Connections

The electric power system (EPS) interface is the means by which the DG unit electrically connects to the power system outside the facility where the unit is installed. Depending on the application and operation of the DG unit, the interface configuration can range from a complex parallel interconnection, to being nonexistent if the DG unit is operated in isolation (Figure 14.11).

In remote applications, due to the high costs of the power grid expansion to the consumption site, the option of interconnecting with the local grid may be impractical. In these cases, the DG units become the unique means of energy supply at low cost. In this configuration the DG unit provides power for all loads completely isolated from grid, providing the utility no backup or supplemental power.

In near to the grid applications, the DG unit owner can choose several types of interconnections. Depending on the application and the operation mode of the DG unit, the

**FIGURE 14.11**

Interface complexity vs. interaction. (From Little, A.D., *Distributed generation: System interfaces*, ADL Publishing, Boston, MA, 1999, <http://www.encorp.com/dwnld/pdf/whitepaper/ADLittleWhitePaperDGSystemInterfaces.pdf>. With permission.)

connection system with the grid can represent a complex parallel interconnection or can be nonexistent if the DG is operating isolated from the grid. The complexity of the interconnection systems increases with the required interaction level between the DG unit and the distribution grid.

For most customers, DG systems are most cost-effective and efficient when they are interconnected with the utility grid. In simplest terms, interconnected with the grid means that both the DG system and the grid supply power to the facility at the same time. Paralleled systems offer added reliability, because when the DG system is down for maintenance, the grid meets the full electrical load, and vice-versa.

DG systems can be designed to keep a facility up and running without an interruption if the grid experiences an outage. Also, grid-interconnected systems can be sized smaller to meet the customer's base load as opposed to its peak load. Not only is the smaller base load system cheaper, it also runs closer to its rated capacity and, therefore is more fuel efficient and cost effective.

Two different types of grid interconnection are possible: parallel or roll-over. With the parallel operation, the DG system and the grid are interconnected and both are connected to the load. In the roll-over operation, the two sources are interconnected, but only one is connected with the load.

A typical interconnection system includes three kinds of equipment:

1. Control equipment for regulating the output of the DG
2. A switch and circuit breaker (including a "visible open") to isolate the DG unit
3. Protective relaying mechanisms to monitor system conditions and to prevent dangerous operating conditions

#### 14.2.3.1 Isolated Operation

In remote applications, the DG units become the unique means of energy supply at low cost. In this configuration, the DG unit provides power for all loads completely isolated from grid, providing the utility no backup or supplemental power (Figure 14.12). Isolated operation is also possible in sites which are normally connected to the grid, but in which continuous supply is required in the event of an outage. Some generating facilities, such as a hospital emergency generator, power the customer's partial or entire load isolated from the utility.

Isolated operation involves no interaction with the utility's distribution system, since the generator does not operate in parallel with the utility. In some isolated systems, the

**FIGURE 14.12**  
Isolated operation.

generator is sized for a specific load that is always powered from the generator and never from the utility. There are two ways of transferring load to isolated operation:

1. A break-before-make transfer switch (also known as open transition switching) disconnects the load from the utility prior to making the new connection with the on-site electric generating facility
2. A momentary-parallel (or closed transition) switch, a control system starts the customer's generator and parallels it with the utility's distribution system, quickly ramps the generator output power to meet the customer's load demand and then disconnects the load from the utility.

#### 14.2.3.2 Roll-Over Operation

When a roll-over connection exists (Figure 14.13), the load can be connected only to one of the two sources (grid or DG system) at any given moment. Both the sources are connected to a load control center with a load transfer switch. When the source that is feeding the load fails, this device makes the commutation, ensuring that the other source feeds the load. This commutation can be automatic or manual, to allow the interchange between the two sources due to technical or economic reasons, even when a failure does not exist. In this configuration, the DG unit provides power to load 2 for peaking, baseload, or backup power and the utility provides power to load 1 and occasionally to load 2.

The automatic commutation devices achieve the fast transition between sources, but there is always a time period in which the load is not fed. This kind of connection does not allow the decrease of the frequency of interruption, but reduces considerably their duration. To eliminate the feeding interruption the installation of energy storage devices, between the switch and the load, would be necessary. In this configuration, the transfer time of the load switch is typically 0.1–0.15 s.

The roll-over operation is cheaper and simpler, because it does not need a high number of control, protection, and coordination equipment. This type of operation can easily ensure the impossibility of the DG system injecting energy into the grid when the grid is out of service. This phenomenon called backfeed or islanding can be harmful to the grid operation, and can put people and goods at risk. For example, if a line is disconnected due to technical reasons a worker can be electrocuted, thinking that the line does not have voltage.

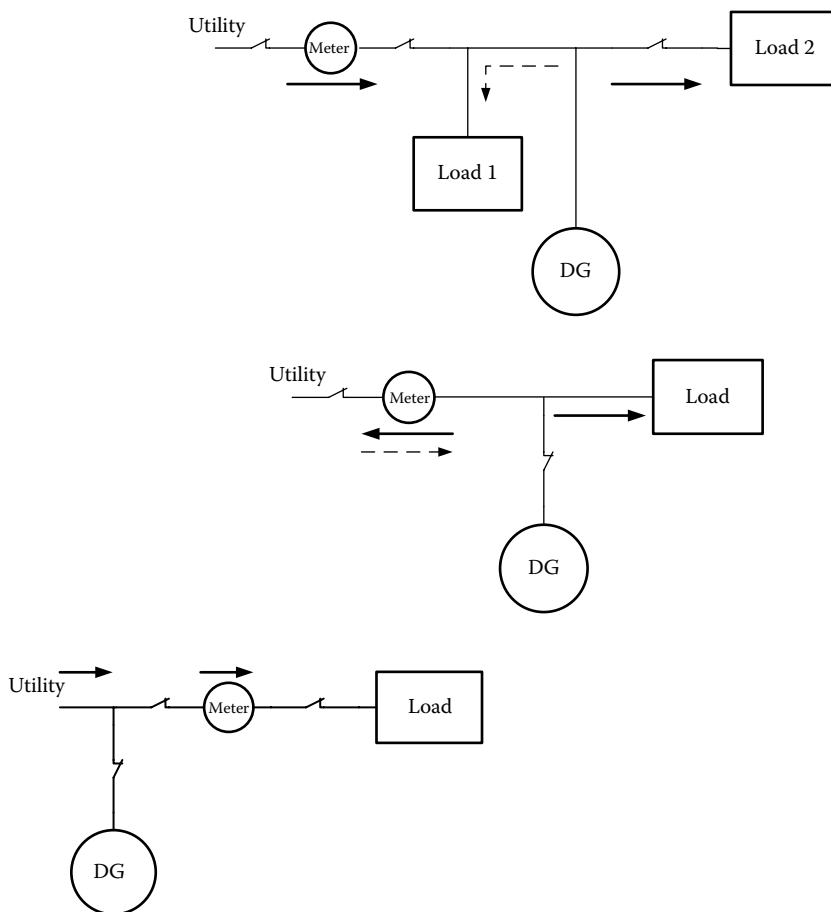

**FIGURE 14.13**  
Roll-over operation.

### 14.2.3.3 Parallel Operation

When a parallel operation exists, the sources are interconnected and both are connected with the load. If one of the sources fails, the load passes to be instantaneously fed exclusively by the other, without any interruption in the load supply. The fact of the two sources operating in parallel implies that the DG unit will be in operation and in synchronism with the grid, aggregating the necessary conditions to feed the load at the moment of the grid failure. This kind of operation is more expensive because besides the necessary additional protection and control equipment, there are additional fuel and equipment wear out costs, which occur in generating equipment even without electricity generation.

The parallel operation requires a large quantity of monitoring, control, synchronization, and protection devices. Both the sources must be protected against the failures of the other, including the backfeed phenomenon. This kind of connection is necessary in the cases in which the DG unit owner wants to sell energy to the grid.

Several types of parallel connections are available (Figure 14.14), depending on the DG unit localization and the possibility of selling energy to the grid. In the first configuration, the DG unit operates in parallel with the grid supplying energy to all the loads or

**FIGURE 14.14**  
Parallel operation.

to some loads, particularly providing the utility supplemental or backup power. In this configuration, it is impossible to supply energy to the grid. In the second configuration, the DG unit operates in parallel with the grid supplying energy to all the loads. With this configuration, it is possible to supply energy to the grid. The DG unit provides peak or baseload power to load and exports power to the grid, providing the utility supplemental and backup power. In the third configuration the DG unit operates in parallel with the grid supplying energy to the grid and to the consumer. In this configuration, the DG unit usually does not belong to the consumer.

#### **14.2.4 Advantages of the Grid Interconnection**

##### **14.2.4.1 Economic Advantages**

The cost of the electricity provided by the grid can be smaller than the cost of the local production in some time periods. Thus, during the periods in which the marginal production cost in the local unit is superior to the grid electricity cost, it makes sense to use the grid energy. During a peak period, the cost of the grid electricity is higher and therefore the local production can become advantageous.

Sometimes it is not advantageous to size the DG unit to meet all the required power by the loads. In this situation, when the requested power is higher, the additional required energy is provided by the grid. When the unit is working below the full capacity and the marginal production cost is lesser than the grid price, it is possible to increase the local production, thus increasing the profits.

##### **14.2.4.2 Voltage Regulation**

The electric power grid is projected to approach an ideal voltage source, with lower internal impedance. In this kind of source the voltage is the same to all the connected loads, ensuring that the start of a large load does not disturb the feeding voltage to the other loads. In a nonideal voltage source, the start of a large load (e.g., a large induction motor) causes a momentary voltage sag, affecting the other loads negatively.

In general, the grid achieves a good voltage regulation, because as the power of the load varies, the grid adjusts the power flows automatically, with very small variations in the voltage. Only at some points of the grid, especially toward the end of long lines, this variation is relatively high. DG units do not have a voltage regulation as good as the grid. As the load varies, the unit controller monitors the output voltage, that tends to decrease with the load increase and increase with the load reduction. When the voltage varies, the unit controller automatically responds, but it is almost impossible to equal the nearly instantaneous response of the grid.

The interconnection, with the DG unit working in parallel with the grid solves the voltage regulation problem, even in cases in which all the consumed energy is provided by the DG unit. When the load varies, the grid ensures the transitory instantaneous response, allowing the unit to make a relatively slow change.

##### **14.2.4.3 Reliability**

When properly managed, two energy sources work better together than isolated. Either with DG reserve units or with normal operating units, the DG system owner can view the grid like a reserve energy source. In fact, in almost all the sites, the grid reliability is

higher than the reliability of any isolated DG unit. In the DG projects, it is common to use values of 92%–93% for the units' availability. Considering an availability of 99%, which is extremely difficult to obtain, the corresponding unavailability will be higher than 80 h by year, which is unacceptable to most of the appliances.

Even in areas with poor performance of the electrical grid, the grid availability is normally higher than the DG unit, being many times higher than the availability of a DG system, even with several units. The grid utilization as reserve source makes sense in most of the cases, if the charged costs by the grid operator are reasonable.

## **14.2.5 Disadvantages of the Grid Interconnection**

### **14.2.5.1 Costs with the Grid Operator**

In any kind of market, the grid operator will charge a considerable value for interconnection with the grid. The DG unit owner, making the interconnection, will normally pay, not only the energy supplied by the grid, but also a charge dependent upon the maximum power delivered by the grid.

### **14.2.5.2 Additional Equipment and Maintenance**

DG system operation with interconnection with the grid is more complex than an isolated operation. Besides all the necessary equipment for the system operation, it is necessary to install additional control, metering, and protection devices to isolate the DG system from the grid. Usually the additional equipment, besides increasing the cost, increases the system complexity, thus increasing the maintenance needs.

### **14.2.5.3 Increasing Maintenance Needs to Ensure High Reliability Levels**

The potential reliability improvement achieved by the interconnection does not appear automatically. It is necessary to have a constrained management of the DG/grid combination to obtain the expected reliability levels. There are three essential points to pay attention to.

In the first place, the DG system operation in parallel with the grid needs an exhaustive monitoring of the grid operation conditions of the DG system, the load, and the interconnection. The existence of two sources and a load cause a complex control problem that is easily solved with the modern electronic devices, but it is a potential weakness. Problems can occur either due to an incorrectly programmed system or due to a failure in a key element of the system that can deactivate the entire system. Usually, in the critical DG units interconnected with the grid, redundant control equipment is installed with auto-monitoring.

Second, problems at grid points distant from the DG installation can cause perturbations in the DG unit operation. The most common problems are the atmospheric discharges. Reaching a line, a lightning discharge causes a current impulse that, without the appropriated protection, can reach the DG system. To mitigate this problem, since it is impossible to avoid it completely, additional protection equipment is needed, increasing the total cost of the system.

Third, undesirable events in the grid can disturb the DG unit operation, especially if the control and protection equipment is very sensitive. Momentary failure of a line can cause an abrupt fall in the voltage (voltage sag), that can be interpreted by the control system as

a risk situation to the DG unit, removing it from service, or it can also be interpreted as an abrupt increase in the load. In the last situation, the control device responds by increasing the power of the DG unit. After the automatic reclosure of the line, the voltage level increases very fast and the unit is not able to react in time, while it continues to try follow what seems a load increase. In this situation, an overvoltage occurs that is detected by the control system and which can remove the DG unit from service.

#### **14.2.6 Ancillary Services**

Ancillary Services is the designation given to a number of functions, which are necessary to support the reliable and efficient operations of the power system network. Besides energy (kW h) and power (kW), DG can provide other additional benefits including spinning reserve capacity, peaking, load following, reactive power and voltage support, and other ancillary services.

Generally, a customer can use DG together with the traditional utility service or as a separate service. There are two ways of DG utilization: to supply power and energy during peak periods or during the entire demand period. DG equipment can also be used as backup or standby power. Some ancillary services provided by the conventional generators can also be provided by DG, thus minimizing the cost of supplying ancillary services.

In addition to generating energy, DG operation can provide the following benefits:

- Eliminate the need to upgrade the size of feeders
- Improve voltage levels at the feeder ends
- Eliminate the need for capacitor banks
- Provide reactive power compensation
- Eliminate the need for voltage regulators
- Reduce feeder loading and delay replacement
- Reduce line losses and transmission system load

The main types of ancillary services, which can be provided by generators, include

- Regulation service and frequency response
- Spinning reserves
- Supplementary (nonspinning) reserves
- Replacement or operating reserves
- Voltage support
- Reactive power support
- Black-start generation capability

To the regulation service and frequency response it is provided capacity that is available and running, and that can be used to maintain real-time balance in the transmission system. As system loads fluctuate minute-by-minute, generators must be available to match instantly the fluctuations due to the increase or decrease of the loads. An automated generation control (AGC) reacts to perceived system fluctuations by adjusting its output to oppose or dampen the fluctuation, whether it is caused by load changes or changes in the output of other bulk system generators as they ramp up or down. Generation units

equipped with AGC can follow load variations on the timescale of seconds. The load balance is a critical service to the stability of day-to-day grid operation.

The load following capability service is associated with the “regulation service and spinning reserves.” Load following is the use of available generation capacity to meet the variations in system load. Spinning reserves refers to supplemental generation capacity that is ready to quickly ramp up at short notice. Spinning reserves is the incremental generating supply that an active unit can ramp up to within 10 min and then sustain, typically for 30–120 min. An amount of generating capacity must be kept fully warmed up and ready to take over within seconds in the event of a generator or transmission line failure. The term spinning refers to the fact that the generator is on, spinning at rated speed (in the case of turbine generators), and synchronized to the grid. It only needs to adjust its power output to the prescribed level.

Large DG and aggregated small DG alike can provide spinning reserve service. Implicit in the definition, however, is the availability of the capacity to be called upon at any time. Therefore, for example, a DG unit cannot use its full capacity for peak shaving a local load, and at the same time qualify that capacity for spinning reserve. This limitation is true for nonspinning and replacement reserve services as well. A generator designed to run at 80% of its normal capacity for local purposes can qualify the remaining 20% capacity for spinning reserve, as long as it is synchronized to the grid for the defined reserve period. Some quick-release hydro units allow a change from 0 to full power in 1 min. Alternatively, quick-response loads (using demand response controls) can also contribute to achieve a fast balance between supply and demand.

Supplementary (nonspinning) reserves refer to generation that is available but not running. Generation is kept on standby so that it can be started rapidly in the event that generators or lines suddenly fail, but not as rapidly as spinning reserves above. The incremental generation that can be achieved by units with slower responses, and those requiring start-up, is considered nonspinning reserve. Jurisdictions differ as to the ramping time allowed, varying from 10 to 30 min. Generators that can start, synchronize, and ramp to full power in short time periods can therefore participate in the quick-response reserve market without running at all times. Fast-start combustion turbines can serve this function. In addition, customers in the form of medium fast-response load may provide nonspinning reserve services.

Nonspinning reserve in most cases will be a more appropriate choice over spinning reserve for unused DG capacity. Most distribution level DG technologies do not require 10 min to start up, and therefore would not gain from remaining synchronized to the grid when not needed. Nonspinning reserves further provide ample opportunity for generators installed as emergency backup systems to participate in the reserve market, where they would not under spinning reserve. These generators are designed to remain off under normal circumstances and serve the customer’s load only if the utility experiences an outage, so their capacity during normal utility operation is always available.

Replacement or operating reserve is the incremental generation that can be obtained in the next hour to replace spinning and nonspinning reserves used in the current hour. Replacement reserve is very similar to nonspinning reserve with the exception that the generator has 60 min to start and ramp up instead of only 10. Each resource providing replacement reserve must be capable of supplying any level of output up to and including its full reserved capacity within 60 min after issue of dispatch instructions by the Independent System Operator (ISO). Each resource providing replacement reserve must be capable of sustaining the required output for at least 2 h.

Replacement reserve may be supplied from resources already providing another ancillary service, such as spinning reserve. However, the sum of the ancillary services capacity plus the replacement reserve cannot exceed the capacity of such resource. Replacement reserve can be provided by large and aggregated small DG that requires more than 10 min (and less than 1 h) to start and ramp to full power. This would be appropriate in cases where the generator technology itself has ramping limitations, or where the generator starting functions are not automated in response to a signal from the ISO, and therefore require delayed manual intervention.

Voltage support services are required to maintain transmission voltage level margins within the criteria in force. Dispatchers at the control center alter the settings on transformers, transmission lines, and other downstream grid-connected equipment, as well as provide sufficient reactive power in areas where needed.

Reactive power support is the injection or absorption of reactive power from generators to maintain transmission-system voltage within required ranges. Generators and loads may be dispatched and operated within a prescribed power factor range to boost the voltage during heavy load periods, or reduce the voltage during light load periods. The service can be provided by generators, loads, and utility distribution companies alike, as long as they have the proper power factor adjustment capabilities.

Black-start generation capability is the ability of a generating unit to go from a shutdown condition to an operating condition without assistance from the electrical grid and to then energize the grid to help other units start after a blackout occurs. Generators are started in a sequence so that each subsequent generator has an energized bus with which to synchronize. Strategically located black-start generators are a key factor for ensuring timely restoration after a major outage. Each black-start generating unit must be able to start up with a dead primary and station service bus within 10 min of issue of a dispatch instruction by the ISO requiring a black start. Each unit must also provide sufficient reactive capability to keep the energized transmission bus voltages within emergency voltage limits over the range of no-load to full load and must be capable of sustaining its output for a minimum period of 12 h from the time when it first starts delivering energy.

The other characteristics that may influence the adoption of DG technologies for ancillary service applications will vary according to the service performed and the ultimate shape of the ancillary service market. Start-up time for all electrical generators is an extremely important parameter to determine if the particular unit can be used as the reserve or can operate in the load following mode. The part-load capabilities of DG technologies and the start-up time periods of each are presented in [Table 14.6](#).

#### **14.2.7 Power Quality Applications**

PQ-related issues are of most concern nowadays. The widespread use of electronic equipment, such as information technology equipment, power electronics such as adjustable speed drives (ASD), programmable logic controllers (PLC), energy-efficient lighting, led to a complete change of electric loads nature. These loads are simultaneously the major causes and the major victims of PQ problems. Due to their nonlinearity, all these loads cause disturbances in the voltage waveform.

Along with technology advance, the organization of the worldwide economy has evolved toward globalization and the profit margins of many activities tend to decrease. The increased sensitivity of the vast majority of processes (industrial, services, and even residential) to PQ problems turns the availability of electric power with quality as a crucial factor for competitiveness in every activity sector. The most critical areas are the continuous

**TABLE 14.6**

Summary Table of Some Performance Characteristics by Distributed Generation Technology Type

Technology	Part-Load	Start-Up Time
PV	Fair to good (dependent on resource availability)	Less than 10 s
Wind	Fair to good (dependent on resource availability)	30 s
Steam turbine	Satisfactory	1 h–1 day
Diesel engine	Good	10 s
Nat. gas engine	Satisfactory	10 s
Gas turbine	Poor	10 min–1 h
Microturbine	Satisfactory	60 s
PAFC	Satisfactory	1–4 h
MCFC	Poor	More than 10 h
SOFC tubular	Poor	5–10 h
SOFC planar	Poor	Not available
PEMFC	Satisfactory	<0.1 h

process industry and the information technology services. When a disturbance occurs, huge financial losses may happen, with the consequent loss of productivity and competitiveness.

Although many efforts have been taken by utilities, some consumers require a level of PQ higher than the level provided by modern electric networks. This implies that some measures must be taken in order to achieve higher levels of PQ. The most common types of PQ problems are presented in Table 14.7.

Even the most advanced T&D systems are not able to provide electrical energy with the desired level of reliability for the proper functioning of the loads in the modern society. Modern T&D systems are projected for 99.9%–99.99% availability. This value is highly dependent of redundancy level of the network, which is different according to the geographical location and the voltage level (availability is higher at the HV network). In some remote sites, availability of T&D systems may be as low as 99%. Even with a 99.99% level, there is an equivalent interruption time of 52 min/year. The most demanding processes in the modern digital economy need electrical energy with 99.9999999% availability (9-nines reliability) to function properly.

The mitigation of PQ problems may take place at different levels: transmission, distribution, and end-use equipment. As seen in Figure 14.15, several measures can be taken at these levels. Many PQ problems have origin in the transmission or distribution grid. Thus, a proper T&D grid, with adequate planning and maintenance, is essential to minimize the occurrence of PQ problems.

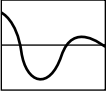

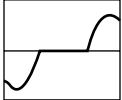

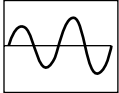

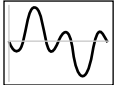

Interest in the use of distributed energy resources has increased substantially over the last few years because of their potential to provide increased reliability. These resources include DG and energy storage systems. Energy storage systems, also known as restoring technologies, are used to provide the electric loads with ride-through capability in poor PQ environment. Recent technological advances in power electronics and storage technologies are turning the restoring technologies as one of the premium solutions to mitigate PQ problems (Figure 14.16).

DG units can be used to provide clean power to critical loads, isolating them from disturbances with origin in the grid. DG units can also be used as backup generators to ensure

TABLE 14.7

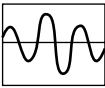

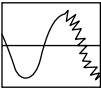

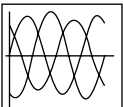

## Most Common Power Quality Problems

1. Voltage sag (or dip)	 <p><i>Description:</i> A decrease of the normal voltage level between 10% and 90% of the nominal RMS voltage at the power frequency, for durations of 0.5 cycle to 1 min.</p> <p><i>Causes:</i> Faults in the transmission or distribution network (most of the times on parallel feeders). Faults in consumer's installation. Connection of heavy loads and start-up of large motors.</p> <p><i>Consequences:</i> Malfunction of information technology equipment, namely microprocessor-based control systems (PCs, PLCs, ASDs, etc.) that may lead to a process stoppage. Tripping of contactors and electromechanical relays. Disconnection and loss of efficiency in electric rotating machines.</p>
2. Very short interruptions	 <p><i>Description:</i> Total interruption of electrical supply for duration from few milliseconds to 1 or 2 s.</p> <p><i>Causes:</i> Mainly due to the opening and automatic reclosure of protection devices to decommission a faulty section of the network. The main fault causes are insulation failure, lightning, and insulator flashover.</p> <p><i>Consequences:</i> Tripping of protection devices, loss of information and malfunction of data processing equipment. Stoppage of sensitive equipment, such as ASDs, PCs, PLCs, if they are not prepared to deal with this situation.</p>
3. Long interruptions	 <p><i>Description:</i> Total interruption of electrical supply for duration greater than 1–2 s</p> <p><i>Causes:</i> Equipment failure in the power system network, storms and objects (trees, cars, etc.) striking lines or poles, fire, human error, bad coordination, or failure of protection devices.</p> <p><i>Consequences:</i> Stoppage of all equipment.</p>
4. Voltage spike	 <p><i>Description:</i> Very fast variation of the voltage value for durations from several microseconds to few milliseconds. These variations may reach thousands of volts, even in low voltage.</p> <p><i>Causes:</i> Lightning, switching of lines or power factor correction capacitors, disconnection of heavy loads.</p> <p><i>Consequences:</i> Destruction of components (particularly electronic components) and of insulation materials, data processing errors or data loss and electromagnetic interference.</p>
5. Voltage swell	 <p><i>Description:</i> Momentary increase of the voltage, at the power frequency, outside the normal tolerances, with duration of more than one cycle and typically less than a few seconds.</p> <p><i>Causes:</i> Start/stop of heavy loads, badly dimensioned power sources, badly regulated transformers (mainly during off-peak hours).</p> <p><i>Consequences:</i> Data loss, flickering of lighting and screens, stoppage or damage of sensitive equipment, if the voltage values are too high.</p>
6. Harmonic distortion	 <p><i>Description:</i> Voltage or current waveforms assume nonsinusoidal shape. The waveform corresponds to the sum of different sine-waves with different magnitudes and phases, having frequencies that are multiples of power-system frequency.</p> <p><i>Causes:</i> Classic sources: electric machines working above the knee of the magnetization curve (magnetic saturation), arc furnaces, welding machines, rectifiers, and DC brush motors. Modern sources: all nonlinear loads, such as power electronics equipment including ASDs, switched mode power supplies, data processing equipment, high efficiency lighting.</p> <p><i>Consequences:</i> Increased probability of occurrence of resonance, neutral overload in three-phase systems, overheating of all cables and equipment, loss of efficiency in electric machines, electromagnetic interference with communication systems, errors in measures when using average reading meters, nuisance tripping of thermal protections.</p>

(Continued)

TABLE 14.7 (Continued)

Most Common Power Quality Problems

7. Voltage fluctuation		<p><i>Description:</i> Oscillation of voltage value, amplitude modulated by a signal with frequency of 0–30 Hz.</p> <p><i>Causes:</i> Arc furnaces, frequent start/stop of electric motors (for instance, elevators), oscillating loads.</p> <p><i>Consequences:</i> Most consequences are common to undervoltages. The most perceptible consequence is the flickering of lighting and screens, giving the impression of unsteadiness of visual perception.</p>
8. Noise		<p><i>Description:</i> Superimposition of high frequency signals on the waveform of the power-system frequency.</p> <p><i>Causes:</i> Electromagnetic interferences caused by Hertzian waves, such as microwaves, television diffusion, and radiation due to welding machines, arc furnaces, and electronic equipment. Improper grounding may also be a cause.</p> <p><i>Consequences:</i> Disturbances on sensitive electronic equipment, usually not destructive. May cause data loss and data processing errors.</p>
9. Voltage unbalance		<p><i>Description:</i> A voltage variation in a three-phase system in which the three voltage magnitudes or the phase-angle differences between them are not equal.</p> <p><i>Causes:</i> Large single-phase loads (induction furnaces, traction loads), incorrect distribution of all single-phase loads by the three phases of the system (this may be also due to a fault).</p> <p><i>Consequences:</i> Unbalanced systems imply the existence of a negative sequence that is harmful to all three-phase loads. The most affected loads are three-phase induction machines.</p>

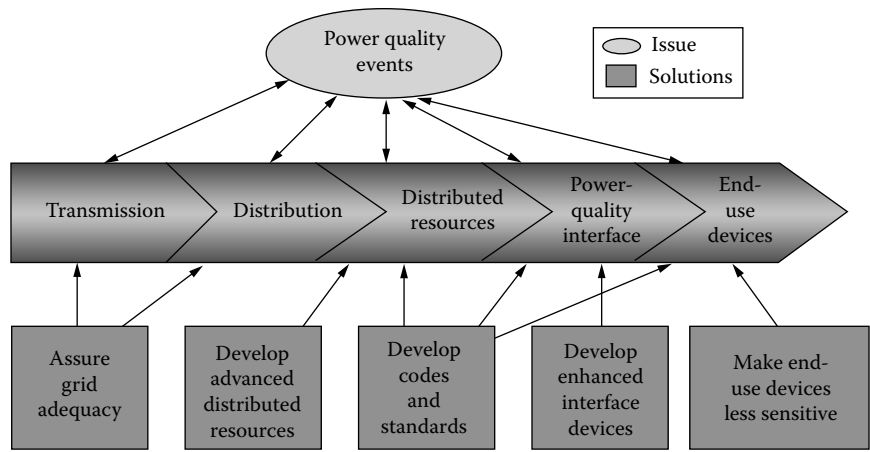

FIGURE 14.15 Solutions for power quality.

FIGURE 14.16 Restoring technologies principle.

energy supply to critical loads during sustained outages. Additionally, DG units can be used for load management purposes to decrease the peak demand.

If DG units are to be used as backup generation, a storage unit must be used to provide energy to the loads during the period between the origin of the disturbance and the start-up of the emergency generator. The most common solution is the combination of electro-chemical batteries' UPS and a diesel genset. At present, the integration of a flywheel and a diesel genset in a single unit (Figures 14.17 and 14.18) is also becoming a popular solution, offered by many manufacturers.

**FIGURE 14.17**

### 14.2.8 Standards for Interconnecting Distributed Resources

Many of the technical concerns that the companies of distributed electricity usually raise for the distributed resources (DRs) interconnection with the grid are related to reliability, security, and quality of service. *The IEEE 1547 Standard for Interconnecting Distributed Resources with Electric Power Systems* defines interconnection technical specifications and requirements that are universally needed for interconnection of DR. This standard was approved by the IEEE Standards Board in June 2003 and approved as an American National Standard in October 2003, being an important step to overcome the barriers and increase the development of DG installations.

This standard provides requirements relevant to the performance, operation, testing, safety considerations, and maintenance of the interconnection. General requirements are related to voltage regulation, integration with area EPS grounding, synchronization, DR on secondary grid and spot networks, inadvertent energization and reconnection to area EPS, monitoring and isolation devices. The standard applies to all DR technologies, with aggregate capacity of 10 MVA or smaller at the point of common coupling, and to all EPS at typical primary and/or secondary distribution voltages.

Abnormal conditions can arise on the area EPS that require a response from the connected DR. This response contributes to the safety of utility maintenance personnel and the general public, as well as the avoidance of damage to the connected equipment, including the DR. The abnormal conditions of concern are voltage and frequency excursions above or below the values stated in the IEEE 1547 (Table 14.8), and the isolation of a portion of the area EPS with some DR, presenting the potential for an unintended island.

PQ issues are also addressed in the IEEE 1547, namely, limitation of DC injection, voltage flicker induced by the DR, harmonic current injection (Table 14.9), immunity protection and surge capabilities, as well as the islanding considerations.

The standard also provides test requirements for an interconnection system to demonstrate that it meets all the requirements. The following tests are required for all interconnection systems:

- Interconnection test
- Production tests
- Interconnection installation evaluation
- Commissioning tests
- Periodic interconnection tests

**TABLE 14.8**

Interconnection System Response to Abnormal Voltages

Voltage Range (% of Base Voltage)	Clearing Time (s) <sup>a</sup>
$V < 50$	0.16
$50 \leq V < 88$	2
$110 < V < 120$	1
$V \geq 120$	0.16

Source: From Institute of Electric and Electronics Engineers (IEEE), *IEEE 1547 Standard for Interconnecting Distributed Resources with Electric Power Systems*, IEEE Standards Coordinating Committee 21 (IEEE SCC21) on Fuel Cells, Photovoltaics, Dispersed Generation, and Energy Storage of the IEEE Standards Association, New York, 2003.

<sup>a</sup> Clearing time: Time between the start of the abnormal condition and the DR ceasing to energize the area EPS.

**TABLE 14.9**Maximum Harmonic Current Distortion in Percent of Current (I)<sup>a,b</sup>

Individual Harmonic Order (Odd Harmonics)	<11	11 ≤ h < 17	17 ≤ h < 23	23 ≤ h < 35	35 ≤ h	TDD
Percent (%)	4.0	2.0	1.5	0.6	0.3	5.0

Source: Institute of Electric and Electronics Engineers (IEEE), *IEEE 1547 Standard for Interconnecting Distributed Resources with Electric Power Systems*, IEEE Standards Coordinating Committee 21 (IEEE SCC21) on Fuel Cells, Photovoltaics, Dispersed Generation, and Energy Storage of the IEEE Standards Association, New York, 2003.

Note: TDD, total demand distortion.

<sup>a</sup> I = the greater of the local EPS maximum load current integrated demand (15–30 min) without the DR unit, or the DR unit rated current capacity (transformed to the PCC when a transformer exists between the DR unit and the PCC).

<sup>b</sup> Even harmonics are limited to 25% of the odd harmonic limits above.

IEEE P1547 is part of a family of IEEE interconnection standards for DR. The other standards are as follows (IEEE, 2013):

- *IEEE P1547.1 Standard for Conformance Tests Procedures for Equipment Interconnecting Distributed Resources with Electric Power Systems* (published in 2005)—This standard specifies the type, production, and commissioning tests that shall be performed to demonstrate that the interconnection functions and equipment of a DR conform to IEEE Standard 1547.
- *IEEE 1547.2 Application Guide for IEEE 1547 Standard for Interconnecting Distributed Resources with Electric Power Systems* (published in 2008)—This guide provides technical background and application details to support the understanding of *IEEE 1547 Standard for Interconnecting Distributed Resources with Electric Power Systems*.
- *IEEE 1547.3 Guide for Monitoring, Information Exchange, and Control of Distributed Resources Interconnected with Electric Power Systems* (published in 2007)—This document provides guidelines for monitoring, information exchange, and control for DRs interconnected with EPSs.
- *IEEE 1547.4 Guide for Design, Operation, and Integration of Distributed Resource Island Systems with Electric Power Systems* (published in 2011)—This document provides alternative approaches and good practices for the design, operation, and integration of DR island systems with EPSs.
- *IEEE P1547.5 Draft Technical Guidelines for Interconnection of Electric Power Sources Greater than 10 MVA to the Power Transmission Grid* (withdrawn in 2011)—This document provides guidelines regarding the technical requirements, including design, construction, commissioning acceptance testing, and maintenance/performance requirements, for interconnecting dispatchable electric power sources with a capacity of more than 10 MVA to a bulk power transmission grid.
- *IEEE 1547.6 Recommended Practice for Interconnecting Distributed Resources with Electric Power Systems Distribution Secondary Networks* (published in 2011)—This standard establishes recommended criteria, requirements, and tests, and provides guidance for interconnection of distribution secondary network system types of area EPSs with DRs providing electric power generation in local EPSs.

- *IEEE P1547.7 Draft Guide to Conducting Distribution Impact Studies for Distributed Resource Interconnection*—This guide describes criteria, scope, and extent for engineering studies of the impact on area EPSs of a DR or an aggregate DR interconnected to an area electric power distribution system.
- *IEEE P1547.8 Recommended Practice for Establishing Methods and Procedures that Provide Supplemental Support for Implementation Strategies for Expanded Use of IEEE Standard 1547*—This recommended practice applies to the requirements set forth in IEEE 1547 and provides recommended methods that may expand the usefulness and uniqueness of IEEE 1547 through the identification of innovative designs, processes, and operational procedures.

Nowadays, there are a Working Group (IEEE P1547a) to establishing updates to voltage regulation, response to area EPSs abnormal conditions of voltage and frequency, and considering if other changes to IEEE Standard 1547. At the same time, there are other Working Groups (IEEE P1547.1a) to establishing updates to IEEE Standard 1547.1 in relation to the details of the IEEE P1547a revisions.

#### 14.2.9 Smart Grids

The efforts to reduce greenhouse gas emissions related to electricity generation have been leading to a fast increase in the deployment of renewable generation, in particular PV and wind power. Such renewable energy sources are being deployed not only as bulk generation facilities but also as distributed local generation facilities connected to the electricity distribution grids or even to private consumption infrastructures. DG has the potential to provide site-specific reliability improvement, as well as T&D benefits. However, the renewable generation resources have characteristics that differ from conventional energy sources. The output of wind and solar power is determined by random meteorological processes, outside the control of the generators or the system operators. Therefore, unlike conventional capacity, wind and solar generated electricity cannot be reliably dispatched or perfectly forecasted, and exhibits significant temporal variability.

EPSs have been designed for more than a century ago in a top-down perspective, based on highly predictable bulk generation power plants following load variations, controlled by centralized systems. The basic topology of the existing electrical grid has remained unchanged, being a strictly hierarchical system with clear demarcations between its generation, transmission, and distribution subsystems. It is unidirectional in nature, with an energy flow from the power plant to the customer without any real-time share of information between the consumption and generation points.

However, the defined scenarios for decarbonizing the energy sector will lead to important impacts on the electricity grid, namely high penetration of intermittent renewable technologies. In addition, such new generation resources are deployed mostly as DG, creating a more decentralized system, where the figure of the “prosumer” emerges. With the increasing connection of renewable generation sources at all voltage levels due to the mismatching between local generation (mainly PV) and consumption ([Figure 14.19](#)), in some distribution grids, the power flow can invert the way, flowing from the distribution network to the transmission network. As a result, the scalability of the grid

**FIGURE 14.19**

Typical photovoltaic generation and demand profiles in a residential building.

is improved and the energy flows, and so the losses, are reduced, but the complexity of managing such an infrastructure increases dramatically.

As penetration rates of variable generation increase over levels of 15%–20%, and depending on the electricity system in question, it can become increasingly difficult to ensure the reliable and stable management of electricity systems relying solely on conventional grid architectures and limited flexibility. Therefore, new monitoring and control tools are needed to increase the system flexibility and maintain stability and balance at the distribution grid level.

The increasing energy consumption, in most countries, must be also properly addressed by the electrical grid. To achieve it, a change on the paradigm of the electric grid management is needed, moving from an approach where the generation must always follow the load to a new approach where the load is also considered a manageable resource, which can be controlled to follow the available generation, using demand response programs. Therefore, the electrical grid must have new tools to optimize the resources and to promote energy efficiency, both in the supply and in the demand sides, through monitoring and control infrastructures based on sensors and actuators networks and demand response programs.

Part of the new electricity consumption will be caused by deployment of electric vehicles. However, they can also be an important tool to the grid management with the possible control of the charging cycles and the use of the battery as a local energy storage device. At the same time, the improvements achieved on other energy storage technologies bring new solutions to the grid management. Thus, the control of consumption together with energy storage will ensure the needed flexibility to ensure the generation/consumption matching.

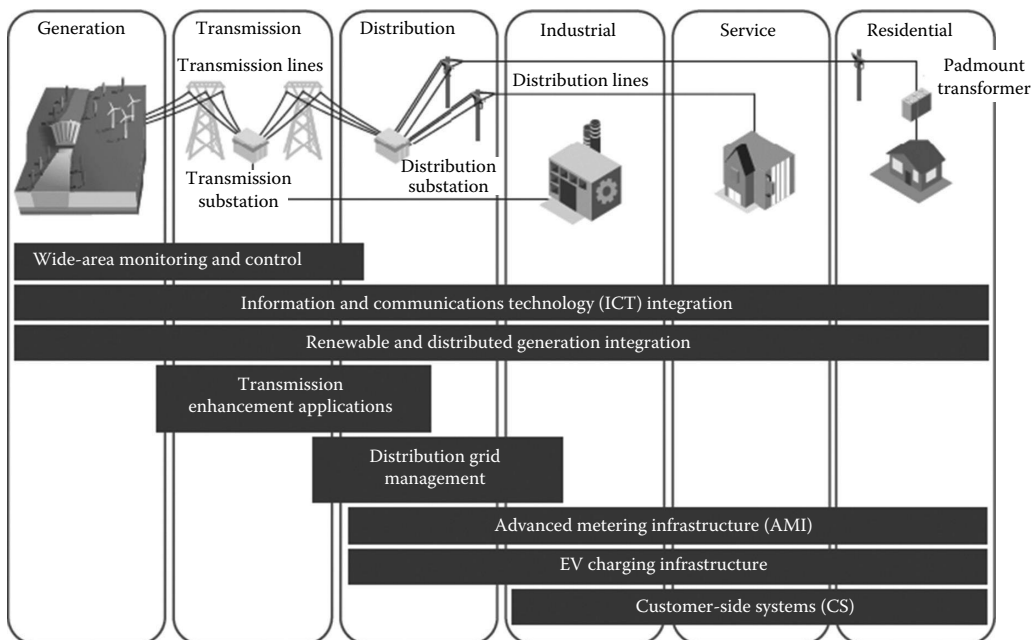

To deal with such challenges and take advantage of the new resources, new technology has been developed and deployed. ICT and M2M (machine-to-machine) communications will definitely play a key role to make the smart grid a reality, since they will enable the required bidirectional communication between the high volume of devices to be monitored and controlled, and the end users and the information systems where the intelligence resides.

The metering side of the distribution system has been the focus of the smart grid investments so far, with the initial introduction of one-way AMR (automated meter reading) systems to read meter data. However, due to its one-way communication system, AMR systems do not allow the transition to the smart grid, due to the absence of control capabilities. In a second stage, the AMI (advanced metering infrastructure) has been used to provide a two-way communication system to the meter, as well as the ability to ensure load management and revenue protection.

The next step is the leverage of the AMI to implement distributed command and control strategies with pervasive control and intelligence across all geographies, components, and functions of the system. To ensure it several different smart grid technological areas have to be developed, such as wide-area monitoring and control, information and communications technology integration, renewable and DG integration, transmission enhancement applications, distributed grid management, AMI, electric vehicles charging infrastructure, and customer-side systems (Figure 14.20).

Smart grids are expected to address the major shortcomings of the existing grid and explore the new resources. The smart grid still depends on the support of large central-station generation, but it includes energy storage and renewable energy generation facilities in the different grid levels. In addition, the smart grid needs to provide the utility companies with enhanced sensory and control capability to ensure the full visibility and pervasive control over their assets and services.

The aim of smart grids is to maximize the system reliability, resilience and stability, and minimize costs and environmental impacts by coordinating the needs and resources of end-users and generation, grid and market operators. Due to the available technology,

**FIGURE 14.20**

Smart grid technology areas. (From International Energy Agency, *Technology Roadmaps: Smart Grids*, International Energy Agency, Paris, France, 2011.)

the smart grids are no longer just a future vision, but already a reality. A high number of implemented projects and pilots have been proving the impacts of smart grids which can ensure multiple benefits, not only to the utilities but also to the users and society. smart grids will facilitate the integration of diverse supply-side resources, support the integration of distributed and on-site generation on the customer side, promote more active engagement of demand-side resources and participation of customers' loads, and allow the widespread permeation of dynamic pricing to beyond-the-meter applications.

### 15.1 Introduction

Since the mid-1980s, demand-side management has been an important element of the electric utility planning approach referred to as *integrated resource planning*. At that time, annual demand-side management expenditures in the United States were measured in billions of dollars, energy savings were measured in billions of kWh, and peak load reductions were stated in thousands of MW. While activities nationally slowed during the couple of decades that followed the 1980s, activity has again been on the rise since the turn of the millennium. Expenditures for utility and third-party administered electric efficiency programs were nearly \$6 billion in 2012, up from a low of \$0.9 billion in 1998; in addition, estimated electric savings nationwide exceeded 22 billion kWh in 2011 (Hayes et al. 2013). Therefore, demand-side management practices have continued to persevere and have recently regained a considerable and growing influence on the demand for energy resources. This chapter defines demand-side management, describes the role demand-side management plays in integrated resource planning, discusses the main elements of demand-side management programs, and summarizes the key best practices for program design and delivery. It then presents case studies of four successful demand-side management programs.

---

## 15.2 What Is Demand-Side Management?

The term *demand-side management* is the result of a logical evolution of planning processes used by utilities in the late 1980s. One of the first terms, *demand-side load management* was introduced by the author, Clark W. Gellings, in an article for *IEEE Spectrum* in 1981. Shortly after the publication of this article, at a meeting of The Edison Electric Institute (EEI) Customer Service and Marketing Executives in 1982, Mr. Gellings altered the term to *demand-side planning*. This change was made to reflect the broader objectives of the planning process. Mr. Gellings coined the term *demand-side management* and continued to popularize the term throughout a series of more than 100 articles since that time, including the five volume set *Demand-Side Management* which is widely recognized as a definitive and practical source of information on the demand-side management process.

Perhaps the most widely accepted definition of demand-side management is the following:

Demand-side management is the planning, implementation, and monitoring of those utility activities designed to influence customer use of electricity in ways that will produce desired changes in the utility's load shape, i.e., changes in the time pattern and magnitude of a utility's load. Utility programs falling under the umbrella of demand-side management include: load management, new uses, strategic conservation, electrification, customer generation, and adjustments in market share (Gellings 1984–1988).

However, demand-side management is even more encompassing than this definition implies because it includes the management of all forms of energy at the demand-side, not just electricity. In addition, groups other than just electric utilities (including natural gas suppliers, government organizations, nonprofit groups, and private parties) implement demand-side management programs.

In general, demand-side management embraces the following critical components of energy planning:

1. Demand-side management *will influence customer use*. Any program intended to influence the customer's use of energy is considered demand-side management.
2. Demand-side management *must achieve selected objectives*. To constitute a desired load-shape change, the program must further the achievement of selected objectives; that is, it must result in reductions in average rates, improvements in customer satisfaction, achievement of reliability targets, etc.
3. Demand-side management *will be evaluated against non-demand-side management alternatives*. The concept also requires that selected demand-side management programs further these objectives to at least as great an extent as non-demand-side management alternatives, such as generating units, purchased power, or supply-side storage devices. In other words, it requires that demand-side management alternatives be compared to supply-side alternatives. It is at this stage of evaluation that demand-side management becomes part of the integrated resource planning process.
4. Demand-side management *identifies how customers will respond*. Demand-side management is pragmatically oriented. Normative programs (we ought to do this) do not bring about the desired; positive efforts (if we do this, that will happen) are required. Thus, demand-side management encompasses a process that identifies how customers will respond not how they should respond.

5. Demand-side management *value is influenced by load shape*. Finally, this definition of demand-side management focuses upon the load shape. This implies an evaluation process that examines the value of programs according to how they influence costs and benefits throughout the day, week, month, and year.

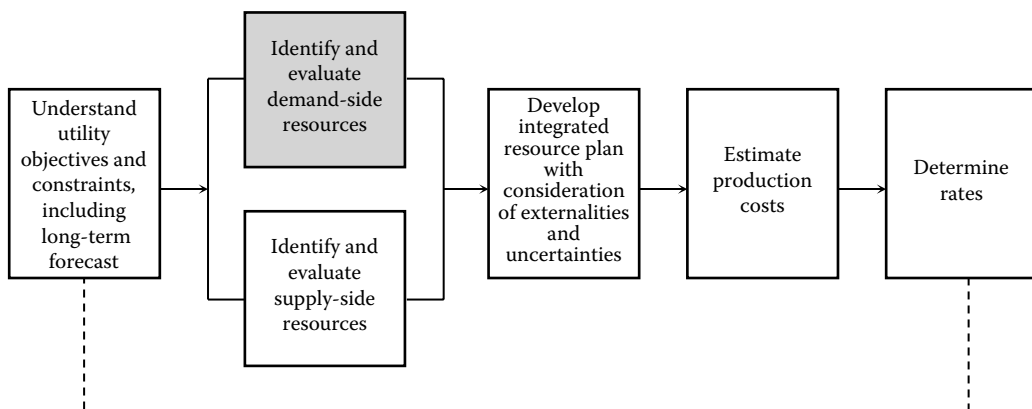

Subsets of these activities have been referred to in the past as *load management*, *strategic conservation*, and *marketing*.

### 15.3 Demand-Side Management and Integrated Resource Planning

A very important part of the demand-side management process involves the consistent evaluation of demand-side to supply-side alternatives and vice versa. This approach is referred to as *integrated resource planning*. Figure 15.1 illustrates how demand-side management fits into the integrated resource planning process. For demand-side management to be a viable resource option, it has to compete with traditional supply-side options.

### 15.4 Demand-Side Management Programs

A variety of programs have been implemented since the introduction of demand-side management in the early 1980s. Mr. Gellings and the EPRI (Electric Power Research Institute) have been instrumental in defining a framework for utilities and other implementers to follow when planning demand-side management programs (Gellings 1984–1988; Evans et al. 1993; Gellings and Chamberlin 1993; Gellings 2002; Siddiqui et al. 2008). This section describes the main elements of the demand-side management planning framework. It then discusses the types of end-use sectors, buildings, and end-use technologies targeted during program development. It also lists the various entities typically responsible for implementing programs, along with several program implementation methods. Lastly, this section summarizes specific characteristics of successful program design and delivery.

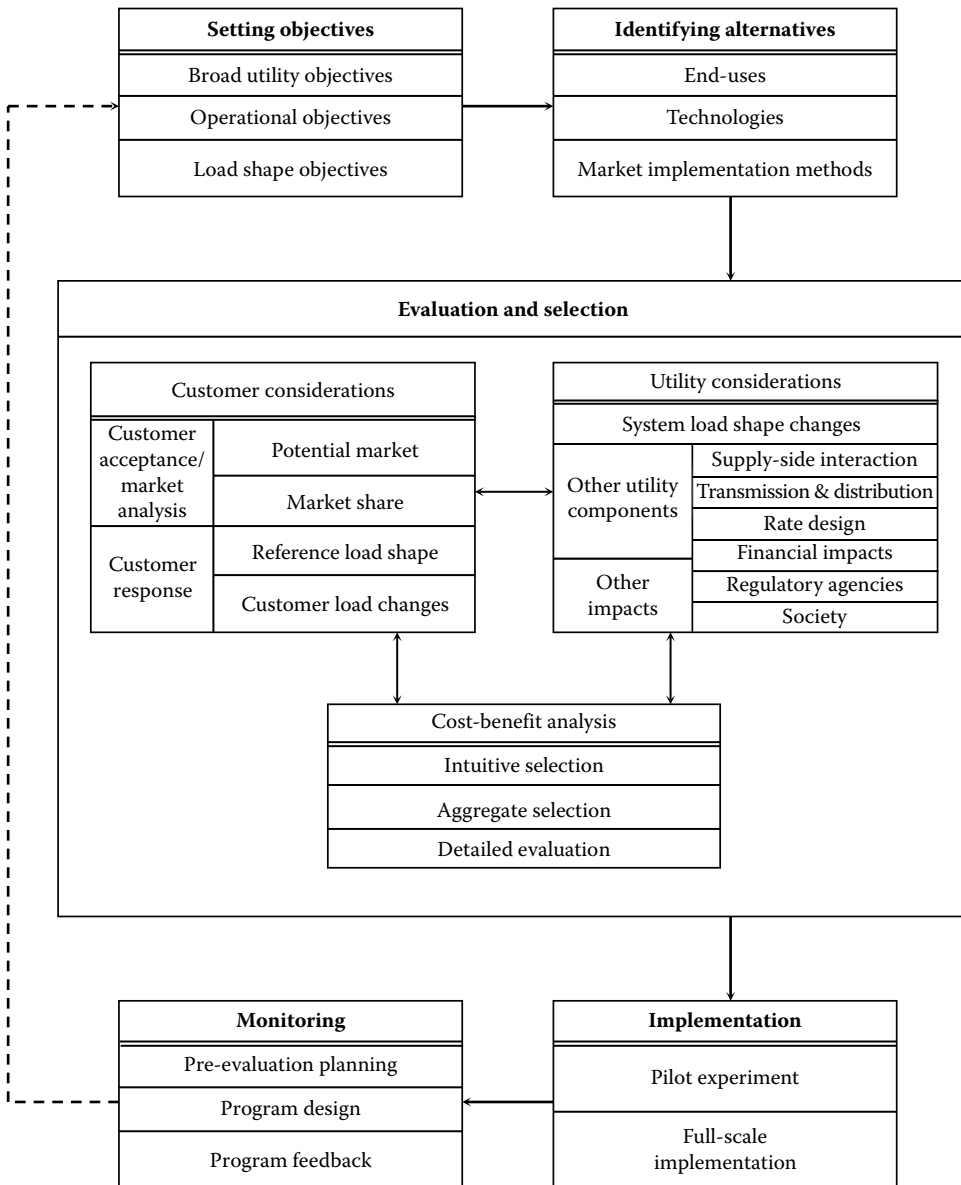

**FIGURE 15.1**

How demand-side management fits into integrated resource planning.

### 15.4.1 Elements of the Demand-Side Management Planning Framework

Figure 15.2 illustrates the five main elements of the demand-side management planning framework. These five elements are summarized as follows:

1. *Set objectives*: The first step in demand-side management planning is to establish overall organizational objectives. These strategic objectives are quite broad and generally include examples such as conserving energy resources, reducing peak demand (thereby deferring need to build new power plants), decreasing

**FIGURE 15.2**  
Elements of the demand-side management planning framework.

greenhouse gas emissions, reducing dependence on foreign imports, improving cash flow, increasing earnings, and improving customer and employee relations. In this level of the formal planning process, the planner needs to operationalize broad objectives to guide policymakers to specific actions. It is at this operational level or tactical level that demand-side management alternatives should be examined and evaluated. For example, an examination of capital investment requirements may show periods of high investment needs. Postponing the need for new construction through a demand-side management program may reduce investment needs and stabilize the financial future of an energy company, or a utility and its state or country. Specific operational objectives are established on the basis of the conditions of the existing energy system—its system configuration, cash reserves, operating environment, and competition. Once designated, operational objectives are translated into desired demand-pattern changes or load-shape changes that can be used to characterize the potential impact of alternative demand-side management programs. Although there is an infinite combination of load-shape-changing possibilities, six have been illustrated in Figure 15.3 to show the range of possibilities, namely peak clipping, valley filling, load shifting, strategic conservation, strategic load growth, and flexible load shape. These six are not mutually exclusive, and may frequently be employed in combinations.

2. *Identify alternatives:* The second step is to identify alternatives. The first dimension of this step involves identifying the appropriate end-uses whose peak load and energy consumption characteristics generally match the requirements of the load-shape objectives established in the previous step. In general, each

**Peak clipping**—or the reduction of the system peak loads, embodies one of the classic forms of load management and is now commonly referred to as *demand response*. Peak clipping is generally considered as the reduction of peak load by using time-based rate options or incentive-based strategies, with or without enabling technologies. While many utilities consider this as a means to reduce peaking capacity or capacity purchases and consider strategies only during the most probable days and times of system peak, these strategies can be used to reduce operating cost and dependence on critical fuels by economic dispatch.

**Valley filling**—is the second classic form of load management and applies to both gas and electric systems. Valley filling encompasses building off-peak loads. This may be particularly desirable where the long-run incremental cost is less than the average price of energy. Adding properly priced off-peak load under those circumstances decreases the average price. Valley filling can be accomplished in several ways, one of the most popular of which displaces loads served by fossil fuels with electric loads that are operated during off-peak periods (e.g., water heating and/or space heating).

**Load shifting**—is the last classic form of load management and also applies to both gas and electric systems. This involves shifting load from on-peak to off-peak periods. Popular applications include use of storage water heating, storage space heating, coolness storage (the most common type of thermal energy storage), and customer load shifts. The load shift from storage devices involves displacing what would have been conventional appliances.

**FIGURE 15.3**

Six generic load-shape objectives that can be considered during demand-side management planning. (Continued)

**Strategic conservation**—is the load-shape change that results from programs directed at end-use consumption. Not normally considered load management, the change reflects a modification of the load shape involving a reduction in consumption as well as a change in the pattern of use. In employing energy conservation, the planner must consider what conservation actions would occur naturally and then evaluate the cost-effectiveness of possible intended programs to accelerate or stimulate those actions. Examples include weatherization and appliance efficiency improvement.

**Strategic load growth**—is the load-shape change that refers to a general increase in sales beyond the valley filling described previously. Load growth may involve increased market share of loads that are or can be, served by competing fuels, as well as economic development. Load growth may include electrification. Electrification is the term being employed to describe the new emerging electric technologies surrounding electric vehicles, industrial process heating, and automation. These have a potential for increasing the electric energy intensity of the industrial sector. This rise in intensity may be motivated by reduction in the use of fossil fuels and raw materials resulting in improved overall productivity.

**Flexible load shape**—is a concept related to electric system reliability, a planning constraint. Once the anticipated load shape, including demand-side activities, is forecast over some horizon, the power supply planner studies the final optimum supply-side options. Among the many criteria he or she uses is reliability. Load shape can be flexible—if customers are presented with options as to the variations in quality of service that they are willing to allow in exchange for various incentives. The program involved can be variations of interruptible or curtailable load; concepts of pooled, integrated energy management systems; or individual customer load control devices offering service constraints.

**FIGURE 15.3 (Continued)**

Six generic load-shape objectives that can be considered during demand-side management planning.

end-use (e.g., residential space heating, commercial lighting) exhibits typical and predictable demand or load patterns. The extent to which load pattern modification can be accommodated by a given end-use is one factor used to select an end-use for demand-side management. The second dimension of demand-side management alternatives involves choosing appropriate technology alternatives for each target end-use. This process should consider the suitability of the technology for satisfying the load-shape objective. Even though a technology is suitable for a given end-use, it may not produce the desired results. For example, although water-heater wraps are appropriate for reducing domestic water-heating energy consumption, they are not appropriate for load shifting. In this case, an option such as electric water-heating direct load control would be a better choice. The third dimension involves investigating market implementation methods (see Section 15.4.5 for a description of potential implementation methods).

3. *Evaluate and select program(s)*: The third step balances customer considerations, supplier considerations, and cost/benefit analyses to identify the most viable demand-side management alternative(s) to pursue. Although customers and suppliers act independently to alter the pattern of demand, the concept of demand-side management implies a supplier/customer relationship that produces mutually beneficial results. To achieve that mutual benefit, suppliers must carefully consider such

factors as the manner in which the activity will affect the patterns and amount of demand (load shape), the methods available for obtaining customer participation, and the likely magnitudes of costs and benefits to both supplier and customer prior to attempting implementation.

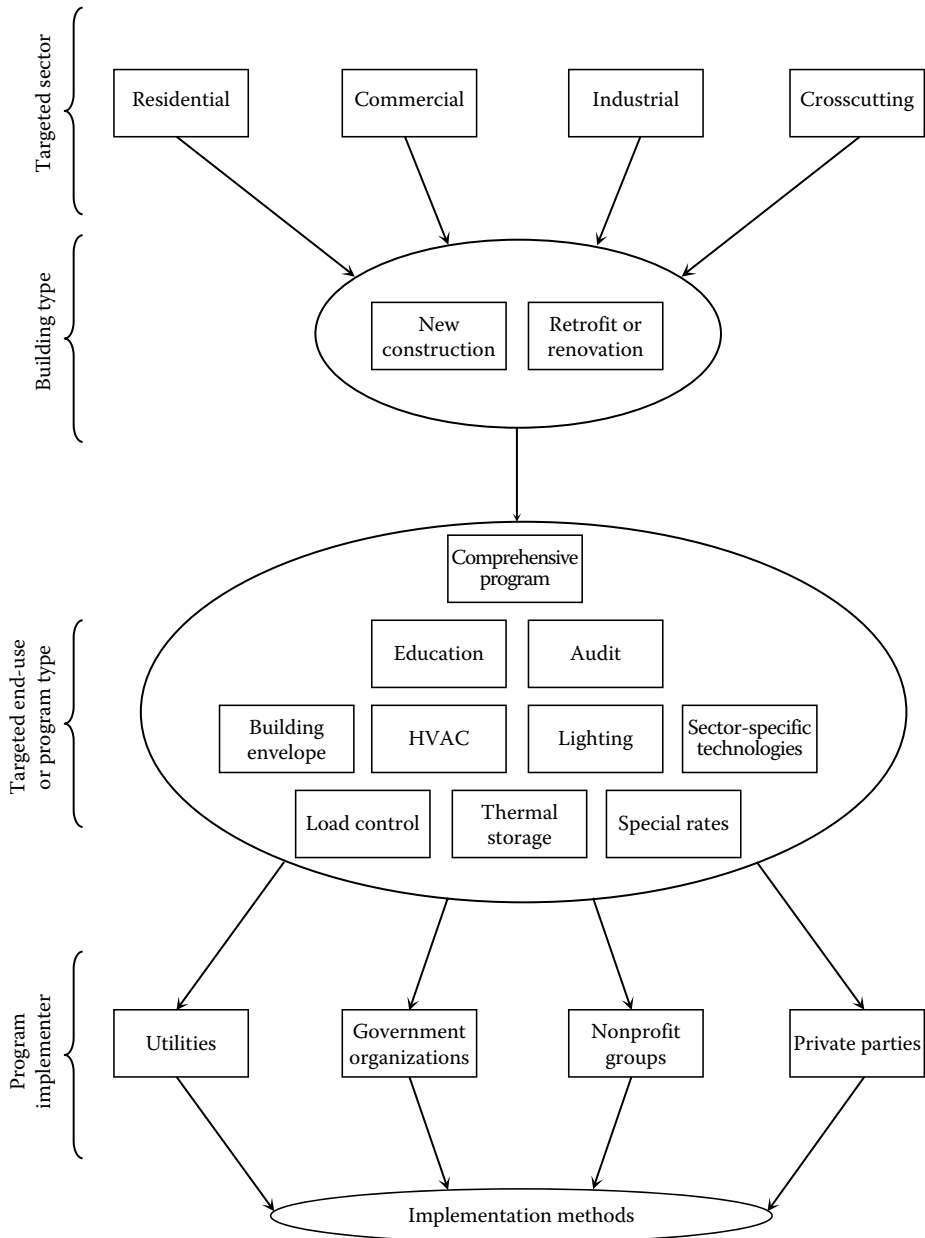

4. *Implement program(s)*: The fourth step is to implement the program(s), which takes place in several stages. As a first step, a high level, demand-side management project team should be created with representation from the various departments and organizations, and with the overall control and responsibility for the implementation process. It is important for implementers to establish clear directives for the project team, including a written scope of responsibility, project team goals and time frame. When limited information is available on prior demand-side management program experiences, a pilot experiment may precede the program. Pilot experiments can be a useful interim step toward making a decision to undertake a major program. Pilot experiments may be limited either to a subregion or to a sample of consumers throughout an area. If the pilot experiment proves cost-effective, then the implementers may consider initiating the full-scale program.
5. *Monitor program(s)*: The fifth step is to monitor the program(s). The ultimate goal of the monitoring process is to identify deviations from expected performance and to improve both existing and planned demand-side management programs. Monitoring and evaluation processes can also serve as a primary source of information on customer behavior and system impacts, foster advanced planning and organization within a demand-side management program, and provide management with the means of examining demand-side management programs as they develop.

#### 15.4.2 Targeted End-Use Sectors/Building Types

The three broad categories of end-use sectors targeted for demand-side management programs are residential, commercial, and industrial. Each of these broad categories includes several subsectors. In some cases, the program will be designed for one or more broad sectors; in other cases, it may be designed for a specific subsector. For example, the residential sector can be divided into several subsectors including single family homes, multifamily homes, mobile homes, low-income homes, etc. In addition, the commercial sector can be split into subsets, such as offices, restaurants, health care facilities, educational facilities, retail stores, grocery stores, hotels/motels, etc. There are also numerous specific industrial end-users that may be potentially targeted for a demand-side management program. Moreover, the program designer may want to target a specific type or size of building within the chosen sector. The program could focus on new construction, old construction, renovations and retrofits, large customers, small customers, or a combination. Crosscutting programs target multiple end-use sectors and/or multiple building types. [Figure 15.4](#) illustrates the broad types of end-use sectors and building types and how they relate to other aspects of demand-side management program planning.

#### 15.4.3 Targeted End-Use Technologies/Program Types

There are several end-use technologies or program types targeted in demand-side management programs (see [Figure 15.4](#)). Some programs are comprehensive, and crossover between end-use technologies. Other programs target specific end-use equipment, such as lighting,

**FIGURE 15.4**

Relationship between end-use sectors, building types, end-use programs, and program implementers.

air conditioners, dishwashers, etc. Still others target load control measures, such as demand response programs whereby customers temporarily curtail loads in response to peak demand events or programs that permanently shift loads to off-peak hours (e.g., via thermal energy storage). [Figure 15.4](#) shows representative end-use technologies or program types and how they relate to other aspects of demand-side management program planning.

#### 15.4.4 Program Implementers

Implementers of demand-side management programs are often utilities. However, other possible implementers include government organizations, nonprofit groups, private parties, or a collaboration of several entities (see [Figure 15.4](#)). Utilities and governments, in particular, have a special interest in influencing customers' demand—treating it not as fate but as choice—in order to provide better service at lower cost while increasing their own profits and reducing their business risks. Energy planners can choose from a wide range of market push and pull methods designed to influence consumer adoption and reduce barriers, as discussed in the next section.

#### 15.4.5 Implementation Methods

Among the most important dimension in the characterization of demand-side alternatives is the selection of the appropriate market implementation methods. Planners and policy makers can select from a variety of methods for influencing customer adoption and acceptance of demand-side management programs. The methods can be broadly classified into six categories. [Table 15.1](#) lists examples for each category of market implementation method. The categories include the following:

1. *Customer education*: Many energy suppliers and governments have relied on some form of customer education to promote general customer awareness of programs. Websites, brochures, bill inserts, information packets, clearinghouses, educational curricula, and direct mailings are widely used. Customer education is the most basic of the market implementation methods available and should be used in conjunction with one or more other market implementation method for maximum effectiveness.
2. *Direct customer contact*: Direct customer contact techniques refer to face-to-face communication between the customer and an energy supplier or government representative to encourage greater customer acceptance of programs. Energy suppliers have for some time employed marketing and customer service representatives to provide advice on appliance choice and operation, sizing of heating/cooling systems, lighting design, and even home economics. Direct customer contact can be accomplished through energy audits, specific program services (e.g., equipment servicing), store fronts where information and devices are displayed, workshops, exhibits, on-site inspection, etc. A major advantage of these methods is that they allow the implementer to obtain feedback from the consumer, thus providing an opportunity to identify and respond to major customer concerns. They also enable more personalized marketing, and can be useful in communicating interest in and concern for controlling energy costs.

**TABLE 15.1**

Examples of Market Implementation Methods

Market Implementation Method	Illustrative Objective	Examples
Customer education	<ul style="list-style-type: none"> <li>• Increase customer awareness of programs</li> <li>• Increase perceived value of energy services</li> </ul>	<ul style="list-style-type: none"> <li>• Websites</li> <li>• Bill inserts</li> <li>• Brochures</li> <li>• Information packets</li> <li>• Displays</li> <li>• Clearinghouses</li> <li>• Direct mailings</li> </ul>
Direct customer contact	<ul style="list-style-type: none"> <li>• Through face-to-face communication, encourage greater customer acceptance and response to programs</li> </ul>	<ul style="list-style-type: none"> <li>• Energy audits</li> <li>• Direct installation</li> <li>• Store fronts</li> <li>• Workshops/energy clinics</li> <li>• Exhibits/displays</li> <li>• Inspection services</li> </ul>
Trade ally cooperation (i.e., architects, engineers, appliance dealers, heating/ cooling contractors)	<ul style="list-style-type: none"> <li>• Increase capability in marketing and implementing programs</li> <li>• Obtain support and technical advice on customer adoption of demand-side technologies</li> </ul>	<ul style="list-style-type: none"> <li>• Cooperative advertising and marketing</li> <li>• Training</li> <li>• Certification</li> <li>• Selected product sales/service</li> </ul>
Advertising and promotion	<ul style="list-style-type: none"> <li>• Increase public awareness of new programs</li> <li>• Influence customer response</li> </ul>	<ul style="list-style-type: none"> <li>• Mass media (Internet, radio, TV, and newspaper)</li> <li>• Point-of-purchase advertising</li> </ul>
Alternative pricing	<ul style="list-style-type: none"> <li>• Provide customers with pricing signals that reflect real economic costs and encourage the desired market response</li> </ul>	<ul style="list-style-type: none"> <li>• Demand rates</li> <li>• Time-of-use rates</li> <li>• Real-time pricing</li> <li>• Critical peak pricing</li> <li>• Off-peak rates</li> <li>• Seasonal rates</li> <li>• Inverted rates</li> <li>• Variable levels of service</li> <li>• Promotional rates</li> <li>• Conservation rates</li> </ul>
Direct incentives	<ul style="list-style-type: none"> <li>• Reduce up-front purchase price and risk of demand-side technologies to the customer</li> <li>• Increase short-term market penetration</li> <li>• Provide incentives to employees to promote demand-side management programs</li> </ul>	<ul style="list-style-type: none"> <li>• Low- or no-interest loan</li> <li>• Cash grants</li> <li>• Subsidized installation/modification</li> <li>• Rebates</li> <li>• Buyback programs</li> <li>• Rewards to employees for successful marketing of demand-side management programs</li> </ul>

3. *Trade ally cooperation:* Trade ally cooperation and support can contribute significantly to the success of many demand-side management programs. A trade ally is defined as any organization that can influence the transactions between the supplier and its customers or between implementers and consumers. Key trade ally groups include home builders and contractors, local chapters of professional societies, technology/product trade groups, trade associations, and associations representing wholesalers and retailers of appliances and energy consuming devices. Depending on the type of trade ally organization, a wide range of services are performed, including

development of standards and procedures, technology transfer, training, certification, marketing/sales, installation, maintenance, and repair. Generally, if trade ally groups believe that demand-side management programs will help them (or at least not hinder their business), they will likely support the program.

4. *Advertising and promotion:* Energy suppliers and government energy entities have used a variety of advertising and promotional techniques. Advertising uses various media to communicate a message to customers in order to inform or persuade them. Advertising media applicable to demand-side management programs include the Internet, radio, television, magazines, newspapers, outdoor advertising and point-of-purchase advertising. Promotion usually includes activities to support advertising, such as press releases, personal selling, displays, demonstrations, coupons, and contest/awards.
5. *Alternative pricing:* Pricing as a market-influencing factor generally performs three functions: (a) transfers to producers and consumers information regarding the cost or value of products and services being provided, (b) provides incentives to use the most efficient production and consumption methods, and (c) determines who can afford how much of a product. These three functions are closely interrelated. Alternative pricing, through innovative schemes can be an important implementation technique for utilities promoting demand-side options. For example, rate incentives for encouraging specific patterns of utilization of electricity can often be combined with other strategies (e.g., direct incentives) to achieve electric utility demand-side management goals. Pricing structures include time-of-use rates, real-time pricing, critical peak pricing, inverted rates, seasonal rates, variable service levels, promotional rates, off-peak rates, etc. A major advantage of alternative pricing programs over some other types of implementation techniques is that the supplier has little or no cash outlay. The customer receives a financial incentive, but over a period of years, so that the implementer can provide the incentives as it receives the benefits.
6. *Direct incentives:* Direct incentives are used to increase short-term market penetration of a cost control/customer option by reducing the net cash outlay required for equipment purchase or by reducing the payback period (i.e., increasing the rate of return) to make the investment more attractive. Incentives also reduce customer resistance to options without proven performance histories or options that involve extensive modifications to the building or the customer's lifestyle. Direct incentives include cash grants, rebates, buyback programs, billing credits, and low-interest or no-interest loans. One additional type of direct incentive is the offer of free, or very heavily, subsidized, equipment installation or maintenance in exchange for participation. Such arrangements may cost the supplier more than the direct benefits from the energy or demand impact, but can expedite customer recruitment, and allow the collection of valuable empirical performance data.

Energy suppliers, utilities, and government entities have successfully used many of these marketing strategies. Typically, multiple marketing methods are used to promote demand-side management programs. The selection of the individual market implementation method or mix of methods depends on a number of factors, including the following:

- Prior experience with similar programs
- Existing market penetration
- The receptivity of policy makers and regulatory authorities

- The estimated program benefits and costs to suppliers and customers
- Stage of buyer readiness
- Barriers to implementation

Some of the most innovative demand-side marketing programs started as pilot programs to gauge consumer acceptance and evaluate program design before large-scale implementation.

The objective of the market implementation methods is to influence the marketplace and to change the customer behavior. The key question for planners and policy makers is the selection of the market implementation method(s) to obtain the desired customer acceptance and response. Customer acceptance refers to customer willingness to participate in a market implementation program, customer decisions to adopt the desired fuel/appliance choice and efficiency, and behavior change as encouraged by the supplier, or state. Customer response is the actual load-shape change that results from customer action, combined with the characteristics of the devices and systems being used.

Customer acceptance and responses are influenced by the demographic characteristics of the customer, income, knowledge, and awareness of the technologies and programs available, and decision criteria, such as cash flow and perceived benefits and costs, as well as attitudes and motivations. Customer acceptance and response are also influenced by other external factors, such as economic conditions, energy prices, technology characteristics, regulation, and tax credits.

#### **15.4.6 Characteristics of Successful Programs**

Numerous demand-side management programs are implemented in the United States yearly by various organizations including utilities, state agencies, and third-party implementers. In addition, some businesses implement their own internal or corporate-wide energy efficiency programs. Over the years, groups such as the EPRI, American Council for an Energy-Efficient Economy (ACEEE), Energy Trust of Oregon, and California Best Practices Project Advisory Committee with contractor, Quantum Consulting Inc., have reviewed and compared demand-side management programs to identify exemplary programs and best practices. The results of those studies are included in an assortment of reports (Peters 2002; Quantum Consulting 2004; Wikler et al. 2008; Nowak et al. 2013; Young and Mackres 2013).

EPRI conducted an assessment of best practices in demand-side management programs (Wikler et al. 2008). The study included interviews with utility program staff, an online survey of utility representatives, and a comprehensive review of recent best practices studies in the literature. The study revealed a number of elements associated with successful program design and delivery. Some of the elements vary by customer segment and program type, while others are common across multiple program types. [Table 15.2](#) lists the challenges faced by selected types of Residential and Commercial & Industrial (C&I) programs and identifies the key factors that have contributed to programs' success. The table also includes examples of programs that have applied these best practices. The following subsections distill some of the more generally applicable best practices for program design and delivery.

**TABLE 15.2**

Synthesis of Key Challenges and Success Factors for Selected Energy Efficiency and Load Management Programs

Program Type	Key Challenges	Key Success Factors	Program Example
Residential conservation	<ul style="list-style-type: none"> <li>• Technology developments</li> <li>• Easy access to pay stations</li> </ul>	<ul style="list-style-type: none"> <li>• Enhancing customer knowledge and control over their consumption</li> </ul>	Salt River Project—M Power
Residential lighting	<ul style="list-style-type: none"> <li>• Low customer motivation, especially if electricity prices are low</li> <li>• Utility resource allocation toward marketing and outreach efforts</li> <li>• Overcome customer experience or perception of poor quality products</li> <li>• CFL disposal issues</li> </ul>	<ul style="list-style-type: none"> <li>• Aggressive customer awareness and outreach efforts</li> <li>• Strong publicity campaigns</li> <li>• Leverage ENERGY STAR® brand</li> <li>• Build and maintain relationships with manufacturers and retailers</li> </ul>	Georgia Power—ENERGY STAR Change a Light (CAL) Campaign Snohomish County PUD—Residential CFL Program
Residential load management	<ul style="list-style-type: none"> <li>• Obtain customer trust to install equipment</li> <li>• Address customer complaints unrelated to the program</li> <li>• Low level of customer motivation if electricity prices are low</li> </ul>	<ul style="list-style-type: none"> <li>• Simple program design</li> <li>• Widespread customer awareness and outreach efforts</li> <li>• Establish system reliability</li> <li>• Maintain continuity in customer participation</li> <li>• Build strong customer relationships</li> <li>• Provide customer choice and control on electricity usage</li> </ul>	Florida Power and Light—Residential On Call Gulf Power—Good Cents Select

#### 15.4.6.1 Key Elements of Program Design

Successful program design effectively translates the program design theories into a practical program structure with actionable policies and procedures aimed at meeting program goals and objectives. Key elements of success include the following:

- Maintain simplicity in program design
- Design incentive structure to fit customer requirements
- Maintain flexibility in program design to accommodate measures
- Maintain dynamism in program design to fit market requirements in specific industries

- Develop sound performance tracking mechanisms
- Incorporate customer choice and control features in program design
- Ensure resource allocation is commensurate with program tasks
- Obtain stakeholder support right at the design stage
- Maintain high quality of products
- Establish program branding
- Undertake program improvements over time

#### **15.4.6.2 Key Elements of Program Delivery**

Program delivery consists of marketplace actions to promote demand-side management practices and to increase adoption of technologies and measures. Specific delivery activities encompass the implementation methods discussed in Section 15.5. There are several key elements of successful program delivery:

- Foster trade ally relationships and partnerships
- Undertake contractor capacity building efforts
- Build networks and alliances with other relevant parties and groups
- Undertake program publicity campaigns
- Establish strong customer education and outreach efforts
- Foster utility–customer relationships
- Coordinate with other utilities and program administrators
- Build customer–contractor relationships
- Maintain strong in-house capabilities
- Integrate energy efficiency into customer’s business strategy
- Deliver nonenergy benefits
- Maintain consistency over time
- Enhance program delivery through collaborative efforts

---

### **15.5 Case Studies**

This section examines case studies of four successful demand-side management programs and a smart grid demonstration project. Each of the four programs targets a different sector and set of end-uses. In addition, each program represents a different U.S. geographical region and has a different implementation structure. The smart grid demonstration project is a widespread effort involving a collaboration of over 20 utilities in the United States and abroad with the common goal of advancing the integration of distributed energy resources into the electric power grid.

[Table 15.3](#) presents the first case study, which is a comprehensive industrial energy efficiency program administered by Bonneville Power Administration (BPA). The second

**TABLE 15.3****Case Study #1—2012 Bonneville Power Administration (BPA) Energy Smart Industrial (ESI) Program***Description:*

BPA's ESI program was designed and rolled out in 2009 with partner Cascade Energy to help BPA meet aggressive industrial energy savings goals. The program targets the industrial sector in BPA's service territory in the Pacific Northwest and incorporates a wide range of retrofit and operation and maintenance measures as well as continuous improvement options aimed at behavioral changes. BPA's participating utility customers can choose from this assortment of measures and several different market delivery options to serve their industrial customers. Customers receive incentives for projects and many are eligible for subsidized technical consulting services. A unique program aspect is the use of a qualified ESI partner (ESIP) assigned by the ESI program to act as a single point of contact for the program to the utilities and industrial customers. In addition, a pilot feature of the program incorporates three innovative Energy Management options to improve operation and maintenance and management aspects of energy use so that savings persist: (1) co-funding for an Energy Project Manager to serve as a staff resource to promote energy efficiency projects at qualifying facilities, (2) support for no-cost/low-cost operation and maintenance improvements including tools for data collection and tracking and incentive funding (referred to as Track and Tune), and (3) use of behavior-based and continuous improvement approaches to train industrial facilities to incorporate energy management into core business practices (referred to as High Performance Energy Management). The program's success is reflected in its high performance over a short period of time, cost-effectiveness, utility and industrial customer satisfaction with offerings, and simplified communications approach.

*Targeted sector/building type:*

Industrial customers of BPA's multiple utility customers in the Pacific Northwest.

Any industrial customer of a participating utility is eligible.

Targeted industries include pulp and paper, wood products, food processing, and water and wastewater.

*Targeted end-use technology/program type:*

Targets multiple end-users through various measure types: custom and prescriptive retrofit projects; no-cost/low-cost operation and maintenance improvements; and behavior-based measures

*Program administrator/implementer:*

Administered by Bonneville Power Administration

Implemented by Cascade Energy

*Program expenditures for 2012 (estimated):*

\$15.2 million

*Program results for 2012 (estimated):*

Net energy savings: 91,980 MWh

Net demand savings: 10.50 aMW

Participation: 105 enrolled utilities; 86 engaged utilities; 478 end-users

*Source:* Nowak, S. et al., Leaders of the pack: ACEEE's third national review of exemplary energy efficiency programs, Report No. U132, ACEEE, Washington, DC, 2013.

Personal communication with Jennifer Eskil, Agriculture/Industrial Sector Lead, Bonneville Power Administration, August 20, 2013.

case study (Table 15.4) is a retrocommissioning (RCx) program offered to the commercial sector by Commonwealth Edison (ComEd) with a focus on controls optimization and other operational energy efficiency improvements. The third case study (Table 15.5) is a Southern California Edison (SCE) pilot program that was offered to water utilities and targeted both water and energy savings. These first three programs received the distinction of *exemplary* by ACEEE in 2013 for their excellence in program design and delivery. Table 15.6 presents the fourth case study, a smart grid-enabled demand response program offered to residential and small commercial customers by Oklahoma Gas and

**TABLE 15.4**

Case Study #2—2011/2012 Commonwealth Edison (ComEd) Smart Ideas for Your Business Retrocommissioning (RCx) and Monitoring-Based Commissioning (MBCx) Program

---

*Description:*

In ComEd's Smart Ideas for Your Business RCx and MBCx programs, approved engineering firms (Service Providers) provide onsite assessments and analysis of building energy systems that focus on controls optimization and other operational improvements. ComEd pays the Service Providers to do the study, at no cost to the customer. The customer in exchange agrees to invest at least a minimum amount on operational improvements with paybacks of 18 months or less. A newer feature of the program is the inclusion of natural gas measures in the analysis, which is enabled by partnerships with local gas companies. Investigating electric and gas measures simultaneously optimizes the Service Providers' time at the site and provides additional value to the customers and utilities. Another enhancement to the program is the addition of an MBCx option in which the customer receives an incentive to help offset the cost of installing advanced building automation software to monitor energy use and identify opportunities for operational improvements over a period of 18 months or more. Then, the customer is paid an additional incentive for verified energy savings resulting from these improvements. Some of the reasons for the program's success include the use of preapproved Service Providers as a sales channel, the partnerships with natural gas utilities and ability to identify electric and gas measures, and the program's continued efforts to enhance processes and adapt to reach more customers and savings opportunities.

*Targeted sector/building type:*

Commercial sector in Northern Illinois: retail and office buildings; commercial real estate; hospitals; education; hospitality; and other buildings with > 150,000 sq. ft. of air-conditioned floor space

*Targeted end-use technology/program type:*

RCx and MBCx programs

Targets operation and maintenance improvements such as economizer and ventilation control, equipment scheduling, and fan optimization and air distribution modifications

Include electric and gas saving measures

*Program administrator/implementer:*

Administered by ComEd in partnership with Nicor Gas, North Shore Gas, and Peoples Gas

Implemented by Nexant

*Program expenditures for program year 4 (2011/2012):*

\$4.84 million

*Program results for program year 4 (2011/2012):*

Net electricity savings: 25,021 MWh

Participation: 50 customers

---

*Source:* Nowak, S. et al., Leaders of the pack: ACEEE's third national review of exemplary energy efficiency programs, Report No. U132, ACEEE, Washington, DC, 2013.

Personal communication with Rick Tonielli, Sr. Energy Efficiency Program Manager, ComEd, August 14, 2013.

Electric (OG&E). OG&E was recognized as Utility of the Year in 2011 by *Electric Light & Power*, in part due to OG&E's successful demand management programs and their high customer satisfaction rating during a period of very high Smart Meter deployment. The smart grid demonstration project (Table 15.7) is a large-scale EPRI initiative focused on demonstrating grid integration of distributed energy resources, such as demand response technologies, electric vehicles, thermal energy storage, electric storage, solar photovoltaics, wind generation, conservation voltage reduction, and distributed generation. The project just completed its fifth year of a 7-year effort. As Tables 15.3 through 15.7 show, all of the programs and initiatives presented in these case studies have yielded impressive results. Even more importantly, their innovative approaches have contributed to the advancement of demand-side management practices.

**TABLE 15.5****Case Study #3—Southern California Edison (SCE) Leak Detection Pilot Program***Description:*

The SCE Leak Detection Pilot Program was one of nine *Embedded Energy in Water Pilots* established by the California Public Utility Commission (CPUC) to study alternatives for reducing water-related energy use. The pilot program involved conducting audits and repairing leaks in water distribution systems. Saving water through leak repair also reduces the embedded energy requirements associated with the supply, conveyance, treatment, and distribution of water to end-users. The pilot consisted of three partners: SCE, participating water agencies, and the audit implementation contractor, Water Systems Optimization Inc. The program demonstrated the largest energy savings potential for relatively low cost compared to the CPUC pilots and was successful as measured by the satisfaction of program partners. Success was due to a combination good planning, dedicated involvement by the SCE program manager, good communication between partners, and professional and high quality work. The potential for larger scale deployment of the program hinges on the CPUC and California Energy Commission. Of particular relevance is whether or not the CPUC will publish a rule allowing electric utilities to claim embedded energy savings arising from water saving measures.

*Targeted sector/building type:*

Municipal water utilities in Southern California

*Targeted end-use technology/program type:*

Targets leaks in water distribution systems

Pilot program that includes audits of distribution systems and repairs of leaks

*Program administrator/implementer:*

SCE

*Program expenditures for an 18-month period (July 08–December 09):*

\$300,000

*Program results:*

Annual energy savings: 498 MWh

Annual water savings: 83 million gallons

Participation: three water agencies (Las Virgenes Municipal Water District, Apple Valley Ranchos Water Company, and Lake Arrowhead Community Services District)

*Source:* Young, R. and Mackres, E., Tackling the nexus: Exemplary programs that save both energy and water, Report No. E131, ACEEE, Washington, DC, 2013.

Personal communication with Gene Rodrigues, Director of DSM Strategy, Portfolio Oversight and Technical Support, Southern California Edison Company, August 13, 2013.

**TABLE 15.6****Case Study #4—2012 OG&E SmartHours Program***Description:*

OG&E's SmartHours Program is a multilevel voluntary dynamic pricing program designed to encourage participants to reduce on-peak energy use by offering them lower rates during off-peak periods. The on-peak hours are defined as 2:00–7:00 p.m. on weekdays during the summer from June 1 through September 30, excluding holidays. The rest of the time is considered off-peak. During the on-peak, there are several pricing levels based on system demand and weather conditions: low, standard, high, and critical. Pricing events are called via e-mail, text message, and/or voice mail the day ahead for the first three levels. For the critical level, pricing events can be called a day ahead or there is also a provision for a critical price overcall event (CPE) in which participants receive a minimum of 2-h notice and then the price rises to the critical level. A CPE lasts 2–8 h and the maximum number of CPE hours per year is 80.

OG&E has deployed Smart Meters throughout its service territory. All SmartHours participants have Smart Meters and access to their energy information through a website. Program participants are also offered a free programmable communicating thermostat (PCT) to help them automate their response to pricing events (62% of 2012 participants accepted the PCT). OG&E does not directly control the thermostat; instead, customers set thresholds based on pricing events and their personal preferences.

Aspects of the program that have contributed to its success include free enabling technology and services, customer empowerment of thermostat control and overall energy use, pricing that reflects the true cost of electricity, and the no-lose proposition provided to customers for the first year to guarantee they will not pay more on the SmartHours rate than they would have on the standard flat rate.

*Targeted sector/building type:*

Residential and small commercial customers

*Targeted end-use technology/program type:*

Program targets reduction in on-peak loads through time-based pricing and smart grid products and services

*Program implementer:*

OG&E

*Program expenditures for 2012 (approximate):*

\$20 million

*Program results for 2012:*

Overall maximum demand reduction: 51.4 MW on day of the system peak at hour-ending 4:00 p.m.

System peak demand reduction: 44.1 MW on day of system peak at system peak hour (hour-ending 5:00 p.m.)

Participation: 35,144 participants as of September 2012

Participants without PCTs responded significantly less than those with PCTs

*Source:* Marrin, K. and Williamson, C., 2012 *Evaluation of OG&E SmartHours Program*, Prepared for Oklahoma Gas & Electric, EnerNOC, Walnut Creek, CA, 2012.

Personal communication with Mike Farrell, Director of Customer Programs, Oklahoma Gas and Electric, October 1, 2013.

**TABLE 15.7****Case Study #5—EPRI Smart Grid Demonstration Initiative***Overview of initiative:*

EPRI's Smart Grid Demonstration Initiative is a 7-year collaborative research effort involving two dozen utilities from Australia, Canada, France, Ireland, Japan, and the United States. The focus of the initiative is to design, deploy, and evaluate ways to integrate distributed energy resources into the electric grid and into market operations. The goal of the collaborative effort is to leverage electric utility Smart Grid investments and share research and demonstration results with smart grid technologies and applications to create a *smarter* grid. Each project that is undertaken by a member of the initiative contributes to the collective knowledge. With the initiative recently completing its fifth year, many projects addressing a wide range of research questions have been completed or are underway. EPRI and utility members of the initiative have created hundreds of reports and case studies describing the results (see [www.smartgrid.epri.com](http://www.smartgrid.epri.com)).

*Collaborators:*

The collaborators consist of host sites and non-host sites. Host site collaborators are conducting the majority of the field projects.

*Host sites:* American Electric Power, Con Edison, Duke Energy, Electricité de France, Ergon, ESB Networks, Exelon (ComEd/PECO), First Energy, Hawaiian Electric Company, Hydro Québec, Kansas City Light and Power, PNM Resources, Sacramento Municipal Utility District, Southern California Edison, Southern Company

*Non-host sites:* Ameren, Central Hudson Gas and Electric, CenterPoint Energy, Entergy, Salt River Project, Tennessee Valley Authority, Tokyo Electric Power Company, Wisconsin Public Service

*Distributed energy resources under investigation:*

The initiative is studying grid integration of eight different types of distributed energy resource technologies: demand response technologies, electric vehicles, thermal energy storage, electric storage, solar photovoltaics, wind generation, conservation voltage reduction, and distributed generation

*Communications and standards under investigation:*

Customer Domain (SEP, WiFi, etc.), Distribution (DNP3, IEC 61850, etc.), Cyber Security, Advanced Metering Infrastructure or Automated Meter Reading (AMI or AMR), Radio Frequency (RF) Mesh or Tower, Public or Private Internet, Cellular 3G (GPRS, CDMA, etc.), and Cellular 4G (WiMAX, LTE, etc.)

*Grid management under investigation:*

Volt/VAR optimization (VVO) and conservation voltage reduction (CVR), Distribution Automation, and Grid Management System (DMS, DERMS, DRMS)

*Demand-side management programs under investigation:*

Price-based (time of use, critical peak pricing, real-time pricing, etc.)  
Incentive-based (direct load control, interruptible, etc.)

*Operations and planning under investigation:*

System Operations Integration, System Planning Integration, and Modeling and/or Simulation Tools

*Source:* Wakefield, M. and Horst, G., EPRI smart grid demonstration initiative: 5 year update, 3002000778, EPRI, Palo Alto, CA, 2013.

---

## 15.6 Conclusions

Since the early 1970s, economic, political, social, technological, and resource supply factors have combined to change the energy industry's operating environment and its outlook for the future. Many utilities are faced with staggering capital requirements for new plants, significant fluctuations in demand and energy growth rates, declining financial performance, and political or regulatory and consumer concern about rising prices and the environment. While demand-side management is not a cure-all for these difficulties, it does provide for a great many additional alternatives that have myriad nonenergy benefits as well as the more obvious energy-related benefits. These demand-side alternatives are equally appropriate for consideration by utilities, energy suppliers, energy-service suppliers, and government entities. Implementation of demand-side measures not only benefits the implementing organization by influencing load characteristics, delaying the need for new energy resources, and in general improving resource value, but also provides benefits to customers such as reduced energy bills and/or improved performance from new technological options. In addition, society as a whole receives economic, environmental, and national security benefits. For example, since demand-side management programs can postpone the need for new power plants, the costs and emissions associated with fossil-fueled electricity generation are avoided. Demand-side management programs also tend to generate more jobs and expenditures within the regions where the programs are implemented, boosting local economies. Moreover, demand-side management programs can help reduce a country's dependence on foreign oil imports, improving national security. Demand-side management alternatives will continue to hold an important role in resource planning in the United States and abroad, and will be a critical element in the pursuit of a sustainable energy future.

### 16.1 Fossil Fuels\*

This section discusses the generation of electric power based on combustion of fossil fuels including coal, natural gas, and fuel oil derived from petroleum (Perry 2008; Riegel 2007). Though the scope of this review is worldwide, the emphasis is on the United States, where

\* Though this chapter was largely written in 2013, [Table 16.6](#) was updated in review to reflect 2015 data.

a wealth of available information and the nation's leading economic position make it a frequent example. Similarly, the worldwide abundance of coal makes it a frequent fuel of choice, though there are environmental-regulatory issues that must be addressed in order for its use in electric power generation to continue.

### **16.1.1 Introduction**

The generation of electric power from fossil fuels has increasingly been called upon to be clean and safe while maintaining affordability. The drive to reduce emissions and increase efficiency, have led to significant technical advances over the past several decades in order to keep electric power generation from fossil fuels economically competitive in the marketplace. Globally, fossil fuel-fired electric generation is about two-thirds of all power produced. More large power plants worldwide burn coal than any other fuel, although many generating companies are adding natural gas-fired plants, particularly where the cost of gas-fired generation and the long-term supply of gas appear favorable.

It is likely, particularly in the developed world, that gas turbine-based plants will continue to be added to the new-generation fleet in the immediate future. The most advanced combustion turbines now achieve more than 40% lower heating value (LHV) efficiency in simple cycle mode and greater than 50% efficiency in combined cycle mode. (See Section 16.1.5.6 for a discussion of combined cycles.) In addition, natural gas combined cycle (NGCC) plants offer siting flexibility, rapid construction schedules, and capital costs between \$728/kW and \$1511/kW (June 2011 basis), less than half that of other plant types (NETL 2012b). These advantages, coupled with adequate natural gas supplies (especially in light of the rapid development of shale gas in the United States) and the potential of coal gasification backup, have made NGCC technology an important choice for green-field and repowered plants in the United States and Europe.

However, new capacity in the developing nations of Asia, such as India and China, as well as existing fleets in the Americas and Europe, remains dominated by pulverized coal (PC) plants. For developing economies, coal-fired power plants become a primary choice for power generation: Coal is plentiful and inexpensive, and sulfur dioxide (SO<sub>2</sub>) scrubbers have proven to be reliable and effective. In fact, up to 99% SO<sub>x</sub> removal efficiency is now possible. Removal of nitrogen oxides (NO<sub>x</sub>) is also well advanced, with removal levels of over 90% possible using selective catalytic reduction (SCR). Technologies for mercury removal are available, and the effort to capture carbon dioxide (CO<sub>2</sub>) from fossil plants and send it to geologic storage is receiving attention as a means to reduce greenhouse gas (GHG) emissions.

Coal is converted to electric power by three basic technologies: PC-fired boilers, combustion in a fluidized bed of coal and other solids, and integrated gasification combined cycle (IGCC) plants. The PC plant, the most common coal-fired power plant, has the potential for much improved efficiency even with full flue gas desulfurization (FGD). Ferritic materials technology has now advanced to the point where higher steam pressures and temperatures are possible. Advanced supercritical and ultrasupercritical PC plants are moving ahead commercially, particularly in Japan and Europe. (For a discussion of steam cycles, including subcritical, supercritical, and ultrasupercritical, see Section 16.1.5.)

Worldwide, the application of atmospheric fluidized-bed combustion (AFBC) plants has increased, and such plants offer reductions in both SO<sub>2</sub> and NO<sub>x</sub> while permitting the efficient combustion of low rank fuels such as lignites, of which there are vast deposits. Since the early 1990s, AFBC boiler technology has become established worldwide

as a mature, reliable technology for the generation of steam and electric power with its advantage of in-bed  $\text{SO}_2$  capture with limestone. In fact, a major driving force in the widespread deployment, since the mid-1980s, of this relatively new boiler technology has been its capability for in situ  $\text{SO}_2$  capture, which would eliminate or reduce the need for FGD. Another advantage is the ability of fluidized-bed combustion (FBC) to handle a range of coal qualities.

IGCC power plants are operating at the 250–600 MW level. Much of the impetus for their development came from the U.S. DOE's clean coal program, which spawned two integrated gasification projects that achieved successful commercial operation. Large gasification plants for power are in operation in Europe and Asia. Gasification with combined cycle operation not only leads to minimum  $\text{SO}_2$ ,  $\text{NO}_x$ , and particulate emissions, but also provides an opportunity to take advantage of gas turbine advances.

Emergent technologies also include ultrasupercritical steam cycles; improved AFBC, including pressurized FBC; oxycombustion; chemical looping combustion; and fuel cell power plants, potentially including fuel cell combined cycle.

### 16.1.2 Fuels for Electric Power

The U.S. Energy Information Administration provides an outlook for existing fossil-fueled electricity-generating capacity from various energy sources for both the United States and the world (see Figures 16.1 and 16.2).

The U.S. electric power industry burns about 930 million short tons of coal each year, accounting for 10%–20% of the power costs of coal-fired plants. Options in the fuel mix for power plants include mixtures of eastern high-sulfur coal and low-sulfur, low-cost coals, often from the Powder River Basin (PRB) in Montana and Wyoming. Compared to eastern bituminous coals, PRB subbituminous coals have reduced LHV and sulfur and higher ash and moisture content. Other mixes include 10%–20% gas with coal in a boiler designed for coal firing, and mixtures of coal and petroleum coke—a by-product of refining with a (currently) low cost but high sulfur content. Table 16.1 shows world fossil fuel reserves.

### 16.1.2.1 Coal as a Fuel for Electric Power

Coal is the altered remains of prehistoric vegetation that originally accumulated as plant material in swamps and peat bogs. The accumulation of silt and other sediments, together with movements in the earth's crust (tectonic movements), buried these swamps and peat bogs, often to great depth. Burial subjected the plant material to elevated temperatures and pressures, which caused physical and chemical changes in the vegetation, transforming it into coal by a process known as coalification. Initially, peat, a precursor of coal, was converted into lignite or brown coal—coal types with low organic maturity. Over time, the continuing effects of temperature and pressure produced additional changes, converting the lignite progressively into subbituminous coal, bituminous coal, and anthracite. As this process continues, the coal becomes increasingly harder, its carbon content increases, and its oxygen content decreases.

The degree of metamorphism or coalification undergone by a coal, as it matures from peat to anthracite, is referred to as the *rank* of the coal; rank has an important bearing on the

physical and chemical properties. Low-rank coals, such as lignite and subbituminous, are typically soft, friable materials with a dull, earthy appearance and are characterized by high moisture level and low carbon content, and hence low energy content. Higher rank coals are harder and stronger and often have a black vitreous luster. Increasing rank is accompanied by a rise in the carbon and energy contents and a decrease in the moisture content. Anthracite ranks at the top of the scale and has higher carbon and energy content and low moisture.

Formation of large coal deposits commenced following the evolution of land plants in the Devonian period, some 400 million years ago. Significant accumulations of coal occurred in the Northern Hemisphere during the Carboniferous period (350–280 million years ago), in the Southern Hemisphere during the Carboniferous/Permian periods (350–225 million years ago) and, more recently, in the late Cretaceous to early Paleogene periods (approximately 100–60 million years ago) in areas as diverse as the United States, South America, Indonesia, and New Zealand.

Worldwide, coal is the most plentiful fossil fuel. It is geographically dispersed, being spread over 100 countries and all continents. Coal reserves have been identified that confirm over 200 years of resource availability. U.S. reserves categorized by type are depicted in Figure 16.3. Over half (54%) is lignite and subbituminous coal used primarily for power generation. [Table 16.2](#) shows world coal reserves by rank.

As it comes from the mine, coal typically contains extraneous mineral matter, often with a high sulfur content. Removal of as much of this material as possible is an important step in preparing coal for shipment to a power plant. Cleaning not only increases the coal's heating value (typically by about 10% but occasionally by 30% or higher) and lowers sulfur (up to 70% SO<sub>2</sub> emissions reduction is possible), but also reduces shipping costs. Coal cleaning is well established in the United States with more than 400 operating cleaning plants, mostly located at mines. Sulfur in coal occurs in two forms: mineral and organic.

Source: Energy Information Administration (EIA), *International Energy Outlook 2013*, DOE/EIA-0484(2013), Table 12, World Recoverable Coal Reserves as of January 1, 2009, p. 85, U.S. Energy Information Administration, July 2013, 2013d.

<sup>a</sup> Data for the United States represent recoverable coal estimates as of January 1, 2012.

<sup>b</sup> Includes Mexico, Chile, Middle East, Japan, South Korea, and Greenland.

Coal cleaning removes primarily mineral (pyritic) sulfur. Concentrations of trace heavy metals are also reduced, with conventional cleaning removing (typically) 30%–80% of arsenic, mercury, lead, nickel, antimony, selenium, and chromium. Removal of organic sulfur, which is bound chemically and is part of the coal matrix, is more difficult. Research has been pursued using microorganisms, enzymes, and chemical methods, but none of these have been commercially successful.

### 16.1.2.2 Natural Gas as a Fuel for Electric Power Generation

Natural gas is a naturally occurring mixture of light hydrocarbons, predominantly methane (CH<sub>4</sub>), plus a few other compounds, such as nitrogen (N<sub>2</sub>), water (H<sub>2</sub>O), carbon dioxide (CO<sub>2</sub>), hydrogen sulfide (H<sub>2</sub>S), and heavier hydrocarbons. It is a gas at ordinary pressure and temperature. Heavier hydrocarbons that may be present include ethane (C<sub>2</sub>H<sub>6</sub>), propane (C<sub>3</sub>H<sub>8</sub>), butane (C<sub>4</sub>H<sub>10</sub>), and possibly other compounds. If appreciable amounts of other hydrocarbons are present, the gas is said to be wet; otherwise, it is said to be dry. If H<sub>2</sub>S is present, the gas is said to be sour; otherwise, it is said to be sweet. The heavier hydrocarbons are typically removed and recovered because of their value as chemical feedstocks and fuels.

Natural gas, like coal and petroleum, is the result of the decomposition of buried plant material. In most cases, it has migrated from its point of formation to a geologic trap, where it remains until being discovered and produced. Natural gas is produced both as a single

**FIGURE 16.4**

World proved natural gas reserves, 2012. (From Central Intelligence Agency (CIA), *The World Factbook*, 2013, <https://www.cia.gov/library/publications/the-world-factbook/>, Accessed November 27, 2013.)

product and as a by-product of crude oil production. Virtually, all natural gas is processed to meet the following pipeline specifications:

- Higher heating value must be within a specified range; a typical specification is  $1035 \pm 50$  Btu/standard cubic foot.
- Gas must meet dew point temperature at delivery point to avoid condensation.
- It must contain no more than trace levels of  $\text{H}_2\text{S}$ ,  $\text{CO}_2$ ,  $\text{N}_2$ ,  $\text{H}_2\text{O}$ , and  $\text{O}_2$ .
- It must be free of solid particulates and liquid water that could cause equipment damage.

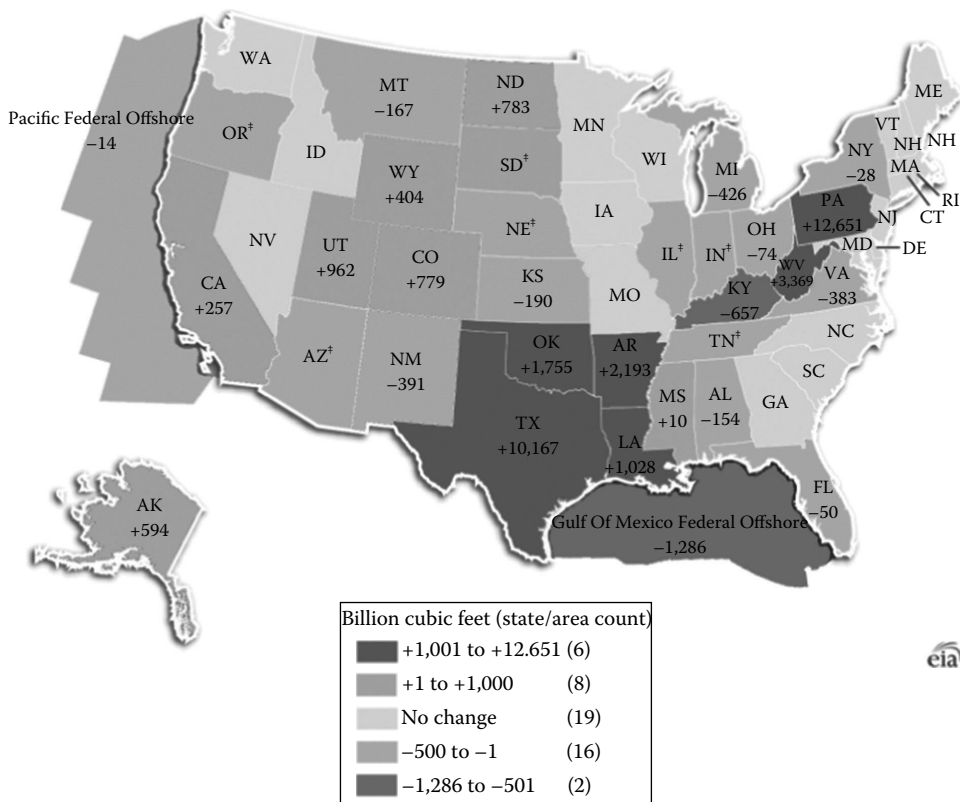

Figure 16.4 shows world proved reserves of natural gas by country. Figure 16.5 shows the changes in U.S. wet natural gas proved reserves from 2008 to 2009, with the single largest difference arising from shale gas exploration.

### 16.1.2.3 Petroleum-Based Fuels for Electric Power Generation

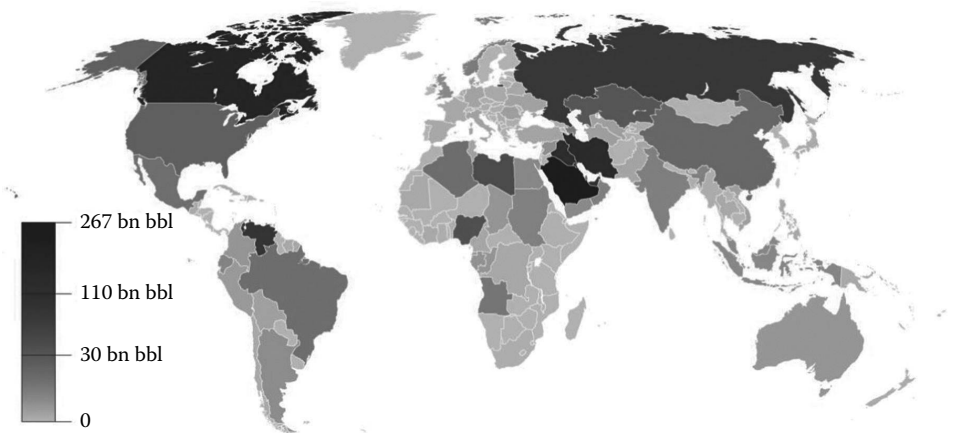

Petroleum is a naturally occurring mineral consisting of a wide boiling range of mainly hydrocarbons, but also containing varying amounts of sulfur, nitrogen, and oxygen compounds and trace elements. Petroleum (also known as crude oil or simply oil) is the fossilized remains of plants and animals buried millions of years ago and trapped in geologic formations with impervious cap rocks. Petroleum reserves are widely distributed around the world (see Figure 16.6) and vary widely in quality from light crude with essentially no asphalt to tar sands, which are practically 100% asphalt. Crude oil is also classified as sweet (low sulfur) and sour (high sulfur).

Petroleum is the major source of transportation fuels (gasoline, diesel fuel, jet fuel, and kerosene). The fraction of each of these components varies widely from crude to crude, and many processes have been developed to increase the yield of desired products.

**FIGURE 16.5**

U.S. wet natural gas proved reserves with changes from 2010 to 2011. Total U.S. increase: 31.2 trillion cubic feet. (From Energy Information Administration (EIA), Natural Gas, "U.S. Crude Oil and Natural Gas Proved Reserves, 2011", Figure 18, Changes in wet natural gas proved reserves by state/area, 2010 to 2011, p. 22, U.S. Energy Information Administration, August 2013, 2013f.) *Note:* † indicates that data is withheld to avoid disclosure of individual company data.

**FIGURE 16.6**

World petroleum reserves. (From Central Intelligence Agency (CIA), *The World Factbook*, 2013, <https://www.cia.gov/library/publications/the-world-factbook/>, accessed November 27, 2013.)

The first step in the refining of petroleum is distillation, which separates the crude into a number of fractions by boiling range. These fractions are then further treated using processes such as catalytic cracking, hydrocracking, reforming, alkylation, and coking. The heaviest fraction from fractionation is referred to as resid. It is the material that is too high boiling to distill. A small amount is used as a fuel for power production, but this usage has declined in recent years, and only about 20,000 barrels a day is now burned for electric power production.

In some refineries, the resid is subjected to a process called coking, which involves heating the resid to a high temperature, which results in decomposition, with part of the resid being converted to gas and liquid products and the rest remaining as petroleum coke or petcoke. In a few instances, this petcoke may be mixed with coal and burned in a PC boiler, or gasified.

### 16.1.3 Current Status of Power Production from Fossil Fuels

Coal is the most widely used fossil fuel for the production of electric power, with natural gas second. Only small quantities of fuel oil are currently used for electric power production.

The U.S. Energy Information Administration listed 874 GW of fossil fuel-fired generating nameplate capacity in the United States in 2012, with approximately 680 GW capacity operated by electric utilities. Coal-fired units predominated, with 1290 units capable of generating over 252 GW, followed by 240 GW gas-fired capacity. Fossil fuel-fired plants represented more than 75% of all electric energy-generating capacity in the United States, and more than 77% of electric utility-generating capacity, with coal-fired plants making up 28% and 37%, respectively. Within the electric utility industry, fossil-fired steam generating plants provided 312 GW or roughly 46% of the generating capacity (EIA 2013c). Although these units are aging—approximately half first went operational before 1966—they will remain a foundation of the power industry for the immediate future.

#### 16.1.3.1 Pulverized Coal Power Plants

In 2012, as shown in Table 16.3, more than one-fourth of total U.S. electricity generation (including industrial and commercial generation, combined heat and power, and auxiliary power supplies as well as generation by electric utilities) was supplied by 1046 generating units burning PC. Of electric utility generation alone, approximately one-third was supplied by 688 generating units burning PC. Roughly half of these units have a capacity

**TABLE 16.3**

U.S. PC-Generating Capacity

Sector	Number of Generators Firing PC	PC Capacity (GW)	PC Percentage of Sector Electricity Generation <sup>a</sup>
Electric utilities	688	230	33.8
All <sup>b</sup>	1046	302	25.8

Source: Energy Information Administration (EIA), Electricity data browser: Net generation by energy source: All sectors, U.S. Energy Information Administration, 2013c, <http://www.eia.gov/electricity/data/browser/>, accessed November 27, 2013.

<sup>a</sup> PC generation as a proportion of electric power generation from all sources within the specified sector. This includes nuclear, hydropower, and renewables as well as all types of fossil fuel generation.

<sup>b</sup> Includes industrial combined heat and power (CHP) and non-CHP; commercial CHP and non-CHP; independent power producers CHP and non-CHP; and electric utilities.

of 250 MW or greater. Like the encompassing fossil-fired steam plant category, the plants utilizing these PC-fired generators are aging, with half built before 1969, and they compete with other regional coal-fired plants at the cost margin. Fuel cost is frequently the determining factor in assuring cost-competitiveness. For this reason—and also to reduce the price of emissions control—many eastern coal-fired units now burn a mixture of eastern coal and coal from the low-sulfur deposits of the Powder River Basin of Wyoming and Montana.

Raising the temperature and pressure of a fossil-fired steam unit into the supercritical (above 373°C, 22 MPa) and ultrasupercritical (up to 760°C, 35 MPa) steam conditions is a way to increase plant efficiency. The selection of a supercritical versus a subcritical cycle for a fossil-fired steam unit is dependent on many site-specific factors including fuel cost, emissions regulations, capital cost, load factor, duty, local labor rates, and estimated reliability and availability. In fact, the use of subcritical cycles for the limited number of fossil-fired steam plants that have been built in the United States since 1995 has been mainly due to relatively low fuel costs, which eliminated the cost justification for the somewhat higher capital costs of the higher efficiency cycles. However, in some international markets where fuel cost is a higher fraction of the total cost, the higher efficiency cycles offer a favorable cost-of-electricity comparison and provide lower emissions compared to a subcritical plant. This is true in both Europe and Asia.

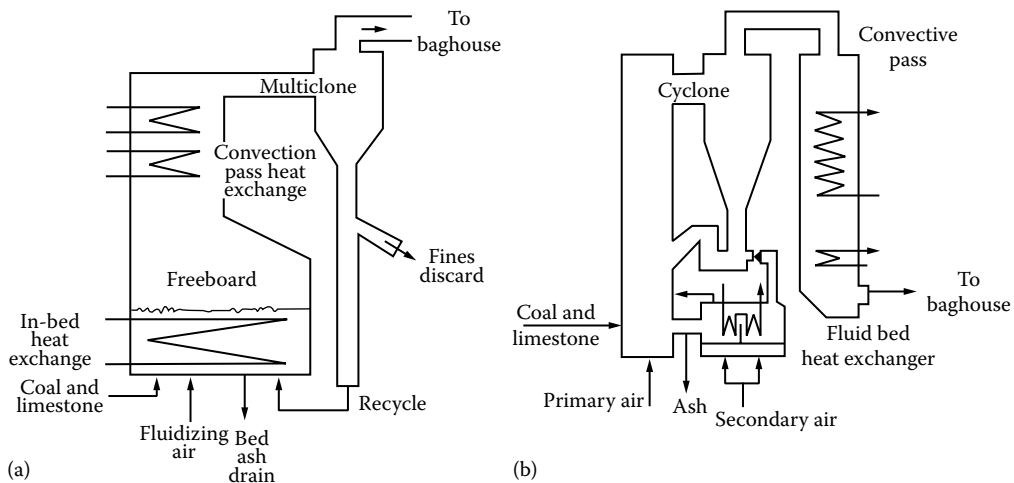

Since 2007, supercritical cycles have gradually increased their share of new steam-based generation capacity even in the United States. The reduction of CO<sub>2</sub> emissions with the supercritical cycle could be a deciding factor as ways are sought to reduce GHG emissions. Ultrasupercritical cycles (discussed in Section 16.1.5.1) have also been introduced in recent years, first in Asia and then in Europe. One such plant is in operation in the United States.

### **16.1.3.2 Fluidized Bed Power Plants**

A variation on PC combustion is FBC. A fluidized bed is an apparatus that mixes solid fuel (typically coal) and air with a sorbent, such as limestone. Combustion occurs in the bed, and the mixing action in the bed results in high heat and mass transfer rates. Often, a component is included to help catalyze combustion. The bed operates at relatively low temperatures, which creates less NO<sub>x</sub> and allows for greater SO<sub>2</sub> capture by the limestone. More than 95% of the sulfur pollutants in coal can be captured in the bed by the sorbent. Additionally, this technology has generated interest because fluid bed combustors are well suited to cofiring of biomass. A 460 MW supercritical fluidized bed plant went into operation in 2009 in Poland. The largest FBC unit constructed in the United States to date is rated at 700 MW.

Following commercial introduction in the early 1980s, the AFBC boiler (Figure 16.7) has found growing application for power generation. From the first FBC boiler in 1967, generating 5000 lb/h of steam, the technology has matured to the 350 MW units available today. Atmospheric fluidized beds are available in two forms: bubbling fluidized beds and circulating fluidized beds (CFBs). Pressurized fluidized beds, discussed in Section 16.1.5, have also entered service. In 2012, 139 generating units in the United States utilized fluidized beds, including 26 generator units at 14 electric utility plants (EIA 2013c).

In the bubbling bed version of the AFBC, fuel and inert solids, together with limestone or dolomite for SO<sub>2</sub> capture, are suspended through the action of fluidizing air, which flows at a velocity of 3–8 ft/s in essentially a one-pass system. CFBs differ from bubbling beds in that much of the bed material passes through a cyclone separator

**FIGURE 16.7**

The primary types of atmospheric fluidized beds are (a) bubbling bed and (b) circulating bed.

before being circulated back to the boiler. In-bed tubes are generally not used with CFB units, permitting a much higher fluidizing velocity of 16–26 ft/s. Experience has shown that bubbling fluidized bed boilers are best suited for wet fuels (greater than 60% moisture) and CFB boilers for high calorific fuels and large-scale power generation (Rainio 2010).

Since the early AFBC designs, attention has been directed toward increasing unit efficiency, and reheat designs are now usual in large units. When  $\text{SO}_2$  capture is important, a key parameter is the ratio of calcium in the limestone to sulfur in coal. Typical calcium to sulfur ratios for 90%  $\text{SO}_2$  reduction are in the range of 3.0–3.5 for bubbling beds and 2.0–2.5 for circulating beds. Nitrogen oxide levels in AFBCs are inherently low due to the low bed temperature, and nominally less than 0.2 lb/million Btu. It is important to note that for CFBs, boiler efficiencies can be as high as those of a PC unit. In fact, plants in Poland and Russia combine CFBs with supercritical steam conditions, and there are prospects for cycles up to 30 MPa (4500 psia), 593°C (1100°F) with double reheat.

In the United States, 139 FBC units generate in excess of 11,000 MW. Burning coal in a suspended bed with limestone or dolomite permits effective capture of sulfur. Fuel flexibility allows a broad range of opportunity fuels, including coal wastes (culm from anthracite, gob from bituminous coal), peat, petroleum coke, and a wide range of coals from bituminous to lignite. A low (816°C; 1500°F) combustion temperature leads to low  $\text{NO}_x$  formation.

Examples of large generating FBC plants in the United States are shown in [Table 16.4](#).

### 16.1.3.3 Power Plants Burning Oil and Gas Fuels

In the United States in 2012, approximately 4% (27.5 GW) of the electricity generated by electric utilities was produced by firing fuel oil. Several technologies are used to generate electricity from fuel oil. Two such technologies are to burn fuel oil in an internal combustion engine to run a generator, or in a boiler to produce steam, which is sent to a steam turbine to generate electricity. A more common method is to burn the oil in a combustion

turbine, which is similar to a jet engine. An advance on this technology is to send the hot exhaust gas from the combustion turbine to a heat recovery steam generator (HRSG) to make steam to drive a steam turbine. This technology is called a *combined cycle* and is more efficient, because it recovers more of the energy in the fuel oil. (For more discussion of combined cycle operations, see Section 16.1.6.)

As with fuel oil, natural gas can be burned in an internal combustion engine or in a boiler to raise steam. Alternatively, the natural gas can be burned in a combustion turbine. In most recent plants, the hot exhaust gas from the combustion turbine is sent to an HRSG to raise steam to drive a second turbine, employing the more efficient combined cycle technology.

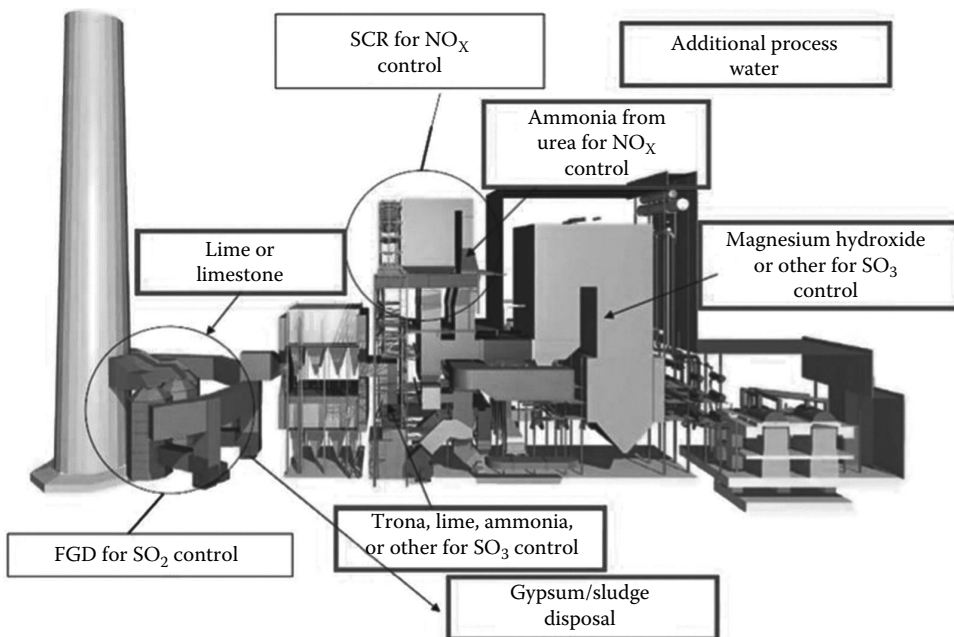

### 16.1.4 Environmental Controls for Fossil-Steam Plants

Because of the many advances in technology over the past several decades, meeting even stricter emissions regulations is much easier now. In the United States by 2012, SO<sub>2</sub> scrubbers were operational on 695 units. These are valuable additions that will permit plants to operate in compliance for many more years. Typically, a 450 MW coal-fired plant will emit 75 tons of SO<sub>2</sub> per day without a scrubber and perhaps 8 tons per day with a 90% FGD system in place.

For the case of NO<sub>x</sub>, where the same plant might emit 10–35 tons/day, NO<sub>x</sub> reductions of up to 90% can reduce emissions to the 1–3.5 tons/day range. Control options range from burner optimization to the use of SCR. Regarding CO<sub>2</sub>, the plant referenced earlier emits about 9000 tons/day at a plant efficiency of 38%, which translates to 2452 tons of carbon. Such emissions are of increasing concern, and potential future carbon taxes must be considered. A combined cycle gas plant, for comparison, emits about half the amount of CO<sub>2</sub> on a per-MWh basis due to the higher efficiency of NGCC plants and the lower carbon content of natural gas. The removal of mercury from the products of fossil fuel combustion will be an increasingly important task for fossil plant operators. Current plant testing for mercury control is exploring several promising options. An overall perspective of emissions control technologies applicable to modern PC-fired plants is shown in Figure 16.8.

#### 16.1.4.1 Clean Coal Technology Development

At an increasing rate in the last few years, innovations have been developed and tested, aimed at reducing emissions through improved combustion and environmental controls in the near term, and in the longer term by fundamental changes in the way coal is

**FIGURE 16.8**

Emission controls on a modern PC-fired power plant.

preprocessed before converting its chemical energy to electricity. Such approaches are referred to as clean coal technologies (CCTs); many of these projects were sponsored by the Department of Energy's National Energy Technology Laboratory (NETL). They consist of a family of precombustion, combustion, postcombustion, and conversion technologies designed to provide the coal user with added technical capabilities and flexibility, and the world with an opportunity to exploit the most abundant fossil resource while minimizing environmental impacts. They can be categorized as follows:

- *Precombustion*: This refers to technologies that remove CO<sub>2</sub> and/or sulfur, ash, and other impurities from a fuel before it is burned. This applies chiefly to cleaning raw syngas from a gasifier before the gas is burned.
- *Combustion*: This refers to techniques applied in the boiler, such as low-NO<sub>x</sub> burners, to reduce the production of pollutants resulting from combustion of the fuel.
- *Postcombustion*: This refers to technologies such as solvent, sorbent, and membrane-based processes that treat flue gas to reduce pollutant emissions.
- *Conversion*: This refers to technologies such as gasification or coal-to-liquids processes that change coal into a form that can be cleaned and used as a fuel or chemical feedstock.

A variety of products of combustion are produced when PC is burned in a boiler. The most important include fly ash from the mineral matter in the coal; SO<sub>x</sub> (mainly SO<sub>2</sub>, but also some SO<sub>3</sub>) from sulfur; NO<sub>x</sub> (mainly NO) from nitrogen and oxygen in air; mercury; and CO<sub>2</sub> from the carbon in the coal. To meet environmental regulations, most of these materials must be removed. Most of the CCT projects were conducted to develop improved processes to reduce pollutants. The following sections discuss environmental controls pertinent to fossil fuel power plants. [Table 16.5](#) shows the range of costs (updated to 2011 basis) and critical performance parameters for several types of power plant.

#### 16.1.4.2 Particulate Control

The first step in flue gas treatment consists of removing the solid particles with a size range of 1 mm to 1 μm. Common practices for particulate removal include the use of cyclones, fabric filters, and electrostatic precipitators (ESPs). Cyclones are satisfactory only for removal of larger particles. Their method of operation is to swirl the gas inside the cyclone and let the centrifugal force drive the particles to the sides of the cyclone. Flue gas is introduced at the top of the cone-shaped cyclone, swirls around, and the clean gas goes up a tube and exits through the top. The particulates drop to the bottom of the cyclone and exit through an opening.

In ESPs, the gas passes between high voltage plates that electrically charge the particles contained in the flue gas due to adsorption of ions and electrons generated by the plates. After the particles are charged, the gas flows to the precipitation electrode where the particles are deposited. Periodically, the power supply is turned off, and a hammer hits the precipitator to shake the accumulated particles loose; they are collected in a bin and removed.

Fabric filters work like a household vacuum cleaner. The raw gas is sent to a filter that allows flue gas to flow through but retains particulates. The particles remain in the filter until compressed air is blown in the opposite direction to clean the filter. The dust falls into a bin where it is collected and removed.

**TABLE 16.5**

Performance Comparisons of Four CCTs

Technology	Units	PC-Sub	PC-SC	AFBC	IGCC
Potential capacity	MW/Unit	250–700	350–800	30–300	300–600
Fuel range/diversity		All grades; lignite to anthracite	All grades; lignite to anthracite	All grades; biomass and wastes	All grades; bituminous preferred
Build time	Years	3	3	3	3

<sup>a</sup> Updated to 2011 costs (NETL 2012b).

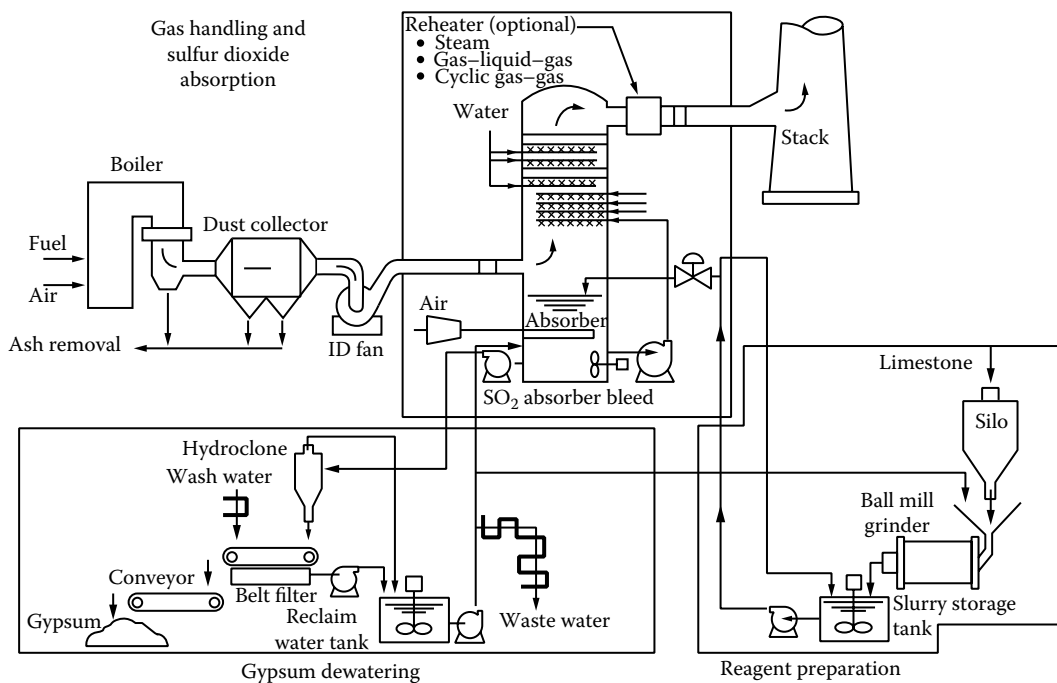

ESPs and fabric filters have a similar operational area requirement, with filters showing slightly better performance for particles smaller than 1  $\mu\text{m}$ . Cyclones alone cannot achieve the emission levels required for modern power plants. Cyclones, however, can be utilized as a complement with other flue gas treatment stages.

### 16.1.4.3 Sulfur Dioxide Control

The need for removal of sulfur dioxide from flue gases has led to the installation of FGD units on much of the coal-fired capacity in the United States (Figure 16.9).

More than 200 coal-fired units in the United States use wet or dry scrubbing to remove sulfur. Of these, the majority use wet lime or limestone scrubbers with perhaps between 20 and 30 using dry scrubbing when the sulfur content of the coal is generally lower. Lime may be used alone or in combination with magnesia, carbides, or with alkaline fly ash if the boiler burns subbituminous coal or lignite.

**FIGURE 16.9**  
Wet limestone flue gas desulfurization system.

In the most common wet systems, flue gas contacts lime or limestone slurry in a spray tower. Sulfur dioxide in the flue gas reacts with the lime or limestone in the slurry and is absorbed according to the following reactions:

The sulfite/sulfate is collected in a reaction tank, where it precipitates. A portion of the slurry is then pumped to a thickener, where the crystals settle out before going to a filter for final dewatering. Some of the calcium sulfate (gypsum) is used to make wallboard, cement, or agricultural products, and the rest is typically disposed of in a landfill.

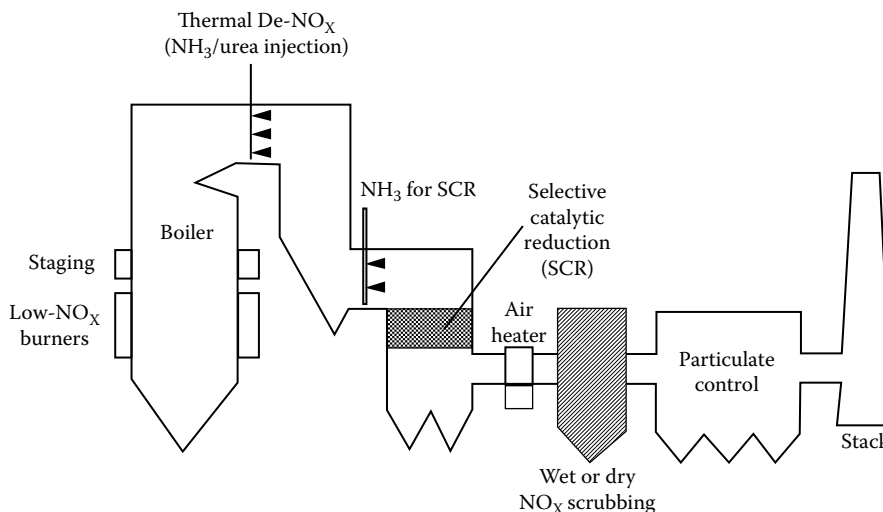

Dry FGD systems employ calcium or sodium reagents that are either injected as dry powders or in spray drying systems as slurries that dry on contact with flue gas. Dry injection systems are most economical for space-constrained sites or applications that require only moderate emissions reductions. Spray drying systems, which can achieve higher  $\text{SO}_2$  removal efficiencies, have mainly been applied at units burning low to medium-sulfur coals.

#### 16.1.4.4 NO<sub>x</sub> Control

Nitrogen oxides are produced during fossil fuel combustion by two main mechanisms: (1) oxidation of nitrogen in the fuel and (2) reaction between oxygen and nitrogen in the combustion air. The options for NO<sub>x</sub> control may be grouped into two broad categories: (1) combustion modifications and (2) postcombustion methods (Figure 16.10).

Combustion modifications include low-NO<sub>x</sub> burners, which are designed to control the air to fuel ratio, which in turn limits the temperature and reduces thermal NO<sub>x</sub> production. Another option is use of overfire air, which involves introducing part of the air downstream in the furnace, again to reduce temperature and NO<sub>x</sub>. Low-NO<sub>x</sub> burners, especially when combined with staging of overfired air, are currently deployed most often. Combustion optimization techniques appear to offer a low cost alternative to hardware options, particularly where modest reductions (up to 30%) are needed, and many units are now operating with some form of optimization of air and fuel flows, perhaps utilizing advanced flame diagnostics or software based on neural networks to do the optimizing.

Several processes have been developed to reduce NO<sub>x</sub> in flue gas. One option is SCR, which is used widely in Europe (especially Germany, where it is installed on more than 30,000 MW of coal-fired boilers), Japan, and increasingly in the United States. In an SCR, ammonia (NH<sub>3</sub>) is injected into the boiler exhaust gases ahead of the catalyst bank (at about 288°C–400°C; 550°F–750°F). Nitrogen oxides and NH<sub>3</sub> then react to produce nitrogen and water according to the following chemical reactions:

**FIGURE 16.10**

NO<sub>x</sub> control options for fossil fuel-fired boilers.

**FIGURE 16.11**  
Selective catalyst reduction system in the boiler flue gas duct.

Under favorable conditions, these reactions can result in  $\text{NO}_x$  removal of more than 90%. Retrofit installation of an SCR system can require considerable space, although the reactor can be placed inside the original ductwork if only a modest  $\text{NO}_x$  reduction is needed (Figure 16.11).

Selective noncatalytic reduction (SNCR) is a promising lower capital cost alternative to SCR (\$10/kW versus more than \$50/kW) but with lower performance (20%–35% reduction compared with 50%–80% for SCR). In SNCR, the injection of a reagent, such as urea or ammonia, into the upper part of the furnace converts  $\text{NO}_x$  from combustion into nitrogen, the conversion level being a direct function of furnace temperature and reagent injection rate.

#### 16.1.4.5 Mercury Control

Various approaches to mercury removal from power plant flue gases are under development, although considerable mercury can be removed through existing air pollution controls for particulate and  $\text{SO}_2$  (Figure 16.12). The removal of mercury from coal-fired units can be accomplished in several ways. Coal cleaning before combustion can remove some mercury and other heavy metals. After combustion, the injection of a sorbent, such as activated carbon, can be very effective. Existing ESPs and  $\text{SO}_2$  scrubbers can capture 20%–60% of the mercury. Catalysts and certain chemicals can be injected that oxidize elemental mercury to enhance scrubber capture. Fixed beds, coated with materials such as gold, can form amalgams with mercury, but may prove too expensive at a utility scale.

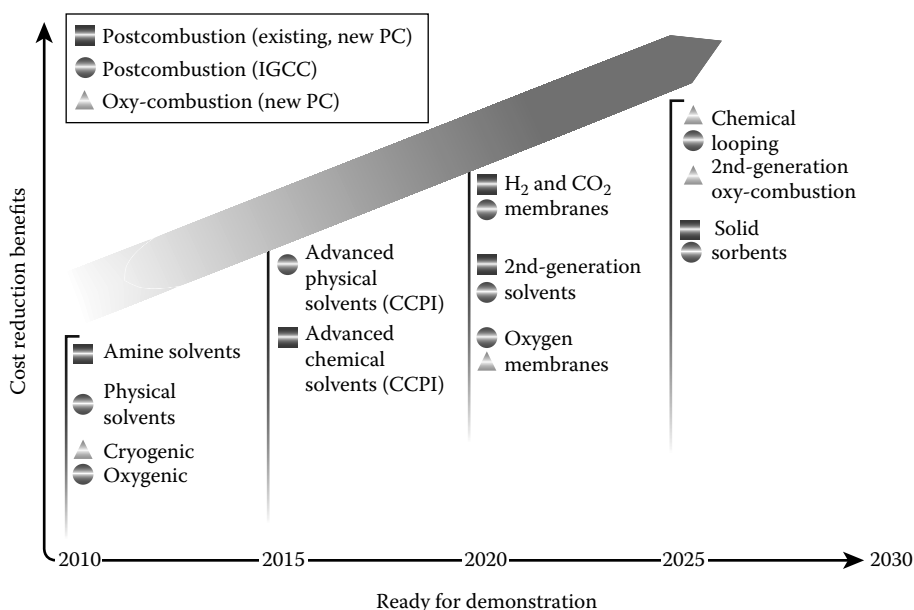

**FIGURE 16.12**  
Options for the removal of mercury.

#### 16.1.4.6 Carbon Dioxide Control and Storage

Carbon dioxide production is a result of the combustion of any fuel containing carbon. The amount released per unit of energy varies from fuel to fuel. Of the common fossil fuels, coal produces the most  $\text{CO}_2$  and natural gas the least. Most climate scientists believe that the buildup of  $\text{CO}_2$  in the atmosphere is contributing to global climate change. To reduce these emissions, considerable effort is being expended to develop technologies for the capture, transport, and geologic storage of  $\text{CO}_2$ , often referred to as carbon capture and storage (CCS). Plant emissions of  $\text{CO}_2$  shown in Table 16.5 (Section 16.1.4.1) are a function of the plant heat rate (efficiency) and the type of fuel. For plants that use limestone for sulfur capture, there are some minor additional contributions of  $\text{CO}_2$  associated with the decomposition of the limestone.

Carbon dioxide capture from coal-fueled power generation can be achieved by various approaches, including postcombustion capture, precombustion capture, and oxycombustion. All three pathways are under investigation, some at an early stage of development. A summary of the inherent advantages and disadvantages of each of these approaches is discussed in detail in Figueroa et al. (2008). Although there have been advances in  $\text{CO}_2$  capture, there is still an impact on overall plant efficiency and the cost of electricity (COE). Thus, an important question when considering  $\text{CO}_2$  control is how the additional control equipment will affect the power output and efficiency of the power plant. This is particularly significant when considering the retrofit of control equipment to an existing unit. There are approximately 1400 large coal-fired plants in the United States that potentially could be retrofitted. Estimates of the impact of 90%  $\text{CO}_2$  control have been developed for several current and advanced plant types.

Studies show that, should  $\text{CO}_2$  control be required, removal from the product gas from a coal gasifier prior to combustion is much less expensive than from the flue gas of a PC power plant where the  $\text{CO}_2$  is at a concentration of only about 15% at atmospheric pressure. Generally, when  $\text{CO}_2$  control is included, the COE increases. This is particularly true for PC plants, where postcombustion capture has to deal with a high volume of flue gas at atmospheric pressure that contains a relatively low concentration (about 15%) of  $\text{CO}_2$ . This results in a low driving force for  $\text{CO}_2$  removal compared to removal from a much smaller volume of raw syngas from a gasifier, where the  $\text{CO}_2$  is at about 60% concentration under a pressure of several hundred psi.

**FIGURE 16.13**

Perspectives on CO<sub>2</sub> control technology development to 2030. (Modified from Figueroa, J.D. et al., *Int. J. Greenhouse Gas Control*, 2(1), 9, 2008.)

Figure 16.13 puts into perspective expected advances in technology and the approximate time frame for their implementation. As advances in innovative CO<sub>2</sub> recovery technologies are made and commercialized, significant cost reductions should be realized. Current state-of-the-art technology for capturing CO<sub>2</sub> in industrial situations involves absorption using solvents—either reactive, such as amines, or physical, such as methanol—to remove CO<sub>2</sub> from various process streams. The figure also indicates that cryogenic oxygen is available for the IGCC option. Considerable effort is being expended on advanced solvents, both physical and chemical, which should be available in 3–5 years. Another area receiving intensive effort is the development of membranes. Membranes can be used in several ways to enhance CO<sub>2</sub> capture. One approach is to use dense ceramic membranes to remove CO<sub>2</sub> from syngas produced by a gasifier; alternatively, one can use a hydrogen-permeable membrane to remove the H<sub>2</sub>. Another use for membranes is to separate O<sub>2</sub> from air. This technology is expected to be available by about 2020. Finally, alternative flow schemes, which inherently produce a concentrated CO<sub>2</sub> stream, such as oxycombustion and chemical looping, are expected to be viable options in the 2020–2025 time frame.

However, as of the end of 2013, there was no U.S. regulation requiring CO<sub>2</sub> removal from flue gas. There are few installations doing this, and those that do are recovering the CO<sub>2</sub> for industrial use, not for geologic storage.

#### 16.1.4.7 CO<sub>2</sub> Storage Technologies Overview

One way to reduce emissions of CO<sub>2</sub> is to increase generating plant efficiency so that less fuel is burned. Another approach is to switch fuels. Burning natural gas produces less CO<sub>2</sub> than burning coal. However, these approaches alone will not reduce GHG emissions sufficiently. Therefore, other solutions are needed. One approach that shows promise is CCS, in which CO<sub>2</sub> is captured from a large stationary source, compressed, shipped by pipeline

to a suitable storage site, and injected into a geologic formation, such as a saline reservoir, with an impervious cap rock, which will contain the CO<sub>2</sub> for thousands of years. An early implementation of this approach is enhanced oil recovery (EOR), in which a fluid such as CO<sub>2</sub> or water is injected into depleted oil fields to yield additional crude oil while leaving the CO<sub>2</sub> trapped in the formation. Carbon dioxide injection reduces oil viscosity, establishing an advantage as a fluid for this application.

Geologic formations have been identified that have the potential to store hundreds of years of GHG production at current production rates (NETL 2012a).

### 16.1.5 Advanced Power Production Technologies

Improvements to power production processes and equipment are under constant development. The following sections discuss some of these developments.

#### 16.1.5.1 Advanced Ultrasupercritical (A-USC) Power Plants

In any PC combustion plant, steam raised from combustion of coal is used to generate electricity. More specifically, electricity is produced when high-pressure steam from the boiler is expanded through a steam turbine. After expansion through the high-pressure turbine, steam is typically sent back to the boiler to be reheated before expanding through the intermediate- and low-pressure turbines. Sometimes there is a second reheat between the intermediate- and low-pressure turbines. Reheating, single or double, increases cycle efficiency by raising the higher average temperature at which heat is converted to work.

The main difference among PC technologies is the operating conditions. Moving from subcritical to supercritical to ultrasupercritical conditions results in an increasingly severe operating environment, with both temperature and pressure increasing. Typical operating conditions and efficiencies are shown in Table 16.6 and Figure 16.14.

Generation efficiency can be further increased by designing new coal-burning units to operate at even higher steam temperature and pressure. Although a number of supercritical units were built in the United States through the 1970s and early 1980s, most of the existing U.S. fleet is in the subcritical category. Since 2007, most new PC plants in the

**TABLE 16.6**

Impact of Steam Conditions on Pulverized Coal Plant Efficiencies

Steam Conditions	Temperature	Pressure	Net Plant Efficiency (% HHV) <sup>a</sup>
Subcritical	~565°C (1050°F)	~16 MPa (2400 psig)	~39%
Supercritical (SC)	~593°C (1100°F)	~24 MPa (3500 psig)	~40–41%
Ultrasupercritical (USC) <sup>b</sup>	>600°C (>1112°F)	>24 MPa (>3500 psig)	≥41%
Advanced USC (DOE Program Goals)	~760°C (1400°F)	~35 MPa (5000 psig)	~44%

Source: NETL 2015, *Cost and Performance Baseline for Fossil Energy Plants, Volume 1: Bituminous Coal and Natural Gas to Electricity*. Revision 3, 2015 draft. National Energy Technology Laboratory, Albany, OR; Anchorage, AK; Morgantown, WV; Pittsburgh, PA; and Sugar Land, TX, March 2015.

<sup>a</sup> Net plant efficiencies are based on a reference plant burning bituminous coal, at ISO conditions, with 50°F reheat, wet flue gas desulfurization, and wet cooling towers. Other design parameters and site conditions impact plant efficiency.

<sup>b</sup> No precise definition exists of what constitutes USC conditions, and criteria are not consistent (especially internationally); rather, USC represents a broad range of steam conditions. Commercially available USC technology results in efficiencies similar to or slightly above the state-of-the-art supercritical pulverized coal plant referenced here.

**FIGURE 16.14**

Impact of steam conditions on pulverized coal plant efficiencies. (From NETL 2015, *Cost and Performance Baseline for Fossil Energy Plants, Volume 1: Bituminous Coal and Natural Gas to Electricity*, Revision 3, 2015 draft, National Energy Technology Laboratory, Albany, OR; Anchorage, AK; Morgantown, WV; Pittsburgh, PA; and Sugar Land, TX, March 2015.)

United States are higher efficiency supercritical designs. Improvements in metallurgy have led to emergence of ultrasupercritical designs.

### 16.1.5.2 Advanced Fluidized-Bed Technologies

Fluidized bed combustion (FBC) is a variation on PC combustion that is receiving considerable attention because of its flexibility in the properties of the fuel it can handle. FBC is discussed in Section 16.1.3.2. An interesting advance in fluidized-bed technology is the use of a pressurized (PFBC) system. As discussed earlier, a fluidized bed operates at a considerably lower temperature than a PC boiler. To make up for this and increase the gas turbine firing temperature, natural gas is introduced in addition to vitiated air from the PFB combustor. This mixture is burned in a topping combustor to provide higher inlet temperatures for greater combined cycle efficiency. One drawback is that the method uses natural gas, which historically has cost more than coal.

A further advance in fluidized-bed combustion can be realized by incorporating a pressurized carbonizer to heat the feed coal and convert it into fuel gas and char, resulting in an advanced circulating pressurized fluidized-bed combustion (APFBC) combined cycle system. The char is burned in the PFBC to raise steam and heat combustion air for the gas turbine. The carbonizer fuel gas is burned in a topping combustor that heats fuel gas to the combustion turbine's rated firing temperature. Heat recovered from the gas turbine exhaust raises steam in a heat recovery steam generator (HRSG). The steam is used to drive a conventional steam turbine, resulting in improved overall efficiency for the combined cycle. These systems are entirely coal fueled. Another advance, the Gasification fluidized-bed combustion combined cycle systems (GFBCC), has a pressurized circulating

fluidized-bed (PCFB) partial gasifier which feeds syngas to the gas turbine topping combustor. The gas turbine exhaust supplies combustion air for the atmospheric circulating fluidized-bed combustor that burns the char from the PCFB partial gasifier.

#### **16.1.5.3 Oxycombustion Power Plants**

Oxycombustion involves the use of oxygen, with a purity of 95%–99%, instead of air, to combust coal. Since the nitrogen present in air is removed and not heated in the boiler, higher flame temperatures are potentially possible with accompanying improved efficiency and reduced fuel consumption.

Oxycombustion cannot simply be substituted for air combustion in existing fossil-fueled power plants due to differences in combustion characteristics. In particular, combustion temperature would be too high for conventional materials of construction. To use oxycombustion in an existing plant, a thermal diluent is required to replace nitrogen and moderate combustion temperature. The diluent is typically recycled  $\text{CO}_2$  that is added to oxygen produced by air separation to approximate the combustion characteristics of air. Oxycombustion produces approximately 75% less flue gas than air fueled combustion and produces exhaust consisting primarily of  $\text{CO}_2$  and  $\text{H}_2\text{O}$ .

A major attraction of oxycombustion is that a highly concentrated  $\text{CO}_2$  stream is produced, reducing the cost of separation from the flue gas. Water vapor is readily separated from the  $\text{CO}_2$  by condensation through cooling and compression. Further treatment of the flue gas may be needed to remove pollutants such as  $\text{SO}_x$  and  $\text{NO}_x$  before the  $\text{CO}_2$  is sent to storage.

A low-cost supply of oxygen is required for oxycombustion to be a cost-effective power generation option. In the most frequently proposed version of this concept, a cryogenic air separation unit is used to supply high-purity oxygen to the boiler. This commercially available technology is both capital and energy intensive and could reduce both the affordability of electricity and plant efficiency. However, novel technologies currently under development, such as ion transport membranes (ITMs), have the potential to significantly reduce the cost of oxygen production.

In an ITM, oxygen is adsorbed on one surface of the membrane and splits into two oxygen atoms. These atoms pick up two electrons each and diffuse through the membrane. At the other surface, the oxygen ions shed their electrons and recombine to form oxygen gas. The driving force is the partial pressure difference across the membrane. Only oxygen passes through the membrane, so selectivity is very high. If successful, ITM could be an economical replacement for cryogenic oxygen.

The justification for using oxycombustion is to produce a  $\text{CO}_2$ -rich flue gas ready for storage. Oxyfuel combustion has significant advantages over traditional air-fired plants. Among these are

- The mass and volume of flue gas are reduced by approximately 75%, which results in less heat lost in the flue gas and also smaller processing equipment.
- The flue gas is primarily  $\text{CO}_2$  suitable for geologic storage.
- The concentration of pollutants in the flue gas is higher, making separation easier.
- Because nitrogen is largely excluded, nitrogen oxide production is greatly reduced.

#### **16.1.5.4 Chemical Looping Power Plants**

A major difficulty associated with oxygen-blown IGCC is the need for an oxygen plant, which is a costly item. A concept for producing electric power from fossil fuels while producing

a concentrated CO<sub>2</sub> stream without the need for an oxygen plant is chemical looping combustion. Chemical looping splits combustion into separate oxidation and reduction stages. A metal (e.g., iron, nickel, copper, or manganese) oxide or other compound is used as an oxygen carrier. The plant typically consists of two vessels, an oxidizer and a combustor. The carrier is sent to the combustor where it reacts with the fuel to release heat and produce CO<sub>2</sub>. The carrier is then recycled to the oxidation chamber, where the metal oxide is regenerated by contact with air. The advantage of using two chambers for the combustion process is that the flue gas is a highly concentrated CO<sub>2</sub> stream, once water is removed, and not diluted with nitrogen as is the case in a typical PC plant. An alternative flow stream for chemical looping combustion is to maintain the solids in fixed beds while periodically switching flows so that the oxygen carrier is alternatively oxidized and reduced. The benefit of chemical looping is that no air separation plant or external CO<sub>2</sub> separation equipment is required.

#### **16.1.5.5 Fuel Cell Power Plants**

A fuel cell is a device for converting chemical energy directly into electric power. Its operation is similar to that of a battery. Since a fuel cell is not a heat engine, its operation is not bound by the restrictions inherent in the second law of thermodynamics that limit the efficiency of a steam turbine. Thus, quite high efficiencies are theoretically possible. In a fuel cell, fuel (typically hydrogen or syngas) is introduced at the anode and oxygen (air) is introduced at the cathode. Oxygen ions flow from the cathode, through the electrolyte that separates the electrodes to the anode, where they react with the fuel to produce water vapor and CO<sub>2</sub>. Electrons flow through an external circuit back to the cathode, thus producing an electric current.

Various types of fuel cells are under development and use for a variety of applications. The types that see the most use for stationary electric power production—on scales ranging from auxiliary residential and commercial power to electric utilities—are the polymer electrolyte membrane fuel cell (PEMFC), molten carbonate fuel cell (MCFC), and solid oxide fuel cell (SOFC). Interest in fuel cells is prompted by their potential high efficiency and clean operation. Some fuel cells can feed methane; others must have hydrogen or syngas. One option for a power station would be to produce syngas by coal gasification as fuel for a fuel cell. In 2012, installed fuel cell capacity for all stationary applications amounted to about 125 MW, nearly evenly divided among PEMFC, MCFC, and SOFC types (Fuel Cell Today 2013). Although the number of fuel cell power plants and their proportion of installed capacity remain low, capacity is rapidly growing, and includes some installations by electric utilities.

#### **16.1.5.6 Combined Cycle Power Plants**

Natural gas or syngas produced by coal gasification is typically burned in a combustion turbine to drive a generator to produce electric power. However, the gas leaving the turbine is still relatively hot and contains considerable energy. In a combined cycle, this waste heat is captured in a HRSG to produce steam that can be expanded in a steam turbine, thus increasing the efficiency of the power plant by generating additional electricity from the same fuel. Such an arrangement is called a combined cycle, because it combines both a Rankine cycle and a Brayton cycle to maximize plant efficiency. Virtually, all modern natural gas–fueled power plants employ a combined cycle to attain greater efficiency.

##### **16.1.5.6.1 Integrated Gasification Combined Cycle Power Plants**

Coal gasification has been employed for some time, and there have been substantial advancements in gasification-based power systems during the last few decades.

Development programs have been in place in the United States and across the world. Two areas of research that are likely to produce significant improvements in coal gasification technology by improving efficiency and reducing costs are advances in air separation for oxygen production and in CO<sub>2</sub> control.

Gasification of coal produces synthesis gas, or syngas, a mixture of H<sub>2</sub> and CO, which is used primarily for two purposes: the production of chemicals and the generation of electricity by combustion in a gas turbine. Since, as noted earlier, a single-cycle gas turbine will not achieve the efficiency attainable when combined with an HRSG and steam turbine, power plants involving coal gasification invariably employ a combined cycle. In addition to coal, petroleum coke is also frequently used as gasifier feed. Other petroleum waste products, asphalt, biomass, and municipal waste are also used.

At present about 14 such plants are in operation worldwide (see Table 16.7). Six gasify coal alone or in a mix with three located in the United States, the largest of which (Duke Energy's Edwardsport Integrated Gasification Combined Cycle plant in Indiana,

Note: Several other IGCC plants worldwide are in development. (See NETL Gasification Portal.)

rated at 618 MW) began commercial operation in June 2013. A larger IGCC plant has been built in the Netherlands (NUON's Magnum; 1311 MW), but an arrangement to burn only natural gas until 2020, rather than gasifying coal, was made in part to allay concerns about CO<sub>2</sub> emissions from gasification. The two smaller U.S. combined cycle projects were supported under the U.S. Department of Energy's (DOE) CCT demonstration program.

The Tampa Electric Integrated Gasification Combined-Cycle Plant, shown in Figure 16.15, is typical of an IGCC plant. PC is slurried with water and pumped into the Texaco (now GE Energy) gasifier where it reacts with oxygen piped in from a cryogenic oxygen plant. The gasifier operates at a high temperature and modest pressure to produce syngas with an LHV of approximately 245 Btu/standard cubic foot. Molten ash flows out of the bottom of the gasifier into a water-filled sump where it forms a solid slag. The syngas flows from the gasifier to a radiant syngas cooler and a convective syngas cooler (CSC), which cool the syngas while generating high-pressure steam. The cooled gases flow to a water-wash scrubber for particulate removal. Next, a hydrolysis reactor converts carbonyl sulfide (COS) in the raw syngas to H<sub>2</sub>S that is more easily removed. The raw syngas is further cooled before entering a conventional amine sulfur removal system. The recovered H<sub>2</sub>S is converted to sulfuric acid in a sulfuric acid plant (SAP). The cleaned gases are reheated and routed to a combined-cycle system for power generation. A GE MS 7001FA gas turbine generates 192 MWe. Thermal NO<sub>x</sub> is controlled to 0.7 lb/MWh by injecting nitrogen from the oxygen plant. A steam turbine uses steam produced by cooling the syngas and superheated by the gas turbine exhaust gases in the HRSG to produce an additional 123 MWe. The air separation unit consumes 55 MW and auxiliaries require 10 MW, resulting in 250 MWe net power to the grid. The plant heat rate is 9650 Btu/kWh (HHV).

### 16.1.6 Clean Coal Options to 2040

An overall comparison of the performance and cost of CCTs discussed earlier—PC supercritical, fluidized bed, oxycombustion, chemical looping combustion, and IGCC—to current subcritical technology is shown in [Table 16.5](#). It should be recognized that comparisons of this type do not capture various site-specific factors, such as variations in availability and cost of fuel, site conditions, and operational and business requirements that ultimately determine the choice of technology for a particular project.

The exploding global demand for electricity, particularly in the developing world, implies practical electric-generating options and significant increases in efficiency throughout the entire energy chain. A strong portfolio of advanced power generation options would include fossil, renewable and nuclear, all essential to meet these growth requirements for power, both domestically and globally.

Through 2040, the developed world will meet the need for additional capacity largely with coal- and gas-fired plants, while the developing world will continue to rely on indigenous resources, particularly coal in the cases of China and India. In the United States, the balance between coal- and gas-fired new generation is ongoing. While gas-fired additions currently predominate, the relative fuel prices (coal to gas) and the timing of additional emissions requirements will ultimately determine the preferred choice between these two fossil fuels. In the longer term, noncarbon sources will begin to supplant both.

Coal and gas fuels are expected to continue to dominate both world and U.S. central stations in the next decade, with gas-fired combined cycles supplanting several older fossil steam stations in the United States. Timing is still a question, though. In 2012, six new coal-fired plants were being planned in as many U.S. states. Based on the expected mix of coal, oil, gas, nuclear, and renewables through the year 2025, U.S. central generation options for fossil fuels are expected to continue to depend on Rankine cycles.

Existing coal, oil, and gas-fired plants of conventional design, mostly Rankine cycles, are expected to continue to dominate the electric power generation market for the next ten years. These represent the majority of plants currently in operation. On average they are 45 years old and many (more than 100,000 MW) are equipped with SO<sub>2</sub> scrubbers, NO<sub>x</sub> control additions, and other environmental upgrades. They provide the bulk of our electricity needs, are extremely reliable, and are increasingly in demand as evidenced by an average capacity factor above 70% in the early years of this century.

There will be a lot of action in repowered plants based on gas firing and combined cycle operation. Many of the coal- and gas-fired steam plants, especially in the United States, that have changed hands, are targeted for repowering—that is, combustion turbines will replace boilers, generating electricity and providing exhaust heat for HRSGs to power the existing steam turbines. This combination of gas and steam turbine cycles adds megawatts, reduces emissions, and improves efficiencies by 5% or more.

Advancing steam temperatures and pressures in PC steam plants greatly improve overall efficiency. Such ultrasupercritical cycles are already in operation both within and outside the United States. Increasing steam temperatures above 700°C (1292°F) from current levels of about 590°C (1100°F) enhances efficiency and reduces emissions. When used in coal combined cycles with temperatures increased to 750°C (1382°F) or higher, efficiencies beyond 55% can theoretically be attained. Significant challenges still exist in materials technology. The fuel cell is an exciting advance that will change the energy picture in the long term. In the shorter term, incremental advances are being made in both mobile and stationary applications.

## 17.1 Introduction

Nuclear power is derived from the fission of heavy element nuclei or the fusion of light element nuclei. This chapter will discuss nuclear power derived from the fission process, since fusion as a practical power source will not reach the stage of commercial development in the next 20–25 years. In a nuclear reactor, the energy available from the fission process is captured as heat which is transferred to working fluids that are used to generate electricity. Uranium-235 is the primary fissile fuel currently used in nuclear power plants. It is an isotope of uranium that occurs naturally at about 0.72% of all natural uranium deposits. When uranium-235 is “burned” (fissioned) in a reactor, it provides about one megawatt day of energy for each gram of uranium-235 fissioned (3.71E+10 Btu/lb).

Nuclear power technology includes not only the nuclear power plants which produce electric power but also the entire nuclear fuel cycle. Nuclear power begins with the mining of uranium. The ore is processed and converted to a form that can be enriched in the U235 isotope so that it can be used efficiently in today’s light-water moderated reactors. The reactor fuel is then fabricated into appropriate fuel forms for use in nuclear power plants. Spent fuel can then be either reprocessed or stored for future disposition. Radioactive waste materials are generated in all of these operations and must be disposed of. The transportation of these materials is also a critical part of the nuclear fuel cycle.

In this chapter, the development, current use, and future of nuclear power will be discussed. The first section is a brief review of the development of nuclear energy as a source for the production of electric power. The second section looks at nuclear power as it is deployed today both in the United States and worldwide. The third section examines the next generation of nuclear power plants that will be built. The fourth section reviews concepts being proposed for a new generation of nuclear power plants. The fifth section provides a brief introduction to small modular reactors. The sixth section describes the nuclear fuel cycle beginning with the availability of fuel materials and ending with a discussion of fuel reprocessing technologies. The seventh section discusses nuclear waste and the options for managing this waste. The eighth section addresses nuclear power economics. Conclusions are presented in Section 17.9.

---

## 17.2 Development of Current Power Reactor Technologies

The development of nuclear reactors for power production began following World War II, when engineers and scientists involved in the development of the atomic bomb recognized that controlled nuclear chain reactions could provide an excellent source of heat for the production of electricity. Early research on a variety of reactor concepts culminated in President Eisenhower's 1953 address to the United Nations in which he gave his famous "Atoms for Peace" speech, where he pledges the United States "to find the way by which the miraculous inventiveness of man shall not be dedicated to his death, but consecrated to his life." In 1954, President Eisenhower signed the 1954 Atomic Energy Act, which fostered the cooperative development of nuclear energy by the Atomic Energy Commission (AEC) and private industry. This marked the beginning of the commercial nuclear power program in the United States.

The world's first large-scale nuclear power plant was the Shipping port Atomic Power Station in Pennsylvania, which began its operation in 1957. This reactor was a pressurized water reactor (PWR) nuclear power plant designed and built by the Westinghouse Electric Company and operated by the Duquesne Light Company. The plant produced 68 MWe and 231 MWt.

The first commercial size boiling water reactor (BWR) was the Dresden Nuclear Power Plant which began its operation in 1960. This 200-MWe plant was owned by the Commonwealth Edison Company and was built by the General Electric Company at Dresden, Illinois, about 50 miles southwest of Chicago.

While other reactor concepts, including heavy-water moderated, gas-cooled, and liquid-metal-cooled reactors, have been successfully operated, the PWR and BWR designs have dominated the commercial nuclear power market, particularly in the United States.

These commercial power plants rapidly increased in size from tens of MWe generating capacity to over 1000 MWe. Today nuclear power plants are operating in 33 countries. The following section presents the current status of nuclear power plants operating or under construction around the world.

### 17.2.1 Current Nuclear Power Plants Worldwide

At the end of 2012, there were 433 individual nuclear power reactors operating throughout the world. More than half of these nuclear reactors are PWRs. The distribution of current reactors by type is listed in [Table 17.1](#). As shown in [Table 17.1](#), there are six types of reactors currently used for electricity generation throughout the world. The following sections provide a more detailed description of these different reactor types.

#### 17.2.1.1 Pressurized Water Reactors

PWRs represent the largest number of reactors used to generate electricity throughout the world. They range in size from about 400 to 1500 MWe. The PWR, shown in [Figure 17.1](#), consists of a reactor core contained within a pressure vessel and is cooled by water under high pressure. The nuclear fuel in the core consists of uranium dioxide fuel pellets enclosed in zircaloy rods that are held together in fuel assemblies. There are 200–300 rods in an assembly and 100–200 fuel assemblies in the reactor core. The rods are arranged vertically and contain 80–100 tons of enriched uranium.

**TABLE 17.1**

Nuclear Power Units by Reactor Type, Worldwide

Reactor Type	Main Countries	# Units Operational	GWe	Fuel
Pressurized light-water reactors (PWR)	United States, France, Japan, Russia	271	251	Enriched $\text{UO}_2$
Boiling light-water reactors (BWR) and Advanced boiling light-water reactors (ABWR)	United States, Japan, Sweden	83	78	Enriched $\text{UO}_2$
Pressurized heavy-water reactors—CANDU (PHWR)	Canada	48	24	Natural $\text{UO}_2$
Gas-cooled reactors (Magnox and AGR)	United Kingdom	15	8	Natural U (metal), enriched $\text{UO}_2$
Graphite-moderated light-water reactors (RMBK)	Russia	15	10	Enriched $\text{UO}_2$
Liquid-metal-cooled fast-breeder reactors (LMFBR)	Japan, France, Russia	1	1	$\text{PuO}_2$ and $\text{UO}_2$

**FIGURE 17.1**

Sketch of a typical PWR power plant. (Courtesy of World Nuclear Association.)

The pressurized water at  $315^{\circ}\text{C}$  is circulated to the steam generators. The steam generator is a tube and shell type of heat exchanger with the heated high pressure water circulating through the tubes. The steam generator isolates the radioactive reactor cooling water from the steam which turns the turbine generator. Water enters the steam generator shell side and is boiled to produce steam which is used to turn the turbine generator producing electricity. The pressure vessel containing the reactor core and the steam generators are

**FIGURE 17.2**

Sketch of a typical BWR power plant. (Courtesy of World Nuclear Association.)

located in the reactor containment structure. The steam leaving the turbine is condensed in a condenser and returned to the steam generator. The condenser cooling water is circulated to cooling towers where it is cooled by evaporation. The cooling towers are often pictured as an identifying feature of a nuclear power plant.

### 17.2.1.2 Boiling Water Reactors

The BWR power plants represent the second largest number of reactors used for generating electricity. BWRs range in size from 400 MWe to the largest being about 1200 MWe. The BWR, shown in Figure 17.2, consists of a reactor core located in a reactor vessel that is cooled by circulating water. The cooling water is heated to 285°C in the reactor vessel and the resulting steam is sent directly to the turbine generators. There is no intermediate loop as in PWR. The reactor vessel is contained in the reactor building. The steam leaving the turbine is condensed in a condenser and returned to the reactor vessel. The condenser cooling water is circulated to the cooling towers, where it is cooled by evaporation.

### 17.2.1.3 Pressurized Heavy-Water Reactor

The so-called “CANDU reactor” was developed in Canada, beginning in the 1950s. It consists of a large tank called calandria containing the heavy-water moderator. The tank is penetrated horizontally by pressure tubes which contain the reactor fuel assemblies. Pressurized heavy water is passed over the fuel and heated to 290°C. As in the PWR, this pressurized water is circulated to a steam generator where light water is boiled to form the steam, used to drive the turbine generators.

The pressure tube design allows the CANDU reactor to be refueled while it is in operation. A single pressure tube can be isolated and the fuel can be removed and replaced while the reactor continues to operate. The heavy water in the calandria is also circulated and the heat is recovered from it. The CANDU reactor is shown in [Figure 17.3](#).

**FIGURE 17.3**  
Sketch of a typical CANDU reactor power station. (Courtesy of World Nuclear Association.)

#### 17.2.1.4 Gas-Cooled Reactors

Gas-cooled reactors were developed and implemented in the United Kingdom. The first generation of these reactors was called “Magnox” and they were followed by the advanced gas-cooled reactor (AGR). These reactors are graphite moderated and cooled by  $\text{CO}_2$ . Magnox reactors are fueled with uranium metal fuel, while the AGRs use enriched  $\text{UO}_2$  as the fuel material. The  $\text{CO}_2$  coolant is first circulated through the reactor core and then to a steam generator. The reactor and the steam generators are located in a concrete pressure vessel. As with the other reactor designs, the steam is used to turn the turbine generator to produce electricity. Figure 17.4 shows the configuration for a typical gas-cooled reactor design.

**FIGURE 17.4**  
Sketch of a typical gas-cooled reactor power station. (Courtesy of World Nuclear Association.)

### **17.2.1.5 Other Power Reactors**

The remaining reactors listed in [Table 17.1](#) are the light-water graphite-moderated reactors used in Russia, and the liquid-metal-cooled fast-breeder reactors (LMFBRs) in Japan, France, and Russia. In the light-water graphite-moderated reactors, the fuel is contained in vertical pressure tubes where the cooling water is allowed to boil at 290°C, and the resulting steam is circulated to the turbine generator system as in BWR. In the case of the LMFBR, sodium is used as the coolant and a secondary sodium cooling loop is used to provide heat to the steam generator.

## **17.2.2 Growth of Nuclear Power**

The growth of nuclear power generation is being influenced by three primary factors. These factors are (1) current plants are being modified to increase their generating capacity, (2) the life of old plants is being lengthened by life extension practices that include relicensing, and (3) new construction is adding to the number of plants operating worldwide. According to the IAEA, following the Fukushima accident, the World Energy Outlook 2011 New Policies scenario has a 60% increase in nuclear capacity to 2035, compared with about 90% the year before. At the end of 2012, there were 433 nuclear power plants in operation with a total net installed capacity of 371 GWe. They now anticipate the installed capacity to reach 630 GWe by 2035. This implies that over 250 new nuclear plants will be built over the next 20 years and this does not account for replacement of current plants that reach the end of life and it assumes that the overall average capacity will remain the same.

### **17.2.2.1 Increased Capacity**

Operating nuclear plants are being modified to increase their generating capacity. Reactors in the United States, Belgium, Sweden, Switzerland, Spain, and Finland are being uprated. In the United States, the Nuclear Regulatory Commission has approved 140 uprates totaling over 6500 MWe since 1977 with some of them having capacity increased up to 20%. The number of operating reactors in the United States as of June 2013 is 102, which have a generating capacity exceeding 100 GWe. The generating capacity increase was due to both power uprating and improvements in operation and maintenance practices to produce higher plant availability. Switzerland increased the capacity of its plants by over 13%, while in Spain uprating has added 11% to that country's nuclear capacity. The uprating process has proven to be a very cost-effective way to increase overall power production capacity, while avoiding the high capital cost of new construction.

### **17.2.2.2 Plant Life Extension**

Life extension is the process by which the life of operating reactors is increased beyond the original planned and licensed life. Most reactors were originally designed and licensed for an operational life of 40 years. Without life extension, many of the reactors that were built in the 1970s and 1980s would reach the end of their operational lives during the years 2010–2030. If they are not replaced with new plant construction, there would be a significant decrease in nuclear-based electricity generation as these plants reached the end of their useful life.

Engineering assessments of current nuclear plants have shown that they are able to operate for longer than their original planned and licensed lifetime. Over 70 plants in the

United States have been granted 20-year extensions to their operating licenses by the U.S. Nuclear Regulatory Commission (NRC). The operators of most of the remaining plants are also expected to apply for license extensions. This will give the plants an operating life of 60 years. In Japan, operating lifetimes of 70 years are envisaged.

The oldest nuclear power stations in the world were operated in Great Britain. Chalde Hall and Chaplecross were built in the 1950s and were expected to operate for 20–25 years. They were authorized to operate for 50 years but were shut down in 2003 and 2004 for economic reasons. In 2000, the Russian government extended the lives of their 12 oldest reactors by 15 years for a total of 45 years.

While life extension has become the norm throughout the world, many reactors have been shut down due to economic, regulatory, and political reasons. Many of these reactors were built early in the development of nuclear power. They tended to be smaller in size and were originally built for demonstration purposes. However the political and regulatory process in some countries has led to the termination of nuclear power programs and the shutdown of viable reactor plants. Germany is probably the best example having made a political decision to phase out nuclear power. Plants such as San Onofre Units 2 and 3, in southern California, and Kewaunee, in Wisconsin, are being shut down for economic reasons.

### **17.2.2.3 New Nuclear Plant Construction**

New nuclear power plants are currently being constructed in several countries. The majority of these constructions are in Asia. Plants currently under construction are listed in [Table 17.2](#).

---

## **17.3 Next-Generation Technologies**

The next generation, Generation III, nuclear power reactors are being developed to meet the power production needs throughout the world. These reactors incorporate the lessons that have been learned by operation of nuclear power systems since the 1950s. The reactors are designed to be safer, more economic, and more fuel-efficient. The first of these reactors were built in Japan and began operation in 1996.

The biggest change in the Generation III reactors is the addition of passive safety systems. Earlier reactors relied heavily on operator actions to deal with a variety of operational upset conditions or abnormal events. The advanced reactors incorporate passive or inherent safety systems that do not require operator intervention in the case of a malfunction. These systems rely on such things as gravity, natural convection, and resistance to high temperatures.

Generation III reactors also have the following advantages:

- Standardized designs with many modules of the reactor being factory constructed and delivered to the construction site leading to expedited licensing, reduction of capital cost, and reduced construction time.
- Simpler designs with fewer components that are more rugged, easier to operate, and less vulnerable to operational upsets.

Source: Information taken from Plans for new reactors worldwide, World Nuclear Association Information Paper, [www.world-nuclear.org](http://www.world-nuclear.org), March, 2013.

<sup>a</sup> Is the latest announced date as of March 2013; ? for the reactors in Japan is because of the uncertainty following the Fukushima event.

- Longer operating lives of 60 years and designed for higher availability.
- Reduced probability of accidents leading to core damage.
- Safety systems that allow 72 h after an accident before active intervention is required.
- Resistance to serious damage that would allow release of radioactivity following an aircraft impact.
- Higher fuel burnup reducing refueling outages and increasing fuel utilization with less waste produced.

The following sections describe the different types of Generation III reactors being developed worldwide. Many of them are larger than their predecessors and involve consortiums of international companies. Certification of the design concepts continues on a country-by-country basis.

In Europe, there is an effort to harmonize requirements for nuclear plant licensing. Plants certified to comply with the European Utilities Requirements (EUR) include the Westinghouse AP1000, Gidropress' AES-92, Areva's EPR, GE-s ABWR, Areva's Kerena, and Westinghouse BWR 90. In the United Kingdom, the Office of Nuclear Regulation is processing the Areva EPR and the Westinghouse AP1000.

In the United States, the commercial nuclear industry in conjunction with the U.S. Department of Energy (DOE) has developed four advanced light-water reactor designs. Two of these are based on experience obtained from operating reactors in the United States, Japan, and Western Europe. These reactors will operate in the 1300 MW range. One of the designs is the advanced boiling water reactor (ABWR). It was designed in the United States and is already being constructed and operated in Asia. The NRC gave final design certification to the ABWR in 1997. It was noted that the design exceeded NRC "safety goals by several orders of magnitude." The other type, designated System 80+, is an advanced PWR. This reactor system was ready for commercialization but the sale of this design is not being pursued.

Advanced thermal reactors currently being marketed are summarized in [Table 17.3](#), and the various types of reactors and specific identified designs will be discussed in the following sections.

### 17.3.1 Light-Water Reactors

Generation III advanced light-water reactors are being developed in several countries.

*EPR:* Areva in France has developed a large 1630-MWe PWR, which is designated as the European pressurized water reactor (EPR). It is designed with double containment with four separate redundant active safety systems. The first EPR is being built in Olkiluoto, Finland, the second two will be built in France. Areva has also designed a US-EPR and has been submitted to the USNRC for design certification. It is known as the Evolutionary PWR (EPR).

*AP1000, CAP1400:* The Westinghouse AP1000 (scaled up from the AP-600) received final design approval from the NRC and has received full design certification 2011. The passive safety systems in this reactor design lead to a large reduction in components including 50% fewer valves, 35% fewer pumps, 80% less pipe, 45% less seismic building volume, and 70% less cable. The AP1000 is designated the CAP1000 in China. Another aspect of the AP1000 is the construction process. Once the plant is ordered, the plant will be constructed in a modular fashion with modules being fabricated in a factory setting and then transported to the reactor site. The anticipated design construction time for the plant is 36 months. The construction cost of an AP1000 is expected to be greater than \$5000 per kW in the United States and less than \$2000 per kW in China. The plant is designed to have a 60 year operating life. AP1000 plants are under construction in China and the United States.

*ABWR:* Advanced boiling water reactor is offered in slightly different versions by GE Hitachi, Hitachi-GE, and Toshiba. This design produces 1350–1600 MWe. Two of the Hitachi versions and two of the Toshiba versions have been built in Japan and are in commercial operation, Hitachi is promoting the UK-ABWR while Toshiba has the EU-ABWR. The design can operate with MOX fuel and has a design life of 60 years. The emergency cooling system uses pump mounted at the bottom of the reactor vessel and are part of an active safety system.

**TABLE 17.3**

Advanced Thermal Reactors Being Marketed

Country and Developer	Reactor	Size (MWe)	Design Progress	Main Features
United States–Japan (GE–Hitachi–Toshiba)	ABWR	1380	Commercial operation in Japan since 1996–1997. In the United States: NRC certified 1997, first-of-a-kind engineering (FOAKE).	Evolutionary design More efficient, less waste Simplified construction (48 months) and operation
South Korea (derived from Westinghouse)	APR-1400 (PWR)	1450	Under construction—Shin Kori 3 and 4. Sold to UAE.	Evolutionary design Increased reliability Simplified construction and operation
United States (Westinghouse)	AP-600	600	AP-600: NRC certified 1999, FOAKE	Passive safety features
	AP1000 (PWR)	1200	AP1000 NRC design approval 2011.	Simplified construction and operation 3 years to build 60-year plant life
Japan (Utilities, Westinghouse, Mitsubishi)	APWR	1530	Basic design in progress, planned for Tsuruga	Hybrid safety features
	US-APWR	1700	U.S.-design certification application.	Simplified construction and operation
	EU-APWR	1700		
Europe (Areva NP)	EPR	1750	Future French standard.	Evolutionary design
	US-EPR (PWR)		French design approval. Being built in Finland, France, and China. Undergoing certification in the United States.	Improved safety features High fuel efficiency Low cost electricity
United States (GE)	ESBWR	1600	Developed from the ABWR, pre-certification in the United States.	Evolutionary design Short construction time Enhanced safety features
	Atmea1 (PWR)	1150	French design approval February 2012, ready for deployment.	Innovative design High fuel efficiency
Russia (Gidropress)	VVER-1200 (PWR)	1200	Under construction at Leningrad, Novovoronezh and Baltic plants.	Evolutionary design 50-year plant life High fuel efficiency
Canada (CANDU Energy)	Enhanced CANDU-6—EC6	750	Improved model Design review in progress.	Evolutionary design Flexible fuel requirements
	HTR-PM	2 × 105 (module)	Demonstration plant being built at Shidaowan.	Modular plant, low cost High temperature High fuel efficiency

Source: World Nuclear Association, Advanced nuclear power reactors. Information paper, [www.world-nuclear.org](http://www.world-nuclear.org), September 2013.

**ESBWR:** GE Hitachi is working on this design which is known as the Economic and Simplified BWR. It is in the final stages of certification by the USNRC. This design eliminates the need for pumps for emergency cooling and uses passive systems and stored energy instead. It has a design life of 60 years and produces 1535 MWe.

**APWR:** APWR is an advanced PWR marketed by Mitsubishi. The first of these reactors was planned for construction at Tsuruga in Japan. The U.S. version of this

reactor will have a 1620 MWe output. Another version of this reactor was planned for construction in Texas but the request for certification has been delayed because the utility is looking at other electrical generating systems. It combines active and passive emergency cooling systems in a double containment and features high burnup fuel.

*APR1400:* The APR1400 is an advanced design, earlier known as Korean Next-Generation Reactor. The design was certified by Korean Institute of Nuclear Safety in 2003 and the first two units have been constructed in Korea. The reactor is being marketed in the Middle East as a heat source for large desalinization systems. It has a generating capacity of 1350–1400 MWe.

*Atmea1:* The Atmea1 was developed by the Atmea joint venture by Areva and Mitsubishi to produce an evolutionary PWR which would use the same steam generators as the EPR. The reactor was designed to have load-following capability and frequency control capacity. The design has been approved by the French regulator ASN and is designed for sale to countries that do not have previous nuclear experience. It has three redundant active and passive safety systems and a backup cooling system similar to the EPR.

*Areva-EdF-CGNPC:* This is a proposed effort between the French companies and China Guangdong Nuclear Power Group to develop a mid-sized PWR with third-generation safety features. No reactor design has yet come from this effort.

*Kerena:* This reactor design was developed by Areva in conjunction with two German utilities. Kerena is based on the design of a German plant designed and built by Siemens and completed in 1999. This reactor can operate with MOX fuel and also has load-following capability.

*AES-92, V392:* These are late model VVER-1000 with enhanced safety systems and are designed by Gidropress. This reactor model is being built in China and India. AES-92 is certified as meeting EUR.

*AES-2006, MIR-1299, VVER-TOI:* These are third-generation standardized VVER-1200 reactors that will operate at 1070 MWe. Models of this system are being built in Russia and are expected to begin operation in 2014. The systems are designed for 60 years of operation at a 90% capacity factor. They have enhanced safety systems including those related to earthquakes and aircraft impact with some passive safety features. The MIR-1200 (Modernized International Reactor) is intended for sale and operation outside of Russia.

*ACPR1000 and ACP1000:* These are essentially Chinese designed versions of French designs with modern features. The ACP1000 is an 1100-MWe plant with load-following capability. The APCR1000 is also an 1100-MWe plant with a double containment and a core catcher.

*IRIS:* An international project being led by Westinghouse is designing a modular 335 MWe reactor known as the “International Reactor Innovative & Secure” (IRIS). This PWR is designed with integral steam generators and a primary cooling system that are all contained in the reactor pressure vessel. The goal of this system is to reach an 8-year refueling cycle using 10% enriched fuel with an 80,000 MWd/t burnup.

*VBER-300:* The VBER is a small PWR based on naval reactors and was designed to be a barge-mounted floating nuclear power plant (295–325 MWE unit) with an

expected life of 90 years with a 90% capacity factor. The first land-based reactor of this design will be built in Kazakhstan.

*RMWR, RBWR:* The reduced moderation water reactor (RMWR) is a light-water reactor with the fuel array packed more tightly than the typical PWR and BWR of today. These Hitachi-designed reactors are expected to produce more plutonium, and thus make better use of the uranium resource. The breeding ratio is near 1 instead of 0.6 of today's reactors. Reprocessing through an advanced fluoride volatility process leaves a uranium-plutonium mixture that can be made directly into MOX fuels of standard light-water reactors. Thor Energy in Norway is exploring the use of an RBWR with a thorium oxide (Th-MOX) fuel because high conversion factors for production of U233 can be achieved with this design. The core of the reactor is flatter with tightly packed fuel rods to ensure sufficient fast neutron leakage and a negative void reactivity coefficient.

### 17.3.2 Heavy-Water Reactors

Heavy-water reactors are primarily designed and used in Canada and India. Both countries are actively taking steps in developing and making advances in this technology. In 2011 AECL sold the reactor division which now operates as Candu Energy, Inc.

*EC6:* The EC6 is an advancement of the CANDU-9, which was designed in the late 1990s and never built. This design is proposed for building in China after the successful construction of CANDU-6 units and is known as the "Enhanced CANDU-6." It is a versatile reactor which will be able to use natural uranium fuel as well as reprocessed PWR uranium and various mixtures of plutonium, uranium, and thorium. The reactor operates at 690 MWe.

*ACR:* The advanced CANDU reactor was designed as a more innovative concept, but the design and regulatory approval efforts have now been terminated.

*AHWR:* Advance heavy-water reactor is being developed in India. The purpose of this reactor is to use a thorium-based fuel cycle. The thorium-based fuel will be seeded with both U233 and Pu239. It is a 284-MWe reactor moderated with heavy water and cooled with boiling light water. It is designed for a 100-year plant life. The AHWR-LEU is an export version of this design. It will use low-enriched uranium and thorium as fuel.

### 17.3.3 High-Temperature Gas-Cooled Reactors

These reactors use high-temperature helium as a coolant at up to 950°C which is used to make steam via a steam generator or is used directly to drive a gas turbine. The fuel is in the form of small particles coated with carbon and silicon carbide which will provide containment of the fission products to temperatures up to 1600°C or more.

*HTR-PM:* The first commercial version of the HTGR will be China's HTR-PM. This reactor is being built in China and will consist of two 105-MWe modules. The reactor will have an outlet temperature of 750°C. This will be a demonstration system for a complete 18-module power station.

*PMRB:* The pebble bed modular reactor is being developed by a consortium in South Africa led by Eskom along with Mitsubishi Heavy Industries. Production

units were planned to be 165 MWe with a direct cycle gas turbine generator. Development of this system has ceased due to lack of funds and customers.

*GT-MHR:* The gas turbine—modular helium reactor is a U.S. design with modules of 285 MWe each, generated by a directly driven gas turbine at a 48% efficiency. The reactor was being developed by General Atomics in partnership with Russia's OKBM Afrikantov and supported by Fuji in Japan. The preliminary design stage was completed in 2001, but the program has stalled then.

#### 17.3.4 Fast Neutron Reactors

Several countries are working on the development of fast breeder reactors (FBR), which are fast neutron reactor (FNR) configured with a breeding ratio greater than 1.0. About 20 of these reactors have been built and operated since the 1950s. The FBR can use uranium much more efficiently than the light-water reactor but they are more expensive to construct; so long as the price of uranium remains low, they are not economic.

India has operated a 40 mMWt fast breeder test reactor since 1985. Construction of 500-MWe prototype fast reactor was started in 2004 with expected operation in 2012. The reactor is fueled with U–Pu fuel with a thorium blanket to breed U233. This will provide support for India's efforts to make use of the abundant supply of thorium available there.

The Russian BN-600 reactor has been supplying electricity to the grid since 1981 and has the best operating and production record of any reactor in the country. The BN-350 reactor is operated in Kazakhstan for 27 years and about half of the output was used for water desalinization.

*BN-800:* The BN-800 is a new and more powerful FBR designed by OKBM. It has a wide fuel flexibility, enhanced safety, and improved economy. It will be used to burn plutonium from dismantled weapons and to test the recycle of minor actinides. Two units of this reactor design have been sold to China and are under construction.

*BN-1200:* The BN1200 is designed to operate with MOX fuel and also U–Pu nitride in a closed cycle. It can be sodium or lead cooled and will produce 1220 MWe. The BN-1200 is being considered to be a Gen-IV design.

*BREST:* Russia has used lead–bismuth cooling for 40 years in submarine reactors. BREST is a new fast neutron reactor designed to produce 300 MWe with lead coolant. Construction of the first reactor of this type is expected to begin in 2015 with operation in 2020. It is designed to have an equilibrium core that will allow it to use its own recycled fuel but will not produce excess material for additional reactors.

*ELSY:* The European Lead-Cooled System is a 600-MWe fast reactor being designed in Italy. ELSY is designed to be fueled by either depleted uranium or thorium and also burn the actinides from light-water reactor fuel. It is cooled by either lead or lead–bismuth eutectic.

*PRISM:* PRISM is a GE-Hitachi design fast reactor of the pool type with passive cooling for decay heat removal. PRISM is designed to produce 311 MWe and will operate in blocks of two reactors using a metal fuel of depleted uranium and plutonium. It is designed to be used with the electrometallurgical reprocessing so that all the transuranics are recycled with the fuel.

**KALIMER:** The Korea Advanced Liquid Metal Reactor is the Korean-designed fast reactor system. This is a 600-MWe pool type system that is expected to be developed as a Gen-IV reactor.

### 17.3.5 Summary of Generation III Reactors

As can be seen from the discussion earlier, there are many reactor systems of many types under development. The key feature of all of these reactors is the enhancement of safety systems. Some of these reactors have already been built and are in operation while others are under construction. This activity indicates that there will be a growth of nuclear reactor generated electricity during the next 20 years. [Table 17.3](#), taken from World Nuclear Association information on advanced nuclear power reactors shows the advanced thermal reactors that are being marketed around the world.

---

## 17.4 Small Modular Reactors

In the early days of nuclear power reactors, most of the reactors had small power outputs and many had unique first of a kind designs. Most of the nuclear power plants had electric power outputs below 100 MW and were considered demonstration plants which used a variety of technologies. Table 17.9 is a partial list of these small reactors. They include sodium-cooled fast reactors, heavy-water moderated reactors, BWRs, PWRs, and gas-cooled reactors.

Today the concept of the small modular reactor (SMR) is being developed using modern technologies with advanced safety systems. The International Atomic Energy Agency (IAEA) defines “small” as under 300 MWe; it also defines a medium-sized reactor as the one up to 700 MWe. The driving force behind the ideas for reactors of this size is based on several factors including

- Smaller reactors can be produced in a factory and moved as a single unit to the reactor site to be installed. This will shorten the time for construction of the power station and should be less costly.
- If a large power station is needed in the future, it could be made up of multiple small units each being added as the need arises. This is not unlike the manner in which fossil-fired plants were originally built with multiple smaller units.
- Smaller reactors can be used to serve remote area, where large amounts of power are not required and where service via transmission from larger plants is difficult.
- Smaller reactors can more easily be designed to operate with passive safety systems since the residual heat loads are smaller.
- They can also be built underground which would protect them from attack and also make siting possible in more urban areas.

The development of SMRs is in process across the world by nuclear system supplier. This development is shown in Table 17.10. The whole industry in this area is in a state of flux and details on specific reactor are changing rapidly. Specific current information of designs being considered is best found in the World Nuclear Association Information Library.<sup>8</sup>

---

## 17.5 Generation IV Technologies

As discussed earlier, the development of nuclear power occurred in three general phases. The initial development of prototype reactor designs occurred in the 1950s and 1960s, development and deployment of large commercial plants occurred in the 1970s and 1980s, and development of advanced light-water reactors occurred in the 1990s.

While the earlier generations of reactors have effectively demonstrated the viability of nuclear power, the nuclear industry still faces a number of challenges that need to be overcome in order for nuclear power to achieve its full potential. Among these challenges are (1) public concern about the safety of nuclear power in the wake of the Three Mile Island accident in 1979 and the Chernobyl accident in 1986, (2) high capital costs and licensing uncertainties associated with the construction of new nuclear power plants, (3) public concern over potential vulnerabilities of nuclear power plants to terrorist attacks, and (4) issues associated with the accumulation of nuclear waste and the potential for nuclear material proliferation in an environment of expanding nuclear power production.

To address these concerns and to fully realize the potential contributions of nuclear power to future energy needs in the United States and worldwide, the development of a new generation of reactors, termed Generation IV, was initiated in 2001. The intent or objective of this effort is to develop multiple Generation IV nuclear power systems that would be available for international deployment before 2030. The development of the Generation IV reactor systems is an international effort, initiated by the U.S. Department of Energy (DOE) with participation from 10 countries. These countries established a formal organization referred to as the Generation IV International Forum (GIF). The GIF countries included Argentina, Brazil, Canada, France, Japan, the Republic of Korea, the Republic of South Africa, Switzerland, the United Kingdom, and the United States. The intent of the GIF is "... to develop future-generation nuclear energy systems that can be licensed, constructed, and operated in a manner that will provide competitively priced and reliable energy products while satisfactorily addressing nuclear safety, waste, proliferation, and public perception concerns."

The process used by the GIF to identify the most promising reactor concepts for development (referred to as the Generation IV Technology Roadmap) consisted of three steps. These steps were (1) to develop a set of goals for new reactor systems, (2) solicit proposals from the worldwide nuclear community for new reactor systems to meet these goals, and (3) using experts from around the world, evaluate the different concepts to select the most promising candidates for further development.

The eight goals developed by the GIF for Generation IV nuclear systems [Ref. 7] were

- *Sustainability-1.* Generation IV nuclear energy systems will provide sustainable energy generation that meets clean air objective and promotes long-term availability of systems and effective fuel utilization for worldwide energy production.
- *Sustainability-2.* Generation IV nuclear energy systems will minimize and manage their nuclear waste and notably reduce the long-term stewardship burden in the future, thereby improving protection for the public health and the environment.
- *Economics-1.* Generation IV nuclear energy systems will have a clear life-cycle cost advantage over other energy sources.
- *Economics-2.* Generation IV nuclear energy systems will have a level of financial risk comparable to other energy projects.

- *Safety and Reliability-1.* Generation IV nuclear energy systems operations will excel in safety and reliability.
- *Safety and Reliability-2.* Generation IV nuclear energy systems will have a very low likelihood and degree of reactor core damage.
- *Safety and Reliability-3.* Generation IV nuclear energy systems will eliminate the need for offsite emergency response.
- *Proliferation Resistance and Physical Protection-1.* Generation IV nuclear energy systems will increase the assurance that they are very unattractive and the least desirable route for diversion or theft for weapons-usable materials, and provide increased physical protection against acts of terrorism.

Over 100 Generation IV candidates were evaluated by experts from the GIF countries and six reactor systems were selected for further evaluation and potential development. These six reactor systems selected are described as follows.

### 17.5.1 Gas-Cooled Fast Reactor (GFR) System

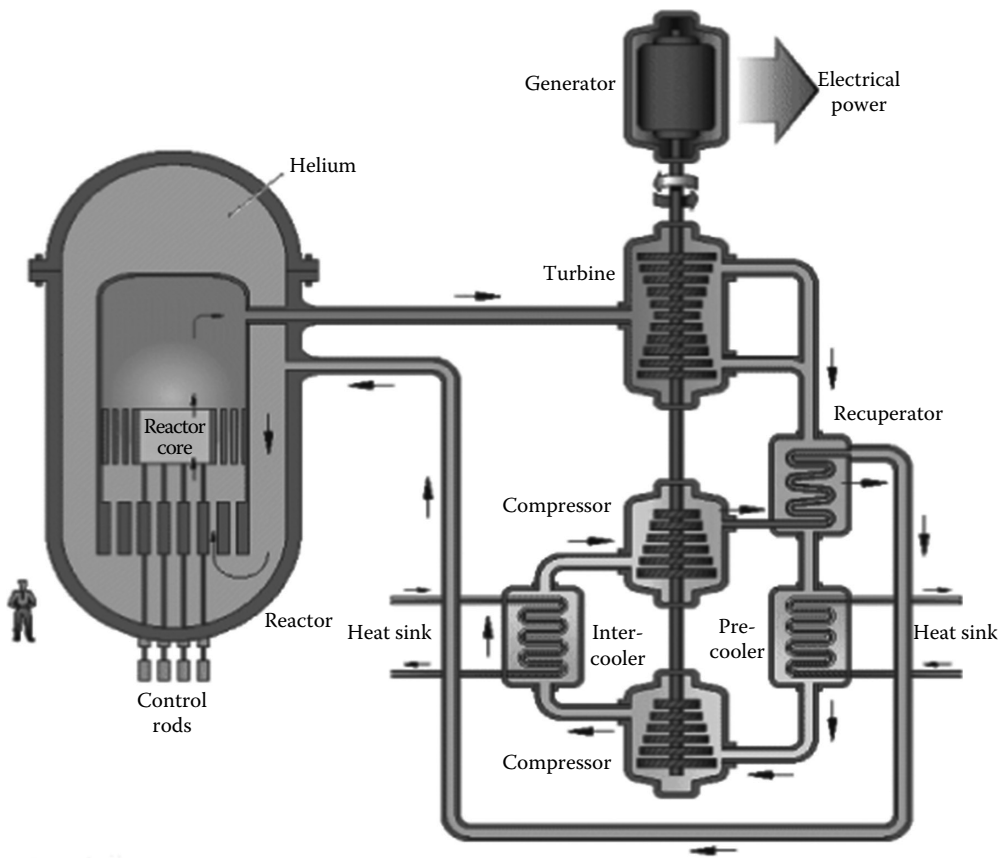

Gas-cooled fast reactor (GFR) System is a fast neutron spectrum reactor that uses helium as the primary coolant. It is designed to operate at relatively high helium outlet temperatures, making it a good candidate for the high-efficiency production of electricity or hydrogen. As shown in [Figure 17.5](#), a direct Brayton cycle is used for the production of electricity with the helium gas delivered from the reactor outlet to a high-temperature gas turbine connected to a generator that produces electricity. In alternative designs, the high-temperature helium can also be used to produce hydrogen using either a thermochemical process or high-temperature electrolysis, or for other high-temperature process heat applications.

The reference plant is designed to produce 288 MWe using the direct Brayton cycle with a reactor outlet temperature of 850°C. The fuel forms being considered for high-temperature operation include composite ceramic fuel, advanced fuel particles, or ceramic clad elements of actinide compounds. Alternative core configurations include prismatic blocks, pin- or plate-based assemblies. GFR's fast neutron spectrum also makes it possible to efficiently use available fissile and fertile materials in a once-through fuel cycle.

### 17.5.2 Very-High-Temperature Reactor

Very-high-temperature reactor (VHTR) is a helium-cooled reactor designed to provide heat at very high temperatures, in the range of 1000°C for high-temperature process heat applications. In particular, the 1000°C reactor outlet temperature makes it a good candidate for the production of hydrogen using either thermochemical or high-temperature electrolysis processes. As shown in [Figure 17.6](#), heat for the production of hydrogen is delivered through an intermediate heat exchanger that serves to isolate the reactor system from the hydrogen production process.

The reference design for VHTR is a 600 MW(t) reactor with an outlet temperature of 1000°C. The reactor core uses graphite as a moderator to produce thermal neutrons for the fission process. The core configuration can be either graphite blocks or pebbles about the size of billiard balls in which fuel particles are dispersed. For electricity production, either a direct Brayton cycle gas turbine using the primary helium coolant as the working

**FIGURE 17.5**

Gas-cooled fast reactor. (Courtesy of *A Technology Roadmap for Generation IV Nuclear Systems*, U.S. DOE, Washington, DC, 2002.)

fluid, or an indirect Rankine cycle using a secondary working fluid can be used. The high-temperature characteristics of this reactor concept also make it an ideal candidate for cogeneration applications to meet both electricity and hydrogen production, or other high-temperature process heat needs.

### 17.5.3 Supercritical-Water-Cooled Reactor (SWR)

Supercritical-water-cooled reactor (SWR) is a relatively high-temperature, high-pressure reactor designed to operate above the thermodynamic critical point of water, which is 374°C and 22.1 MPa. Since there is no phase change in the supercritical coolant water, the balance of plant design, shown in Figure 17.7, utilizes a relatively simple, direct cycle power conversion system. The reference design for this concept is a 1700 MWe reactor operating at a pressure of 25 MPa with a reactor outlet temperature ranging between 510°C and 550°C. This reactor can be designed as either a fast neutron spectrum or thermal neutron spectrum reactor. The relatively simple design also allows for the incorporation of passive safety features similar to those of the simplified BWR (discussed earlier). However, unlike

**FIGURE 17.6**

Very-high-temperature reactor. (Courtesy of *A Technology Roadmap for Generation IV Nuclear Systems*, U.S. DOE, Washington, DC, 2002.)

the previously discussed concepts, lower reactor outlet temperature is not well-suited for the efficient production of hydrogen, which requires minimum temperatures in the range of 850°C–900°C. Therefore, this reactor concept is primarily intended for the efficient, low-cost production of electricity.

#### 17.5.4 Sodium-Cooled Fast Reactor

Sodium-cooled fast reactor (SFR), shown in [Figure 17.8](#), is a sodium-cooled fast-neutron-spectrum reactor designed primarily for the efficient management of actinides and conversion of fertile uranium in a closed fuel cycle. Two reference designs to support different fuel reprocessing options have been defined for this concept. First is a medium-sized, sodium-cooled reactor with a power level between 150 and 500 MW(e) that utilizes uranium-plutonium-minor-actinide-zirconium metal alloy fuel. This reactor concept is supported by a fuel cycle based on pyrometallurgical processing in which the processing facilities are an integral part of the reactor plant design.

The second reactor reference design is a large sodium-cooled reactor with a power output capability between 500 and 1500 MWe that utilizes uranium-plutonium oxide fuel. This reactor design is supported by a fuel cycle based on an advanced aqueous process that would include a centrally located processing facility supporting a number of reactors.

Both versions of this reactor concept would operate at coolant outlet temperatures in the range of 550°C, and are intended primarily for the management of high-level waste

**FIGURE 17.7**

Supercritical water-cooled reactor. (Courtesy of *A Technology Roadmap for Generation IV Nuclear Systems*, U.S. DOE, Washington, DC, 2002.)

(HLW) and the production of electricity. In addition to design innovations to reduce capital costs, these reactors incorporate a number of enhanced safety features that include long thermal response time, a large margin to coolant boiling, a primary system that operates near atmospheric pressure, and an intermediate sodium system between the radioactive sodium in the primary system and the water and steam in the power plant.

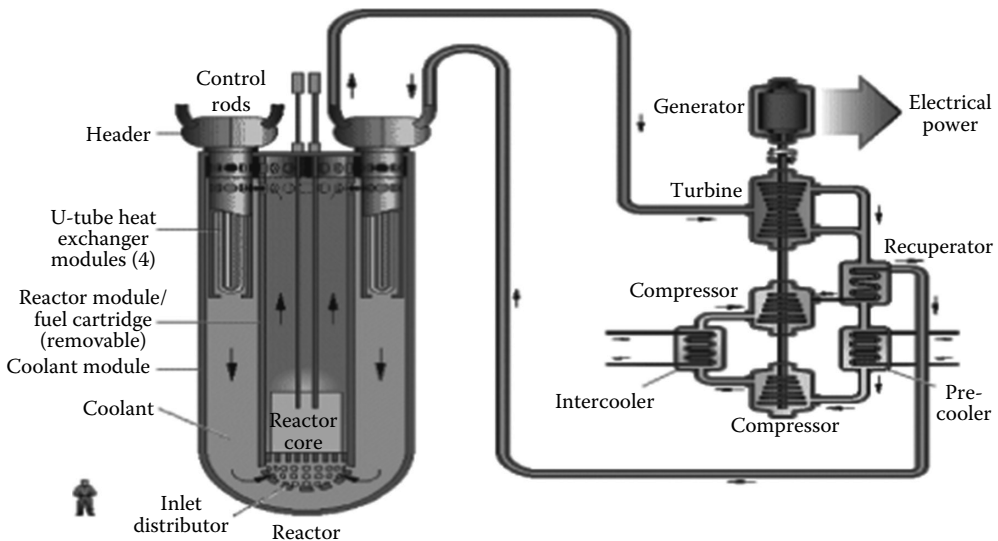

#### 17.5.5 Lead-Cooled Fast Reactor

Lead-cooled fast reactor (LFR) is a fast-neutron spectrum reactor cooled by either molten liquid or a lead-bismuth eutectic liquid metal. It is designed for the efficient conversion of fertile uranium and management of actinides in a closed fuel cycle. The reactor core for this design, shown in Figure 17.9, utilizes a metal- or nitride-based fuel containing fertile uranium and transuranics. As shown in Figure 17.9, LFR relies on natural convection to cool the reactor core. Outlet temperature for the current reactor concept is about 550°C, but with advanced materials, reactor outlet temperatures of 800°C may be possible. An indirect gas Brayton cycle is used to produce electrical power.

There are currently three versions of reference designs for this concept. The smallest design, rated at 50–150 MW(e), is intended for distributed power applications or electricity production on small grids. This reactor design, referred to as a “battery,” features modular

**FIGURE 17.8**

Sodium-cooled fast reactor. (Courtesy of *A Technology Roadmap for Generation IV Nuclear Systems*, U.S. DOE, Washington, DC, 2002.)

**FIGURE 17.9**

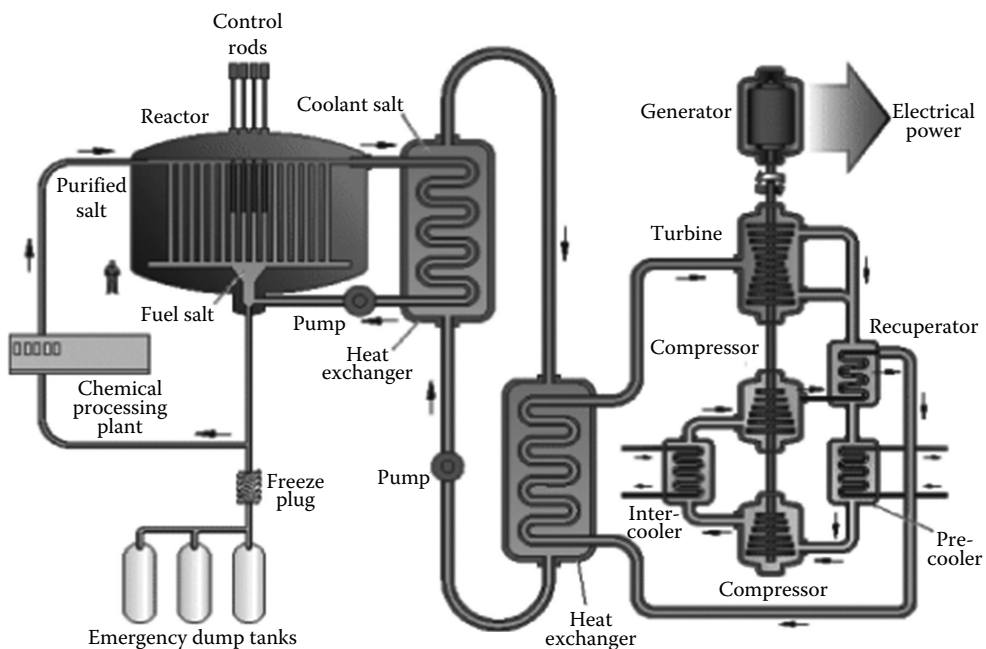

Lead-cooled fast reactor. (Courtesy of *A Technology Roadmap for Generation IV Nuclear Systems*, U.S. DOE, Washington, DC, 2002.)

design with a factory fabrication “cassette” core. The reactor is designed for very long refueling interval (15–20 years), with refueling accomplished by replacement of the cassette core or reactor module.

The other two versions of this design are a modular system rated at 300–400 MWe and a large plant rated at 1200 MWe. The different power options for this design are intended to fulfill different needs or opportunities in the power market, and be economically competitive with comparable alternative power sources.

### 17.5.6 Molten Salt Reactor

The molten salt reactor (MSR), shown in Figure 17.10, produces power by circulating a molten salt and fuel mixture through graphite core flow channels. The slowing down of neutrons by the graphite moderator in the core region provides the epithermal neutrons necessary to produce the fission power for sustained operation of the reactor. The heat from the reactor core is then transferred to a secondary system through an intermediate heat exchanger and then through a tertiary heat exchanger to the power conversion system that produces the electric power. The circulating coolant flow for this design is a mixture of sodium, uranium, and zirconium fluorides. In a closed fuel cycle, actinides such as plutonium can be efficiently burned by adding these constituents to the liquid fuel without the need for special fuel fabrication. The reference design for this concept is a 1000 MWe power plant with a coolant outlet of 700°C. To achieve higher thermal efficiencies for this concept, coolant outlet temperatures as high as 800°C may also be possible.

**FIGURE 17.10**

Molten salt reactor. (Courtesy of *A Technology Roadmap for Generation IV Nuclear Systems*, U.S. DOE, Washington, DC, 2002.)

## 17.6 Fuel Cycle

The process of following the fuel material from uranium or thorium mine through processing and reactor operation until it becomes waste is called the fuel cycle for nuclear systems. After a discussion of fuel cycle in general, it will be examined by looking at uranium and thorium resources, mining and milling, enrichment, reactor fuel use, spent fuel storage, nuclear materials transportation, and reprocessing. Nuclear waste will be addressed in a separate section.

General discussion of the fuel cycle often includes the terms “open” or “closed.” The open fuel cycle is also called the once-through cycle. In the once-through fuel cycle, the uranium fuel is fabricated and run through the reactor once and then disposed-off as waste. There is no reprocessing of the fuel. In the closed cycle, the fuel is reprocessed after leaving the reactor so that it can be reused to improve overall fuel utilization.

In the open cycle, the fuel is introduced into the reactor for 1–2 years. It is then removed and put into long-term storage for eventual disposal. The impact of this cycle is wastage of about 99% of energy contained in the fuel. The United States adopted the open cycle in 1977 when President Jimmy Carter issued an executive order to stop reprocessing as a part of the fuel cycle. Canada has also adopted the open cycle.

The closed cycle was envisioned when the development of nuclear power began. Uranium and plutonium removed from reactors would be reprocessed and returned to reactors as fuel. Breeder reactors would be used to breed additional plutonium for use in thermal reactors. Thorium could also be used as a breeding material to generate U233 as a reactor fuel. The intent of the closed fuel cycle was to maximize the use of available reactor fuel resources while minimizing the waste generated by operating reactors.

Currently, reprocessing is used in Europe and Japan but the benefits of closed cycle have not been fully realized since there has only been limited use of the separated plutonium. As discussed earlier, the United States and Canada, for reasons described later, have not pursued closed cycle reprocessing of spent fuel. As a result, only a small fraction of the available fuel resources are utilized, and disposal of large quantities of potentially usable spent fuels has become a major issue for the U.S. nuclear industry.

### 17.6.1 Uranium and Thorium Resources

Uranium is a common material in the earth’s crust. It is also present in sea water. Thorium is about three times more plentiful than uranium. Typical concentrations of uranium measured in parts per million (ppm) are shown in Table 17.4.

**TABLE 17.4**

Typical Concentrations of Uranium

High-grade ore—2% U	20,000 ppm U
Low-grade ore—0.1% U	1,000 ppm U
Granite	4 ppm U
Sedimentary rock	2 ppm
Earth’s continental crust (avg)	2.8 ppm U
Seawater	0.003 ppm U

Source: World Nuclear Association, Supply of uranium. Information paper, [www.world-nuclear.org](http://www.world-nuclear.org), August, 2012.

The amount of recoverable uranium is dependent on the price. As the price increases, more material is economically recoverable. Also, more exploration will occur and it is likely that additional orebodies will be discovered. An orebody is defined as an occurrence of mineralization from which the metal, in this case uranium, can be recovered economically. Because of the uncertainties of price and its impact on exploration, any statement of recoverable amounts of uranium is simply a picture at an instant in time and is likely to change many times in the future. There is also a store of highly enriched uranium that is being recovered as nuclear weapons are dismantled. In addition, there are millions of tons of U238 which are the results of previous enrichment activities around the world. U238 can be blended with highly enriched uranium or plutonium to make fuel for nuclear power plants. It can also be used to breed plutonium in FBR fuel cycles.

Table 17.5 presents a list of recoverable resources of uranium. The table is taken from information gathered by the World Nuclear Association from other sources and was generated in 2004.

The 3.5 Mt is enough to fuel the world's current reactors for 50 years assuming the same fuel cycles currently in use. IAEA estimates the world supply at over 14 Mt which provides a supply exceeding 200 years at the current rate of use. This estimate does not include the uranium in phosphate deposits estimated at 22 Mt or the uranium available in sea water estimated at 1400 Mt. In addition, the ability of nuclear reactors to achieve higher burnups (utilize more of the uranium in the fuel) has also increased. This increases the efficiency of uranium use. Since thorium is not included in these fuel supply numbers, and as noted earlier is about three times as plentiful as uranium, there does not appear to be a fuel supply limitation for nuclear power in the foreseeable future.

**TABLE 17.5**

Known Recoverable Resources of Uranium

	Uranium (Tons)	Total (%)
Australia	1,661,000	31
Kazakhstan	629,000	12
Russia	487,200	9

### 17.6.2 Mining and Milling

Uranium is being mined using traditional underground and open-pit excavation technologies, and also using in situ leaching or solution mining techniques.

Underground mining is used when the orebody is deep underground, usually greater than 120 m deep. In underground mines, only the orebody material is extracted. Underground mining is hazardous and made more so by high concentrations of radon from the radioactive decay of uranium. Once mined, the extracted ore is sent to a mill where uranium in the ore is concentrated.

Open-pit technology is used when the orebody is near the surface. This leads to the excavation of large amounts of material that does not contain the ore itself. The ore that is recovered is also sent to a mill for further processing.

Solution mining involves the introduction of an aqueous solution into the ore body. The solution, oxygenated ground water, is pumped into the porous orebody and the uranium is dissolved. The uranium-rich solution is then extracted and sent to the mill for further processing.

The milling process for the solid ore material involves crushing the ore and then subjecting it to a highly acidic or alkaline solution to dissolve the uranium. Mills are normally located close to the mining activity and a single mill will often support several mines. The solution containing uranium goes through a precipitation process which yields a material called yellow-cake. The yellow-cake contains about 80% uranium oxide. The yellow-cake is packaged and sent to a conversion and enrichment facility for further processing.

### 17.6.3 Conversion and Enrichment

Prior to entering the enrichment process, the impure  $\text{U}_3\text{O}_8$  is converted through a series of chemical processing steps to  $\text{UF}_6$ . During these processes, the uranium is purified. Conversion facilities are operating commercially in the United States, Canada, France, the United Kingdom, and Russia.  $\text{UF}_6$  is solid at room temperature but converts to its gaseous form at moderate temperature levels making the compound suitable for use in the enrichment process.  $\text{UF}_6$  is very corrosive and reacts readily with water. It is transported in large cylinders in its solid state.

Conversion of  $\text{U}_3\text{O}_8$  to  $\text{UO}_2$  is also done at conversion facilities. Natural  $\text{UO}_2$  is used in reactors such as CANDU which do not require enriched uranium as fuel.

The first enrichment facilities were operated during the 1940s. Electromagnetic isotope separation process was used to separate the U235 used in the first atomic bomb. The process used a magnetic field to separate U235 from U238 as the ions were accelerated and turned, and they moved differently because of the mass difference. Multiple stages were required and the process was very difficult to run efficiently so it was soon abandoned.

Today, only two processes, gaseous diffusion and gas centrifuge are used commercially. The capacity of enrichment plants is measured in separative work units (SWU). SWU is a complex term that is dependent on the amount of uranium processed, and the concentration of U235 in the product and tails. It is a measure of the amount of energy used in the process.

The first commercial enrichment was carried out in large gaseous diffusions plants in the United States. It has also been used in Russia, the United Kingdom, France, China, and Argentina. Today operating plants exist in the United States, France, and China with a total nominal capacity of 30 million SWU.

In the gaseous diffusion process  $\text{UF}_6$  is pumped through a series of porous walls or membranes that allow more of the light U235 to pass through. Because the lighter U235 particles travel faster than heavier U238 particles, more of them penetrate the membrane. This process continues through a series of membranes with the concentration of U235 increasing each time. For commercial reactor fuel, the process continues until U235 concentration is 3%–5%. The slower U238 particles are left behind and collect as a product referred to as “tails.” The tails have a reduced concentration of U235 and are commonly referred to as depleted uranium. This process uses a very large amount of energy and thus is very expensive to operate.

In the centrifuge enrichment process, the gaseous  $\text{UF}_6$  is placed in a high speed centrifuge. The spinning action forces out the heavier U238 particles while the lighter U235 particles remain closer to the center. To obtain the enrichment required for power reactor fuel many stages of separation are required. The arrangement is known as a cascade. Again, the process is continued until U235 concentration is 3%–5%. The centrifuge process uses only about 2% of the energy required by gaseous diffusion.

Table 17.6 shows the location and size of enrichment facilities around the world.

#### 17.6.4 Fuel Fabrication and Use

Following enrichment,  $\text{UF}_6$  is shipped to a fuel fabrication facility where it is converted to  $\text{UO}_2$  and pressed into cylindrical ceramic pellets. The pellets are sintered, heated to high temperature, and inserted in the fuel-cladding tubes. The tubular material is zircaloy, an alloy of zirconium. The tubes are sealed forming fuel rods which are assembled into fuel assemblies and shipped to a reactor for use. All the dimensions of pellets and fuel rods are very carefully controlled to assure uniformity throughout the fuel assemblies.

The primary hazard in the fabrication facility is the potential for an accidental criticality because they are working with enriched uranium. Therefore, all of the processing quantities and the dimensions of the processing vessels must be controlled. This must be done even with the low-enriched uranium.

A typical 1000 MWe reactor will use about 27 tons of  $\text{UO}_2$  each year. Typical burnup in current reactors is 33 GWd/t of uranium fed to the reactor. The energy available from the fission of uranium is 1 MW/g of uranium or 1000 GW/t. Using these numbers the actual amount of uranium burned is only 3%–5%. This means that the unused energy available from the spent fuel, if it could be completely burned, is over 95%. During the operation of the reactor some of the U238 is converted to plutonium and that also contributes to the thermal energy of the reactor.

Advanced fuel use in reactors is estimated to be up to 200 GWd/t. In this case, about 80% of the energy available from the uranium remains in the spent fuel. These facts are the driving force behind the questions regarding reprocessing. In the once-through fuel cycle the spent fuel will be disposed of as waste. In the closed cycle, the spent fuel is reprocessed and the remaining uranium and plutonium are recovered.

#### 17.6.5 Reprocessing

In 1940s reactors were operated solely for the production of plutonium to be used in weapons. The fuels from the production reactors were reprocessed in order to recover plutonium. Chemical processes were developed to separate the fission products and uranium from plutonium. The most common process was the PUREX process. This is the process that is used today by countries that reprocess power reactor fuels.

Source: WISE Uranium Project, World nuclear fuel facilities, [www.wise-uranium.org](http://www.wise-uranium.org), November 2013.

The purpose of reprocessing is to recover the uranium and plutonium in the spent fuel. As discussed earlier these materials contain a large amount of potential energy if they are reused as reactor fuel. Plutonium separated in the PUREX process can be mixed with uranium to form a mixed oxide (MOX) fuel. Plutonium from the dismantlement of weapons can be used in the same way.

The potential availability of separated plutonium is seen by some as a potential mechanism for the proliferation of nuclear weapons. This was the basis of the U.S. decision to halt reprocessing. In the 1970s, research on ways to modify the chemical process began, so that plutonium and uranium would remain together at the end of the process. In this method, called co-processing, the short-lived fission products would be separated and the remaining uranium, plutonium, and other actinide elements would remain together. This remaining mixture would be highly radioactive but could be remotely processed into new reactor fuel. A blend of fast neutron and thermal reactors could be used to maximize the use of this material.

The current world wide reprocessing capability is shown in Table 17.7. All of these facilities use the PUREX technology. More than 80,000 tons of commercial fuel have been reprocessed in these facilities.

Three processes are considered to be the mature options for reprocessing fuel. They are PUREX, UREX+, and Pyroprocessing. Each of them has certain advantages and disadvantages.

#### 17.6.5.1 PUREX

The PUREX process is the oldest and most common reprocessing option. It uses liquid-liquid extraction to process light-water reactor spent fuel. The spent fuel is dissolved in nitric acid, and then the acid solution is mixed with an organic solvent consisting of tributyl phosphate in kerosene. Uranium and plutonium are extracted in the organic phase and the fission products remain in the aqueous phase. Further processing allows the separation of uranium and plutonium. The advantage of this process is the long-term experience with the process. The disadvantage is that it cannot separate fission products such as technetium, cesium, and strontium nor can it separate actinides such as neptunium, americium, and curium.

**TABLE 17.7**

World Commercial Reprocessing Capacity

	Location	Tons/Year

### **17.6.5.2 UREX+**

The UREX+ process is a liquid–liquid extraction process like PUREX. It can be used for light-water reactor fuels and it includes additional extraction steps that allow separation of neptunium/plutonium, technetium, uranium, cesium/strontium, americium, and curium. The advantage of this process is that it meets the requirements for continuous recycle in light-water reactors and it builds on current technology. The disadvantage is that it cannot be used to process short-cooled fuels and it cannot be used for some specialty fuels being developed for advanced reactors.

### **17.6.5.3 Pyroprocessing**

This process was developed and tested at Experimental Breeder Reactor-2 (EBR-2) by Argonne National Laboratory in the United States. It is an electrochemical process rather than a liquid–liquid extraction process. Oxide fuels are first converted to metals in order to be processed. The metallic fuel is then treated to separate uranium and the transuranic elements from the fission products. The advantage of this process is the ability to process short-cooled and specialty fuels designed for advanced reactors. The disadvantage is that it does not meet the requirements for continuous recycle from thermal reactors but it is ideal for fuel for fast neutron reactors.

## **17.6.6 Spent Fuel Storage**

Spent fuel is routinely discharged from operating reactors. As it is discharged it is moved to the spent fuel storage pool that is an integral part of the reactor facility. Reactors are built with storage pools that will hold fuel from many years of operation. The pools are actively cooled by circulating cooling water. The fuel stored at many older reactors is reaching the capacity of the on-site storage pools. At this point, the fuel is being transferred to dry storage. Dry storage takes place in large metal or concrete storage facilities. These dry facilities are passively cooled by the air circulating around them.

## **17.6.7 Spent Fuel Transportation**

Spent fuel is transported in large engineered containers designated as Type B containers (casks). Casks provide shielding for the highly radioactive fuel so that they can be safely handled. They are made of cast iron or steel. Many of them use lead as the shielding material. They are also designed to protect the environment by maintaining their integrity in case of accident. They are designed to withstand severe accidents including fires, impacts, immersion, pressure, heat, and cold, and are tested as part of the design certification process.

Casks have been used to transport radioactive materials for over 50 years. The IAEA has published advisory regulations for safe transportation of radioactive materials since 1961. Casks are built to standards, designed to meet the IAEA advisory regulations, specified by licensing authorities such as NRC in the United States.

Spent fuel is shipped from reactor sites by road, rail, or water. Larger casks can weigh up to 110 tons and hold about 6 tons of spent fuel. Since 1971, about 7000 shipments of spent fuel (over 35,000 tons) have been transported over 30 million km with no property damage or personal injury, no breach of containment, and a very low-dose rate to the personnel involved.

---

## 17.7 Nuclear Waste

Radioactive wastes are produced throughout the reactor fuel cycle. The costs of managing these wastes are included in the costs of the nuclear fuel cycle and thus are part of the electricity cost.

Since these materials are radioactive, they decay with time. Each radioactive isotope has a half-life, which is the time it takes for half of the material to decay away. Eventually, these materials decay to a stable nonradioactive form.

The process of managing radioactive waste involves the protection of people from the effects of radiation. The longer-lived materials tend to emit alpha and beta particles. It is relatively easy to shield people from this radiation but if these materials are ingested the alpha and beta radiation can be harmful. The shorter-lived materials usually emit gamma rays. These materials require greater amounts of shielding.

### 17.7.1 Types of Radioactive Wastes

The strict definitions of types of radioactive waste may vary from country to country. In the following discussion, more generally accepted terminology will be used.

#### 17.7.1.1 Mine Tailings

Mining and milling of uranium produces a sandy type of waste which contains naturally occurring radioactive elements that are present in uranium ore. The decay of these materials produces radon gas which must be contained. This is often done by covering the tailings piles with clay to contain the radon gas. Technically, tailings are not classified as radioactive waste.

#### 17.7.1.2 Low-Level Wastes

Low-level wastes (LLW) is generated from medical and industrial uses of radioactive materials as well as from the nuclear fuel cycle. In general, these wastes include materials such as paper, clothing, rags, tools filters, soils, etc., which contain small amounts of radioactivity. This radioactivity tends to be short-lived. These materials generally do not have to be shielded during transport and they are suitable for shallow land burial. The volume of these materials may be reduced by compacting or incineration prior to disposal. They make up about 90% of the volume of radioactive waste but contain only about 1% of the radioactivity of all the radioactive waste.

#### 17.7.1.3 Intermediate-Level Wastes

Intermediate-level wastes (ILW) are generated during the operation of nuclear reactors, in the reprocessing of spent fuel, and from the decommissioning of nuclear facilities. These materials contain higher amounts of radioactivity and generally require some shielding during storage and transportation. ILW is generally made up of resins, chemical sludge, fuel cladding, and contaminated materials from decommissioning nuclear facilities. Some of these materials are processed before disposal by solidifying them in concrete or bitumen. They make up about 7% of the volume and have about 4% of the radioactivity of all the radioactive waste.

#### 17.7.1.4 High-Level Wastes

High level waste is generated during the operation of a nuclear reactor. This waste consists of fission products and transuranic elements generated during the fission process. This material is highly radioactive and is also thermally hot so that it must be both shielded and cooled. It accounts for 95% of the radioactivity produced by nuclear power reactors.

#### 17.7.2 Managing HLW from Spent Fuel

The form of HLW from spent fuel is either the spent fuel itself or the waste products from reprocessing. The level of radioactivity from spent fuel falls to about one thousandth of the level it was when removed from the reactor in 40–50 years. This means the heat generated is also greatly reduced.

Currently, there are about 270,000 tons of spent fuel in storage at reactor sites around the world. An additional 12,000 tons are generated each year and about 3,000 tons of this are sent for reprocessing.

When spent fuel reprocessing is used, uranium and plutonium are first removed during reprocessing, and then the much smaller volume of remaining HLW is solidified using a vitrification process. In this process, the fission products are mixed in a glass material, vitrified in stainless steel canisters, and stored in shielded facilities for later disposal.

High-level waste will eventually be disposed-off in deep geologic facilities. Several countries have selected sites for these facilities and they are expected to be commissioned for use after 2015.

#### 17.7.3 Managing Other Radioactive Wastes

Generally, ILW and LLW are disposed by burial. ILW generated from fuel reprocessing will be disposed in deep geological facilities. Some low-level liquid wastes from reprocessing plants are discharged to the sea. These liquids include some distinctive materials such as technetium-99 that can be discerned hundreds of kilometers away. Such discharges are tightly controlled and regulated so that the maximum dose any individual receives is a small fraction of natural background radiation.

Nuclear power stations and reprocessing facilities release small quantities of radioactive gases to the atmosphere. Gases such as krypton-85 and xenon-133 are chemically inert and gases such as iodine-131 have short half-lives. The net effect of these gases is too small to warrant further consideration.

[Table 17.8](#) provides a summary of waste management adopted by countries throughout the world.

---

### 17.8 Nuclear Power Economics

Any discussion of the economics of nuclear power involves a comparison with other competitive electric generation technologies. The competing technologies are usually coal and natural gas.

Nuclear power costs include capital costs, fuel cycle costs, waste management costs and the cost of decommissioning after operation. The costs vary widely depending on the

**TABLE 17.8**

Waste Management for Used Fuel and HLW from Nuclear Power Reactors

Country	Policy	Facilities and Progress Toward Final Repositories
Belgium	Reprocessing	Central waste storage at Dessel Underground laboratory established in 1984 at Mol Construction of repository to begin about 2035
Canada	Direct disposal	Nuclear Waste Management Organisation set up in 2002 Deep geological repository confirmed as policy, retrievable Repository site search from 2009, planned for use in 2025
China	Reprocessing	Central used fuel storage at LanZhou Repository site selection to be completed by 2020 Underground research laboratory from 2020, disposal from 2050
Finland	Direct disposal	Program started in 1983, two used fuel storages in operation Posiva Oy set up in 1995 to implement deep geological disposal Underground research laboratory Onkalo under construction Repository planned from this, near Olkiluoto, to open in 2020
France	Reprocessing	Underground rock laboratories in clay and granite Parliamentary confirmation in 2006 of deep geological disposal, containers to be retrievable and policy “reversible” Bure clay deposit is likely repository site to be licensed in 2015, operating from 2025
Germany	Reprocessing but moving to direct disposal	Repository planning started in 1973 Used fuel storage at Ahaus and Gorleben salt dome Geological repository may be operational at Gorleben after 2025
India	Reprocessing	Research on deep geological disposal for HLW
Japan	Reprocessing	Underground laboratory at Mizunami in granite since 1996 Used fuel and HLW storage facility at Rokkasho since 1995 Used fuel storage under construction at Mutsu, start-up in 2013 NUMO set up in 2000, site selection for deep geological repository underway to 2025, operation from 2035, retrievable
Russia	Reprocessing	Underground laboratory in granite or gneiss in Krasnoyarsk region from 2015, may evolve into repository Sites for final repository under investigation on Kola peninsula Pool storage for used VVER-1000 fuel at Zheleznogorsk since 1985 Dry storage for used RBMK and other fuel at Zheleznogorsk from 2012 Various interim storage facilities in operation
South Korea	Direct disposal, maybe change	Waste program confirmed in 1998, KRWM set up in 2009 Central interim storage planned from 2016
Spain	Direct disposal	ENRESA established in 1984, its plan was accepted in 1999 Central interim storage at Villar de Canas from 2016 (volunteered location) Research on deep geological disposal, decision after 2010
Sweden	Direct disposal	Central used fuel storage facility—CLAB—in operation since 1985 Underground research laboratory at Aspo for HLW repository Osthammar site selected for repository (volunteered location)
Switzerland	Reprocessing	Central interim storage for HLW and used fuel at ZZL Wurenlingen since 2001 Smaller used fuel storage at Beznau Underground research laboratory for high-level waste repository at Grimsel since 1983 Deep repository by 2020, containers to be retrievable

location of the generating plant. In countries such as China, Australia, and the United States, coal remains economically attractive because of large accessible coal resources. This advantage could be changed if a charge is made on carbon emissions. In other areas nuclear energy is competitive with fossil fuels even though nuclear costs include the cost of all waste disposal and decommissioning.

### 17.8.1 Comparison of Generation Technologies

As previously stated, nuclear power costs include spent fuel management, plant decommissioning, and final waste disposal. These costs are not generally included in the costs of other power generation technologies.

Decommissioning costs are estimated to be 9%–15% of the initial cost of a nuclear plant. Since these costs are discounted over the life of the plant, they contribute only a few percent to the investment cost of the plant and have an even lower impact on the electricity generation cost. This impact in the United States is about 0.1–0.2 cent/kWh or about 5% of the cost of electricity produced.

Spent fuel interim storage and ultimate disposal in a waste repository contribute another 10% to the cost of electricity produced. This cost is reduced if the spent fuel is disposed-off directly. This does not account for the energy that could be extracted from the fuel if it was reprocessed.

Costs for nuclear-based electricity generation have been dropping over the last decade. This reduction in the cost of nuclear generated electricity is a result of reductions in nuclear plant fuel, operating, and maintenance costs. However, the capital construction costs for nuclear plants are significantly higher than coal and gas-fired plants. Because the capital cost of nuclear plants contribute more to the cost of electricity than for coal- or gas-fired generation the impact of changes in fuel, operation, and maintenance costs on the cost of electricity generation is less than for coal- or gas-fired generation.

One of the primary contributors to the capital cost of nuclear plants has been the cost of money used to finance nuclear plant construction. The financing costs increase when the time required to license and construct a plant increases. Two factors are leading to the reduction in this portion of the cost. First, especially in the United States, the licensing process is changing so that a plant receives both the construction permit and the operating

license prior to the start of construction. Under this process, there is no large investment in plant hardware prior to completion of a significant portion of the licensing process, leading to a reduction in time required for the plant to begin producing revenue. Second, the new generation of nuclear plants will be highly standardized and modularized. This will allow a significant reduction in the time required to construct a new plant. It is estimated that the time from the start of construction to the start of operation will be reduced from nearly 10 years to 4–5 years. This will have a significant impact on capital costs.

The reduced capital costs associated with the licensing and construction of new nuclear power plants, and the fact that nuclear power is inherently less susceptible to large fluctuations in fuel costs, have made nuclear power an attractive energy option for many countries seeking to diversify their energy mix in the face of rising fossil fuel costs.

---

## 17.9 Conclusions

The development of nuclear power began after World War II and continues today. The first power-generating plants were constructed in the late 1950s. During the 1960s and 1970s, there was a large commitment to nuclear power until the accidents occurred at Three Mile Island in 1979 and then at Chernobyl in 1986. The new safety requirements and delays caused by these accidents drove up the costs and at the same time caused a loss of public acceptance. In the United States, many plant orders were canceled and in other countries the entire nuclear programs were canceled.

The ability of nuclear reactors to produce electricity economically and safely without the generation of greenhouse gases has revitalized the interest in nuclear power as an alternative energy source. Many lessons have been learned from the operation of current power plants that have allowed the safety of newly designed plants to be improved. This coupled with the desire of many nations to develop secure energy sources and a diversity of energy options has resulted in the continuing development of a whole new generation of nuclear plants to meet future energy needs.

Nuclear power is also not as susceptible to fluctuation in fuel costs as petroleum and natural gas. As discussed, the supply of uranium is very large, and if it is supplemented with thorium, the fuel supply will seemingly be unlimited. This drives many other aspects of the fuel cycle, such as the choice between closed and open fuel cycles discussed earlier. For example, because of the large uranium resource and the fears of nuclear proliferation, the once-through (open) fuel cycle is favored by many. This will require large, deep, geologic waste repositories for the disposal of large quantities of spent fuel. However, when reprocessing is included in the closed fuel cycle, the amount of needed repository space is greatly reduced but the expense of operation is increased. Finally, it may be possible to essentially eliminate the need for repositories by utilizing advanced fuel cycles that utilize almost all of the energy available in uranium and the other transuranic products of reactor operation.

The need for energy and the use of electricity as the primary energy source for the end-user will drive the increase in electricity generation around the world. The drive to reduce the production of greenhouse gases will contribute to a wider use of nuclear power for electricity generation. The recognition that nuclear power can safely provide large base-load generating capacity at a reasonable cost using known technologies will also be a major factor in its future development.

## 18.1 Executive Summary

The *Annual Energy Outlook 2013* (AEO2013) projection [2] to 2040 summarizes the following:

- The projected growth in U.S. energy production outpaces the growth in energy consumption, particularly for natural gas, and leads to a decline in the net import share of total U.S. energy consumption from 19% in 2011 to 9% in 2040. For reference, in 2005, the import share was 30%. However, the United States does not achieve energy independence by 2040.
- The continued improvement of advanced crude oil and natural gas production technologies—particularly for shale and other tight formations—continues to lift projected U.S. supply, with domestic crude oil production peaking at about 7.5 million barrels per day (bbl/day) in 2019. Domestic natural gas production outpaces domestic consumption and becomes the dominant source of domestic energy production by 2040, reaching 33 trillion cubic feet (Tcf) and accounting for 34% of total U.S. primary energy production.
- The decline in energy imports reflects increased domestic petroleum and natural gas production, an increased use of biofuels (much of which are produced domestically), and decreased demand resulting from rising energy prices and the adoption of new efficiency standards for vehicles;
- Relatively low natural gas prices, facilitated by growing shale gas production, spur increased natural gas use in the industrial and electric power sectors. The share of natural gas in electricity generation rises from 25% in 2011 to 30% in 2040. The share of electricity generated by coal declines from 42% in 2011 to 35% in 2040. Natural gas also makes gains in other areas, such as exports, as a fuel for heavy-duty freight transportation, and as a feedstock for producing diesel and other fuels.
- Electricity generation from solar, and to a lesser degree wind energy sources, grows as recent cost declines coupled with state-level renewable portfolio standards (RPS) and federal tax incentives make renewables a preferred option to other feedstocks such as coal and natural gas.
- EIA projects domestic coal production to grow modestly between 2011 and 2040, but its market share of total energy production falls from about 28% in 2011 to 24% in 2040. Natural gas displaces most of the expansion opportunities for coal in power generation, thereby freeing more coal for potential export. U.S. coal exports grow from 107 million short tons in 2011 to 159 million short tons in 2040.
- The AEO2013 Reference case projects improvements in vehicle efficiency, with total energy demand in the transportation sector falling to its 2011-level by 2040, after increasing early in the projection period.
- Efficiency gains in the residential and commercial sectors offset household and floor-space growth in each sector that would otherwise increase overall energy consumption.

- U.S. energy-related CO<sub>2</sub> emissions remain more than 5% below their 2005 level through 2040, reflecting increased efficiency and the shift to a less carbon-intensive fuel mix in both transportation and power generation [3,5]. Market factors, such as technological improvements and competition with lower-cost renewables, and policy factors, such as the Renewable Fuel Standard [6] and the new CAFÉ [4] standard for light-duty vehicles (LDV), which raised the new car efficiency to 47.5 miles per gallon by 2025, are the principal drivers for the decline in emissions. See Section 18.6.1 for more details on CAFÉ.

---

## 18.2 Introduction: Outlook for U.S. Energy, 2011–2040\*

### 18.2.1 Background

This chapter provides a summary of the U.S. Energy Information Administration's (EIA's) *Annual Energy Outlook 2013* (AEO2013) Reference case (the central scenario with respect to crude oil prices, macroeconomic growth, and technological progress). The AEO2013 provides projections of a number of potential energy futures and explores the impact of different assumptions through the comparison of a series of side cases analyses to the Reference case. Key side cases include different crude oil import prices, differences in domestic resource availabilities (oil and natural gas), different economic growth assumptions, assumed policy changes, and technological changes.

EIA's AEO2013 Reference case is different from many private projections in that the EIA does not attempt to include a "forecast" of policy changes. EIA understands that while changes will occur, the exact nature of those changes is far from certain. EIA uses the term "projection," not "prediction" or "forecast," because all the midterm outlooks—including the AEO2013 Reference case—are highly conditioned on the specific assumptions made for those particular cases.

Central to the Reference case is the assumption that current technological and demographic trends, and current laws and regulations, will continue as usual into the future. EIA does not propose, advocate, or speculate on future legislative or regulatory changes. Thus, the AEO2013 projections provide a policy-neutral basis for analyzing policy initiatives and alternative assumptions regarding economic growth and technological progress, to name a few. For more detail and a more useful treatment of uncertainties related to key assumptions of the Reference case projection, the reader can visit the EIA website at <http://www.eia.gov/forecasts/aeo/er/index.cfm> and observe some of the other cases included in the AEO2013.

---

\* The outlook of U.S. energy markets through 2040, as presented in Sections 18.1 through 18.6, uses the EIA's National Energy Model (NEM)[1] (<http://www.eia.doe.gov/oiaf/aeo/overview/index.html>). This chapter describes the reference case projection for AEO2013, which is available on the EIA website (<http://www.eia.doe.gov/oiaf/aeo/index.html>) along with another 30 side cases. See [http://www.eia.doe.gov/oiaf/aeo/assumption/pdf/0554\(2013\).pdf](http://www.eia.doe.gov/oiaf/aeo/assumption/pdf/0554(2013).pdf) for a detailed description of the assumptions of the AEO2013 Reference case. The outlook and commentary described herein represent solely the views of the authors and do not necessarily reflect the views of EIA, the U.S. Department of Energy, the Administration, or any agency of the U.S. government.

### 18.2.2 The AEO2013 Reference Case

The prevailing assumption of the *AEO2013* Reference case is that current laws and regulations continue as promulgated. One notable exception is that the *AEO2013* Reference case adds a premium to the cost of financing carbon dioxide (CO<sub>2</sub>)-intensive technologies to reflect current perceived risks regarding possible future policies that may be used to mitigate greenhouse gas (GHG) emissions.

Change is the norm in the outlooks for U.S. energy markets, as such the Reference case projection in *AEO2013* is quite different from the Reference case projections from past AEOs. This is largely due to changes in the assumptions underlying each of the projections (e.g., there are differences in the outlook for crude oil prices, economic growth, technological improvements, etc.) and changes to U.S. supply expectations as a result of improved technology and processes (such as fracking). Additionally, crude oil supply and demand have changed substantially since 2005, thereby shifting the expected crude oil price path (Figure 18.1).

Although EIA does not expect the United States to achieve energy independence by 2040 in the Reference case, technological and process advances in oil and gas supply have altered the outlook for U.S. energy imports and exports. The growth in domestically produced crude oil and natural gas from tight formations proves to be an important driver of change across all sectors. For example, natural gas production increases over the projection period, driven primarily by the growth in shale gas development. That development keeps natural gas prices relatively low throughout most of the projection period, compared to previous projections, increasing natural gas use in the industrial sector in the short term and helping natural gas stay competitive with coal in the electricity sector.

New sources of oil and natural gas, coupled with lower economic growth, new end-use efficiency regulations, new regulations on fuel use in the transportation sector, and

**FIGURE 18.1**

Primary energy use by fuel, 1980–2040 (quadrillion Btu).

higher CAFE standards through 2025 result in lower energy demand from LDVs, particularly for gasoline, in the longer term. All of these changes result in much lower CO<sub>2</sub> emission expectations than in previous AEOs. The AEO2013 Reference case projects that CO<sub>2</sub> emissions never exceed the emissions-levels of 2005 throughout the projection's horizon (2040).

---

## 18.3 AEO2013 Key Assumptions and Uncertainties

All projections of energy-economic systems, particularly those that incorporate consumer and producer behavior, are inherently uncertain. However, consumer and producer behavior are not the only sources of uncertainty. Some of the other critical uncertainties on which projections depend include the following:

- The rate of technological progress for end-use and supply technologies
- Changes in energy market regulations and efficiency standards
- The quantity and location of energy resources in the ground (e.g., coal, crude oil, natural gas, nuclear material)
- The costs to explore, locate, and ultimately produce energy resources
- The willingness of financial markets to make energy investments

Consequently, the projections described in this chapter are not a statement of what will happen, but what might happen given the assumptions and methodologies used by EIA.

### 18.3.1 Economy

In the AEO2013 Reference case, annual real gross domestic product (GDP) growth averages 2.5% per year between 2011 and 2040, down by 0.2 percentage points when compared with the 30-year period prior to the projection period, largely reflecting both lower labor productivity and lower levels of consumption. U.S. real consumption growth averages 2.2% per year in EIA's projections. In EIA's projections, U.S. economic output depends on the size of the labor force, the amount of capital in the economy, and the productivity of both labor and capital. Over the past two decades, the labor force has grown faster than the population. Moving forward, not only does EIA project that both the labor force and population will grow more slowly, but the labor force will grow more slowly than population as larger segments of the population reach retirement age. The slower growth in the labor force is offset somewhat by projected faster growth in spending on research and development and business fixed investment; EIA projects the share of GDP devoted to business fixed investment to range from 10% to 17% of GDP through 2040 compared to an average rate of approximately 10% over the past 30 years.

In the AEO2013 Reference case, EIA expects the economic recovery to continue, and increased energy production from domestic resources improves U.S. competitiveness. Growth in U.S. manufacturing output accelerates through 2020, with energy-intensive industries growing at a rate of 1.8% per year from 2011 to 2020. From 2020 to 2040, energy-intensive industries will grow by just 0.6% per year, as manufacturing output declines in the face of stronger foreign competition and higher energy prices (which impact energy-intensive industries more significantly).

Total U.S. energy expenditures decline as a percentage of GDP in the *AEO2013* Reference case. After peaking in 2011, the projected ratio of energy expenditures to GDP falls through 2040, averaging 6.8% from 2011 to 2040, which is below the historical average of 8.8% from 1970 to 2010. In the Reference case, oil's value as a share of U.S. GDP falls from 5% in 2011 to 4% in 2040.

Issues such as financial market reform, fiscal policies, and the solvency of Eurozone member countries will affect both short-run and long-run growth, adding uncertainty to these projections.

### 18.3.2 Oil Prices

The definition of the Reference case benchmark crude oil price changed in the *AEO2013* from the West Texas Intermediate (WTI) spot oil price to the Brent crude oil price. This change was in response to the significant divergence of WTI prices from similar internationally traded crudes, and the observed impact that Brent crude oil prices have had on the price that many U.S. consumers pay for motor gasoline.

The future path of world oil prices is a major uncertainty facing world oil markets. World crude oil prices reached an average high of about \$105 per barrel (in 2011 dollars) in 2008 before declining to an average of \$81.31 per barrel in 2010. Brent crude oil prices increase in the Reference case by an average of 1.3% per year from 2011 to 2040, from \$111.26 to \$162.68 per barrel.

EIA's crude oil price paths represent equilibrium market conditions between supply and demand. Because there is significant uncertainty in future crude oil prices, EIA has developed side cases to help examine how different oil price paths could impact U.S. energy markets. The following graph (Figure 18.2) shows a range of uncertainty surrounding

**FIGURE 18.2**

Brent crude oil spot prices in three cases, 1990–2040 (2011 dollars per barrel).

crude oil prices (Brent light), reflected in the price differential between the *AEO2013*'s Reference case, High Price side case, and Low Price side case. These are annual average prices and do not show the volatility that occurs in oil prices in the short term. Over the last two decades, volatility within a single year averaged about 30%. There are no probabilities associated with any of the crude oil price cases.

## 18.4 Petroleum and Other Liquids

### 18.4.1 Global Petroleum Market

The *AEO2013* Reference case projects total global liquids consumption to grow from 88 million bbl/day in 2011 to 113 million bbl/day in 2040, a 28% increase by 2040. Crude oil represents 85% of the total liquids supply in 2011, but EIA projects a decline to 81% in 2040 as other fuels increase their market share.

Of the major producers, the share of global supply by the Organization of the Petroleum Exporting Countries (OPEC) increases slightly, from 40% in 2011 to 43% in 2040. The Organisation for Economic Cooperation and Development (OECD) share of global supply remains fairly steady at about 25% through 2040, as the United States and Canada increase their liquids production and European North Sea and Mexican production decline. Meanwhile, other non-OECD producers such as Brazil, China, the former Soviet Union countries, and small African producers see their share of total supply fall by an amount roughly equal to the OPEC increase between 2011 and 2040.

### 18.4.2 Global Liquid Prices

Petroleum prices are set in a worldwide marketplace and reflect the interaction of supply and demand forces. Strong growth in global oil demand, particularly in China and other developing countries, is one of the key factors behind the sharp price increases seen since 2002. Another factor contributing to the upward trend in world oil prices is a tight supply situation that—until recently—has had only limited production response by countries outside of OPEC. Finally, concerns about economic and political situations in the Middle East, Venezuela, Nigeria, China, and the former Soviet Union could manifest themselves through higher prices.

Significant uncertainties reside in the long-term trend for both the supplies and prices of crude oil. The sources of uncertainty include the following:

- Size and location of potential resources
- Access to potential resources which vary on geopolitical factors
- Availability and cost of technologies to explore, discover, and develop the resources
- Rate of technological change for resource development technologies
- Willingness to invest in specific resource development projects and the rate of investment
- Rate of growth and location of growth of the demand for oil products
- Cartel behavior
- Other aboveground factors (e.g., geopolitical factors)

In the *AEO2013* Reference case, the projection of crude oil import prices of Brent crude in 2011 real dollars continues to rise, as global demand grows and both belowground (geology, resource availability, and technology) and aboveground (economic, geopolitical, and access) factors constrain supply. In addition, tighter U.S. fuel economy standards, increased use of biofuels, and rising energy prices act together to temper the domestic demand growth, and higher prices and mandates spur increased domestic production of crude oil and biofuels.

As discussed in Section 18.2.2, global crude oil prices were updated in the *AEO2013* Reference case to represent the projected cost of Brent light crude oil. In the Reference case, EIA projects Brent crude oil prices to increase by 1.3% per year from 2011 to 2040, to \$162.68 per barrel (see [Table 18.1](#)) as a result of belowground and aboveground factors. Liquids prices to all domestic end users are shown in [Table 18.2](#).

### 18.4.3 Domestic Liquids

One of the central story lines in the *AEO2013* Reference case is the growth in domestic liquids production, particularly from tight formations. In the *AEO2013* Reference case, total production of petroleum and other liquids in the United States grows from 10.4 million bbl/day in 2011 to 13.1 million bbl/day at its peak in 2019. Most of the growth is the result of higher production of crude oil and natural gas liquids (NGL) from tight oil formations, such as the Bakken and Eagle Ford plays.

EIA projects domestic crude oil production, particularly from tight oil plays, to rise sharply over the next decade. Total domestic crude oil production reaches a peak of 7.5 million bbl/day in 2019 before eventually falling to 6.1 million bbl/day in 2040 (still higher than the levels of 2011). The growth in domestic oil production is due to the application of new processes and technologies (such as fracking) and the relatively attractive world Brent crude oil price ([Figure 18.3](#)).

Total U.S. tight oil production grew to over 1.7 million bbl/day in July 2012, an increase of 690 thousand bbl/day over July 2011. EIA projects tight oil production to increase to 2.8 million bbl/day in 2020. Relatively high initial flow rates from tight formations allow for significant growth in total tight oil production in the short term as drilling activity increases. However, growth in production will slow as producers move to less productive and more expensive areas in known plays unless producers can discover and exploit new productive tight formations—another uncertainty. Following the initial surge, EIA expects tight oil production to decline to 2.2 million bbl/day in 2030 and ends up at 2.0 million bbl/day in 2040. Nevertheless, tight oil represents a large proportion of the growth in U.S. oil production in the Reference case.

Total U.S. liquid fuels consumption sits at approximately 19.0 million bbl/day in both 2011 and 2040, but peaks in 2019 at 19.8 million bbl/day ([Table 18.3](#)). U.S. consumption of liquid fuels increases by 6.4% from 2011 to 2020 and then gradually decreases to the 2011 level (~19.0 million bbl/day) by 2040 primarily because of declining energy use in LDVs. The petroleum content of liquid fuels declines at an average of 0.6% per year over the period, with the difference largely made up by natural gas plant liquids and biofuels (with the latter increasing from 0.9 million bbl/day in 2011 to 1.3 million bbl/day in 2040). As a result, U.S. reliance on net petroleum imports—which was at approximately 60% in 2005 and roughly 45% in 2011—falls to 37% in 2040. Nonetheless, imports continue to meet a large part of total U.S. liquids demand throughout the projection period.

Consumption of domestically produced biofuels increases significantly between 2011 and 2040, rising from 1.3 quadrillion British thermal unit (Btu) in 2011 to 2.1

**TABLE 18.1 (Continued)**

**Total Energy Supply, Disposition, and Price Summary**

*Sources:* 2010 natural gas supply values: U.S. Energy Information Administration (EIA), Natural Gas Annual 2010, DOE/EIA-0131(2010), Washington, DC, December 2011. 2011 natural gas supply values and natural gas wellhead price: EIA, Natural Gas Monthly, DOE/EIA-0130(2012/07), Washington, DC, July 2012; 2010 natural gas spot price at Henry Hub based on daily data from Natural Gas Intelligence; 2010 and 2011 coal minemouth and delivered coal prices: EIA, Annual Coal Report 2011, DOE/EIA-0584(2011), Washington, DC, November 2012; 2011 petroleum supply values and 2010 crude oil and lease condensate production: EIA, Petroleum Supply Annual 2011, DOE/EIA-0340(2011)/1, Washington, DC, August 2012; Other 2010 petroleum supply values: EIA, Petroleum Supply Annual 2010, DOE/EIA-0340(2010)/1, Washington, DC, July 2011; 2010 and 2011 crude oil spot prices: Thomson Reuters; Other 2010 and 2011 coal values: EIA, Quarterly Coal Report, October–December 2011, DOE/EIA-0121(2011/4Q), Washington, DC, March 2012; Other 2010 and 2011 values, EIA, Annual Energy Review 2011, DOE/EIA-0384(2011), Washington, DC, September 2012; Projections: EIA, AEO2013 National Energy Modeling System run ref2013.d102312a.

*Notes:* Totals may not equal sum of components due to independent rounding. Data for 2010 and 2011 are model results and may differ slightly from official EIA data reports. Quadrillion Btu, unless otherwise noted.

Btu, British thermal unit; MMBtu, million Btu; n/a, not applicable.

- <sup>a</sup> Includes waste coal.
- <sup>b</sup> These values represent the energy obtained from uranium when it is used in light water reactors. The total energy content of uranium is much larger, but alternative processes are required to take advantage of it.
- <sup>c</sup> Includes grid-connected electricity from wood and wood waste; biomass, such as corn, used for liquid fuels production; and nonelectric energy demand from wood. Refer to Table A17 (<http://www.eia.gov/forecasts/aeo/pdf/0383%282013%29.pdf>, pp. 153–154) for details.
- <sup>d</sup> Includes grid-connected electricity from landfill gas; biogenic municipal waste; wind; photovoltaic and solar thermal sources; and nonelectric energy from renewable sources, such as active and passive solar systems. Excludes electricity imports using renewable sources and nonmarketed renewable energy. See Table 17 for selected nonmarketed residential and commercial renewable energy data.
- <sup>e</sup> Includes non-biogenic municipal waste, liquid hydrogen, methanol, and some domestic inputs to refineries.
- <sup>f</sup> Includes imports of finished petroleum products, unfinished oils, alcohols, ethers, blending components, and renewable fuels such as ethanol.
- <sup>g</sup> Includes imports of liquefied natural gas that are later reexported.
- <sup>h</sup> Includes coal, coal coke (net), and electricity (net). Excludes imports of fuel used in nuclear power plants.
- <sup>i</sup> Includes crude oil, petroleum products, ethanol, and biodiesel.
- <sup>j</sup> Includes reexported liquefied natural gas.
- <sup>k</sup> Balancing item. Includes unaccounted for supply, losses, gains, and net storage withdrawals.
- <sup>l</sup> Includes petroleum-derived fuels and nonpetroleum-derived fuels, such as ethanol and biodiesel, and coal-based synthetic liquids. Petroleum coke, which is a solid, is included. Also included are natural gas plant liquids and crude oil consumed as a fuel. Refer to Table 17 for detailed renewable liquid fuels consumption.
- <sup>m</sup> Excludes coal converted to coal-based synthetic liquids and natural gas.
- <sup>n</sup> Includes grid-connected electricity from wood and wood waste, nonelectric energy from wood, and biofuels heat and coproducts used in the production of liquid fuels, but excludes the energy content of the liquid fuels.
- <sup>o</sup> Includes non-biogenic municipal waste, liquid hydrogen, and net electricity imports.
- <sup>p</sup> Annual average price for Brent crude oil on the Intercontinental exchange.
- <sup>q</sup> Includes reported prices for both open market and captive mines. Prices weighted by production, which differs from average minemouth prices published in EIA data reports where it is weighted by reported sales.
- <sup>r</sup> Prices weighted by consumption; weighted average excludes residential and commercial prices, and export free-alongside-ship (f.a.s.) prices.

(Continued)

**TABLE 18.2 (Continued)****Energy Prices by Sector and Source**

*Sources:* 2010 and 2011 prices for motor gasoline, distillate fuel oil, and jet fuel are based on prices in the U.S. Energy Information Administration (EIA), Petroleum Marketing Monthly, DOE/EIA-0380(2012/08), Washington, DC, August 2012; 2010 residential, commercial, and industrial natural gas delivered prices: EIA, Natural Gas Annual 2010, DOE/EIA-0131(2010), Washington, DC, December 2011; 2011 residential, commercial, and industrial natural gas–delivered prices: EIA, Natural Gas Monthly, DOE/EIA-0130(2012/07), Washington, DC, July 2012; 2010 transportation sector natural gas–delivered prices are based on EIA, Natural Gas Annual 2010, DOE/EIA-0131(2010), Washington, DC, December 2011 and estimated state taxes, federal taxes, and dispensing costs or charges; 2011 transportation sector natural gas–delivered prices are model results. 2010 and 2011 electric power sector distillate and residual fuel oil prices: EIA, Monthly Energy Review, DOE/EIA-0035(2011/09), Washington, DC, September 2010; 2010 and 2011 electric power sector natural gas prices: EIA, Electric Power Monthly, April 2011 and April 2012, Table 4.2, and EIA, State Energy Data System 2010, DOE/EIA-0214(2010), Washington, DC, June 2012; 2010 and 2011 coal prices based on: EIA, Quarterly Coal Report, October–December 2011, DOE/EIA-0121(2011/4Q), Washington, DC, March 2012 and EIA, AEO2013 National Energy Modeling System run ref2013.d102312a. 2010 and 2011 electricity prices: EIA, Annual Energy Review 2011, DOE/EIA-0384 (2011), Washington, DC, September 2012; 2010 and 2011 E85 prices derived from monthly prices in the Clean Cities Alternative Fuel Price Report; Projections: EIA, AEO2013 National Energy Modeling System run ref2013.d102312a.

*Notes:* Data for 2010 and 2011 are model results and may differ slightly from official EIA data reports. 2011 dollars per million Btu, unless otherwise noted.

Btu, British thermal unit; n/a, not applicable.

<sup>a</sup> Includes combined heat and power plants that have a non-regulatory status, and small on-site generating systems.

<sup>b</sup> Excludes use for lease and plant fuel.

<sup>c</sup> E85 refers to a blend of 85% ethanol (renewable) and 15% motor gasoline (nonrenewable). To address cold starting issues, the percentage of ethanol varies seasonally. The annual average ethanol content of 74% is used for forecast.

<sup>d</sup> Sales weighted-average price for all grades. Includes federal, state, and local taxes.

<sup>e</sup> Kerosene-type jet fuel. Includes federal and state taxes while excluding county and local taxes.

<sup>f</sup> Diesel fuel for on-road use. Includes federal and state taxes while excluding county and local taxes.

<sup>g</sup> Natural gas used as a vehicle fuel. Includes estimated motor vehicle fuel taxes and estimated dispensing costs or charges.

<sup>h</sup> Includes electricity-only and combined heat and power plants that have a regulatory status.

<sup>i</sup> Weighted averages of end-use fuel prices are derived from the prices shown in each sector and the corresponding sectoral consumption.

**FIGURE 18.3**

U.S. oil production by source, 1990–2040 (million bbl/day).

quadrillion Btu in 2040, largely as a result of the incentives provided by the Renewable Fuel Standard and the Low Carbon Fuel Standard of California.\* The share of total U.S. liquid fuels consumption from domestically produced biofuels grows from 3.5% in 2011 to almost 6% in 2040.

## 18.4.4 Liquids Refining and Processing

### 18.4.4.1 Light versus Heavy Crudes and the Changing Product Slate

Refineries generally process a mix of crude oils with a range of API gravities<sup>†</sup> in order to optimize refinery operations. Over the past 15 years, the API gravity of crude oil processed in U.S. refineries averaged between 30° and 31°. As U.S. refiners process more domestic light crude produced from tight formations, they need less imported light oil crude to maintain an optimal API gravity. With increasing U.S. production of light crude oil in the Reference case, EIA expects the average API gravity of crude oil imports to decline overall, as domestic light crudes displace some of the lighter imported crudes. In addition, refinery operations might need to be modified and/or investments made to produce the market desired product mix.

In the AEO2013 Reference case, the trend toward increasing imports of heavier crude oils continues through 2035 before stabilizing. The increase in demand for diesel fuel in the projection, from 3.5 to 4.3 million bbl/day, leads to an increase in distillate hydrocracking capacity (which increases diesel production capability) from 1.6 to 3.0 million bbl/day from 2011 to 2040. In the AEO2013 Reference case, the ratio of gasoline-to-diesel production at

\* For a summary of the Renewable Fuel Standard, see <http://www.fas.org/sgp/crs/misc/R40155.pdf>. For a summary of Low Carbon Fuel Standard of California, see [http://www.energy.ca.gov/low\\_carbon\\_fuel\\_standard/](http://www.energy.ca.gov/low_carbon_fuel_standard/).

<sup>†</sup> API gravity is a measure of the specific gravity, or relative density, of a liquid, as defined by the American Petroleum Institute (API). It is expressed in “degrees,” where a higher number indicates lower density.

*Sources:* 2010 and 2011 consumption based on U.S. Energy Information Administration (EIA), Annual Energy Review 2011, DOE/EIA-0384(2011), Washington, DC, September 2012; 2010 and 2011 population and gross domestic product: IHS Global Insight Industry and Employment models, August 2012; 2010 carbon dioxide emissions: EIA, Monthly Energy Review, DOE/EIA-0035(2011/10), Washington, DC, October 2011; 2011 carbon dioxide emissions and emission factors: EIA, Monthly Energy Review, DOE/EIA-0035(2012/08), Washington, DC, August 2012; Projections: EIA, AEO2013 National Energy Modeling System run ref2013.d102312a.

*Notes:* Totals may not equal sum of components due to independent rounding. Data for 2010 and 2011 are model results and may differ slightly from official EIA data reports. Quadrillion Btu, unless otherwise noted.

Btu, British thermal unit; n/a, not applicable.

<sup>a</sup> Includes wood used for residential heating. See Table A4 and/or Table A17 (<http://www.eia.gov/forecasts/aeo/pdf/0383%282013%29.pdf>, pp. 129–130 and/or 153–154, respectively) for estimates of nonmarketed renewable energy consumption for geothermal heat pumps, solar thermal water heating, and electricity generation from wind and solar photovoltaic sources.

<sup>b</sup> Includes ethanol (blends of 15% or less) and ethers blended into gasoline.

(Continued)

**TABLE 18.3 (Continued)**

Energy Consumption by Sector and Source

- <sup>c</sup> Excludes ethanol. Includes commercial sector consumption of wood and wood waste, landfill gas, municipal waste, and other biomass for combined heat and power. See Table A5 and/or Table A17 (<http://www.eia.gov/forecasts/aeo/pdf/0383%282013%29.pdf>, pp. 131–132 and/or 153–154, respectively) for estimates of nonmarketed renewable energy consumption for solar thermal water heating and electricity generation from wind and solar photovoltaic sources.
- <sup>d</sup> Includes energy for combined heat and power plants that have a nonregulatory status, and small on-site generating systems.
- <sup>e</sup> Includes petroleum coke, asphalt, road oil, lubricants, still gas, and miscellaneous petroleum products.
- <sup>f</sup> Represents natural gas used in well, field, and lease operations, in natural gas processing plant machinery, and for liquefaction in export facilities.
- <sup>g</sup> Includes consumption of energy produced from hydroelectric, wood and wood waste, municipal waste, and other biomass sources. Excludes ethanol blends (15% or less) in motor gasoline.
- <sup>h</sup> E85 refers to a blend of 85% ethanol (renewable) and 15% motor gasoline (nonrenewable). To address cold starting issues, the percentage of ethanol varies seasonally. The annual average ethanol content of 74% is used for this forecast.
- <sup>i</sup> Includes only kerosene type.
- <sup>j</sup> Diesel fuel for on- and off- road use.
- <sup>k</sup> Includes aviation gasoline and lubricants.
- <sup>l</sup> Includes unfinished oils, natural gasoline, motor gasoline blending components, aviation gasoline, lubricants, still gas, asphalt, road oil, petroleum coke, and miscellaneous petroleum products.
- <sup>m</sup> Includes electricity generated for sale to the grid and for own use from renewable sources, and nonelectric energy from renewable sources. Excludes ethanol and nonmarketed renewable energy consumption for geothermal heat pumps, buildings photovoltaic systems, and solar thermal water heaters.
- <sup>n</sup> Includes consumption of energy by electricity-only and combined heat and power plants that have a regulatory status.
- <sup>o</sup> These values represent the energy obtained from uranium when it is used in light water reactors. The total energy content of uranium is much larger, but alternative processes are required to take advantage of it.
- <sup>p</sup> Includes conventional hydroelectric, geothermal, wood and wood waste, biogenic municipal waste, other biomass, wind, photovoltaic, and solar thermal sources. Excludes net electricity imports.
- <sup>q</sup> Includes non-biogenic municipal waste not included above.
- <sup>r</sup> Includes conventional hydroelectric, geothermal, wood and wood waste, biogenic municipal waste, other biomass, wind, photovoltaic, and solar thermal sources. Excludes ethanol, net electricity imports, and nonmarketed renewable energy consumption for geothermal heat pumps, buildings photovoltaic systems, and solar thermal water heaters.

petroleum refineries declines from 2.3 in 2012 to 1.6 after 2035. The transition to lower gasoline and higher diesel production has a significant effect on petroleum refinery operations, investments, and infrastructure.

The large increase in domestic production of light crude oil and the increase in imports of heavier crude oils have prompted significant investments in crude midstream infrastructure, including pipelines that will bring higher quantities of light sweet crudes to petroleum refineries along the U.S. Gulf Coast. In addition, there have been significant investments to move crude oil to refineries by rail. The Reference case assumes that sufficient infrastructure investments will be made through 2040 to move both light and heavy crude oils.

#### **18.4.4.2 Biofuels and Ethanol**

The AEO2013 Reference case, relative to the *Annual Energy Outlook 2012* (AEO2012), projects lower production levels for cellulosic biofuels, resulting from changes to a number of important assumptions, including the following: lower near-term crude oil price assumption, fewer flex-fuel vehicle sales, lower E85 availability, as well as a downward adjustment in the projection of “drop-in” biofuels.

Biofuels consumption grows in the AEO2013 Reference case but falls well short of the Renewable Fuels Standard (RFS) target of 36 billion gallon (gal) ethanol equivalent in 2022, largely because of a decline in gasoline consumption, which results from a newly enacted CAFE standard and lowered expectations for sales of vehicles capable of using E85 (flex-fueled vehicles). Ethanol consumption falls from 16.4 billion gal in 2022 to 14.9 billion gal in 2040 in the AEO2013 Reference case, as gasoline demand continues to drop and E85 consumption levels off. However, domestic consumption of drop-in cellulosic biofuels grows from 0.3 billion gal to 9.0 billion gal ethanol equivalent per year from 2011 to 2040, as rising oil prices lead to price increases for diesel fuel, heating oil, and jet fuel, while production costs for advanced biofuels technologies fall. From 2011 to 2022, demand for motor gasoline ethanol blends (E10 and E15) falls from 8.7 to 8.1 million bbl/day which limits the amount of ethanol that can be splash blended with gasoline—an illustration of the “blend wall” effect.

Domestic ethanol production remains relatively flat throughout the projection, as consumption of motor gasoline decreases and the penetration of ethanol in the gasoline pool is slowed by the limitations of the E10 and E15 blend market and the limited availability of flex-fuel vehicles, few E15- and E85-capable filling stations, and a reluctance of consumers to search out and use higher ethanol blends. Total biofuels production increases by 0.4 million bbl/day in the projection, as drop-in fuels (e.g., biodiesel) from biomass enter the market. Other emerging technologies capable of producing liquids—such as xTL, which includes coal-to-liquids (CTL) and gas-to-liquids technologies—also become more economic as more plants are built through the manufacturing “learning effect” or “technological progress.” In 2040, liquids production from xTL plants total 0.3 million bbl/day. High capital costs and the risk that xTL production will not remain price-competitive with crude oil slow investment in xTL technologies.

#### **18.4.5 Domestic Liquids Prices**

Domestic liquids prices (Table 18.2) reflect the trends in global petroleum pricing as well as shifts in domestic liquids demand. EIA expects that the rate of technological progress for extracting crude oil from tight formations and natural gas from shale, the implementation

of new appliance efficiency standards, and a new LDV efficiency standard in the United States that begins in 2017 and continues through 2025 will all temper U.S. crude oil demand for imports and impact crude oil prices.

In addition, potential new international emission control protocols and significant global concerns about the security of the petroleum supply represent additional factors which may also reduce the upward pressure on crude oil prices. Finally, technological progress, which may lead to cost reductions in xTL technologies and the development of new methods to economically develop domestic oil shale resources, and the discovery of crude oil in other relatively unexplored regions of the world, could also influence oil prices. For a full listing of delivered liquids prices, see [Table 18.2](#).

### 18.5 Natural Gas

In the *AEO2013* Reference case, natural gas becomes the dominant source of U.S. energy production, growing from a 30% market share in 2011 to a 34% share by 2040, primarily as a result of increased production from tight plays. Natural gas consumption rises by more than 20% by 2040, primarily due to its increased use in electric power generation, the industrial sector, and as a transportation fuel in heavy-duty trucks. The growth in natural gas production (and consumption) is another of the major story lines of the *AEO2013* Reference case, as the increase in domestic production has a number of positive follow-on effects in the U.S. energy-economic system (Figure 18.4).

**FIGURE 18.4**  
Natural gas consumption by sector, 1990–2040 (Tcf).

**FIGURE 18.5**  
Natural gas production by source, 1990–2040 (Tcf).

### 18.5.1 Natural Gas Supply

Shale gas production is the major contributor to increased natural gas production, increasing from 7.8 Tcf in 2011 (34% of total U.S. dry gas production) to 16.7 Tcf in 2040 (50% of total production) as shown in Figure 18.5. Much of the growth in natural gas production is the result of drilling in shale plays with high concentrations of NGL and crude oil. High oil prices make drilling attractive to producers and make unconventional plays economical.

U.S. natural gas production exceeds consumption by 2020, and the resulting surplus spurs net exports of natural gas. Unlike the case in previous projections, the *AEO2013* Reference case does not include the construction of a natural gas pipeline from Alaska to the lower 48 states; however, the projections include a natural gas pipeline from the North Slope to southern Alaska to fuel liquefied natural gas (LNG) exports.

### 18.5.2 Natural Gas Prices

Facilitated by growing shale gas production, natural gas prices remain relatively low in the *AEO2013* Reference case. Low prices, in turn, spur increased use of natural gas in the industrial and electric power sectors. Natural gas also expands into new areas of the economy as a fuel for heavy-duty freight transportation (trucking), as a feedstock for producing diesel and other fuels, and as exports to global demand centers.

While natural gas prices remain roughly at parity with coal prices in the early years of the projection—due to the surge in tight gas production—they gradually increase over time as drilling moves into more expensive resources with lower recovery rates. In the Reference case, natural gas prices at the Henry Hub rise from \$3.98 per million Btu (MMBtu) in 2011 to \$7.83 per MMBtu in 2040 (see [Table 18.1](#)).

## 18.6 Energy Consumption, by Sector

In the *AEO2013* Reference case, total U.S. energy consumption grows from approximately 98 quadrillion Btu in 2011 to 108 quadrillion Btu in 2040, an average annual growth rate of just 0.3%. Across sectors, the biggest shifts in demand occur in the industrial and commercial sectors, each of which grows at an average of 0.5% per year to 2040. Please refer to [Table 18.3](#) and Figure 18.6 for a summary of energy demand by sector.

### 18.6.1 Transportation Sector

In the *AEO2013* Reference case, the transportation sector consumes 27.1 quadrillion Btu of energy in 2040, the same level of energy demand as 2011, largely as a result of declining demand from LDVs. This projection differs markedly from the historical trend, which saw 1.1% average annual growth from 1975 to 2011. Energy demand for LDVs, which includes cars and light trucks, declines from 16.1 quadrillion Btu in 2011 to 13.0 quadrillion Btu in 2040, in contrast to 0.9% average annual growth from 1975 to 2011.

EIA's projection includes the National Highway Traffic Safety Administration (NHTSA) and the Environmental Protection Agency (EPA) standards for LDVs, which serve to raise the fuel economy of new LDVs from 32.5 miles per gallon (mpg) in 2012 to 47.3 mpg in 2025. The GHG emissions and CAFE standards are held constant after 2025, but LDV fuel economy continues to rise, to 49.0 mpg in 2040. Passenger car fuel economy averages 56.1 mpg and light-duty truck fuel economy averages 40.5 mpg. LDVs that use diesel, other alternative fuels, hybrid-electric, or all-electric systems play a significant role in meeting more stringent GHG emissions and CAFE standards over the projection period.

**FIGURE 18.6**  
Primary energy use by end-use sector, 2011–2040 (quadrillion Btu).

**FIGURE 18.7**

Natural gas consumption in the transportation sector, 1995–2040 (quadrillion Btu).

Energy demand for heavy duty vehicles (HDVs) increases from 5.2 quadrillion Btu in 2011 to 7.6 quadrillion Btu in 2040, primarily as a result of increased economic output. HDVs are used extensively in ground-based shipping, among other things. As is the case with LDVs, the increase in energy demand for HDVs is tempered by standards for GHG emissions and fuel efficiency starting in 2014. Fuel demand for air, marine, and rail traffic all increase in the Reference case, largely as a result of increased economic output (Figure 18.7).

Compressed natural gas and LNG are the fastest-growing fuels in the transportation sector, with a combined average annual growth rate of 11.9% from 2011 to 2040. HDVs lead the growth in natural gas demand throughout the projection period, as natural gas fuel consumption by HDVs increases from almost zero in 2011 to more than 1 quadrillion Btu in 2040, at an average annual growth rate of 14.6%.

The improved economics of LNG for HDVs result in an increase in natural gas use in transportation that offsets a portion of petroleum liquids consumption. Natural gas use in HDVs displaces 0.7 million bbl/day of other motor fuels in the Reference case in 2040.

### 18.6.2 Industrial Sector

Industrial energy consumption increases by 4.7 quadrillion Btu from 2011 to 2040 in the Reference case, or by an average of 0.6% per year. Most of the growth occurs between 2011 and 2025, and is accounted for by natural gas use, which increases by 18% from 2011 and 2025 and by an additional 6% from 2025 to 2040. The mix of industrial fuels changes relatively slowly, however, reflecting limited capability for fuel switching in most industries. Despite a 76% increase in industrial shipments, industrial-delivered energy consumption

increases by only 19% from 2011 to 2040 in the *AEO2013* Reference case, reflecting a continuing transition to less energy-intensive industries.

Industrial consumption of NGL, consumed predominantly as feedstocks in the bulk chemicals industry, increases by 21% from 2011 to 2025, followed by a 9% decline from 2025 to 2040. NGL usage declines starting in 2025 as shipments of bulk chemicals fall in the face of increased international competition. Consumption of renewable fuels in the industrial sector grows by 22% from 2011 to 2025 and by 37% from 2025 to 2040. The paper industry remains the predominant consumer of renewable energy (mostly biomass) in the industrial sector.

In the projection from 2011 to 2040, the energy-intensive industries' (including chemicals, petroleum refineries, paper products, iron and steel, and food products) share of total industrial output continues declining at a rate of 1.0% per year, a decline that continues the shift of the U.S. economy to less energy-intensive industries. The decline in energy intensity for the less energy-intensive industries is almost twice that for the more energy-intensive industries. While energy-intensive manufacturing shows stable energy intensity, the nonenergy-intensive manufacturing industries—such as plastics, computers, and transportation equipment—show a 33% decline in energy intensity from 2011 to 2040, or an average decline of about 1.4% per year.

Refining is the only industry subsector (energy intensive) that shows an increase in energy intensity. Shipments from refineries are essentially flat in the early years and then decline slightly after 2019, with a 4% decline in shipments overall from 2011 to 2040. In contrast, energy use for refining increases by 13% over the same period, as CTL production and the use of heavy crude feedstock, both of which require more energy to process than typical crude oil, increase after 2022.

### 18.6.3 Residential Sector

The Reference case projection reflects a general population geographical shift to warmer climates. As a result, the average electricity demand per household declines by 6% in the Reference case, from 12.3 MWh in 2011 to 11.5 MWh in 2040. Despite the per-household reduction in electricity demand, the increasing number of households over the projection period results in an increase of 24% of total delivered electricity consumption in the residential sector. Over the same period, residential use of natural gas falls by 12%, and use of petroleum and other liquids falls by 25%. In 2040, space cooling and "other uses" consume 42% and 52% more electricity, respectively, than in 2011, and they remain the largest residential uses of electricity. These shifts reflect not only population geographical shifts to warmer climates but also efficiency changes. Total energy demand for most electric end uses increases, even as it declines on a per-household basis.

EIA projects combined photovoltaic (PV) and wind capacity in the residential sector to grow from 1.5 GW in 2011 to 9.6 GW in 2016. After 2016, expiration of the investment tax credit (ITC) results in slower growth, with only 4.1 GW added from 2017 through 2040. Similarly, ground-source heat pumps and solar water heaters grow from a combined 1.3 million units in 2011 to 2.4 million units in 2016; but after 2016, with expiration of the ITCs, only 1.4 million additional units are added through 2040.

In the *AEO2013* Reference case, the energy intensity of residential demand (defined as annual energy use per household) declines from 97.2 MMBtu in 2011 to 75.5 MMBtu in 2040. The projected 22% decrease in intensity occurs along with a 32% increase in the number of homes (about 1% per year), and total residential square footage increasing by

41% from 2011 to 2040. Without efficiency improvements, energy demand for uses such as heating, cooling, and lighting would increase at rates similar to the increases of households and square footage.

#### 18.6.4 Commercial Sector

While total delivered commercial energy grows over the projection period and commercial floor space grows at about 1% per year in EIA's projections, average delivered energy consumption per square foot of commercial floorspace declines at an annual rate of 0.4% from 2011 to 2040 in the *AEO2013* Reference case. Natural gas consumption increases at about one-half the growth rate of delivered electricity consumption, which grows by 0.8% per year. These changes are largely due to higher efficiency standards and higher efficiency uptake, particularly in electric appliances.

Renewable technologies, including solar PV and wind, account for 61% of commercial distributed generation capacity in 2040 in the *AEO2013* Reference case. Exponential growth of PV capacity occurs as a result of utility incentives, new financing options, and the 30% federal ITC that reverts to 10% in 2017. In the Reference case, commercial PV capacity increases by 5.4% annually from 2011 to 2040. Small-scale wind capacity increases more than eightfold from 2011 to 2040 because it is not hampered by rising fuel prices that offset the effects of the 10% ITC on nonrenewable technologies for distributed generation after 2017. Microturbines using natural gas and fuel cells account for nearly all of the remaining distributed generation in the commercial sector.

The average energy intensity of commercial buildings declines from 105.2 thousand Btu/sq. ft. in 2012 to 93.8 thousand Btu/sq. ft. in 2040, driven largely by federal efficiency standards. However, miscellaneous electric loads—which include medical equipment and video displays—are not all subject to federal standards, and increase the energy intensity from “other” end uses by 34%.

Increasing energy use for miscellaneous electric loads, many of which currently are not subject to federal efficiency standards, leads to a 34% increase in energy intensity from 2011 to 2040 for “other” end uses. Miscellaneous electric loads in the commercial sector include medical equipment and video displays, among many other devices.

With ongoing improvements in equipment efficiency and building shells, the average energy intensity of commercial buildings declines over time by 10.8%, from 105.2 thousand Btu/ft<sup>2</sup> in 2012 to 93.8 thousand Btu/ft<sup>2</sup> in 2040. Federal efficiency standards in end uses such as space heating and cooling, water heating, refrigeration, and lighting, and act to limit growth in energy consumption to less than the growth in commercial floorspace.

#### 18.6.5 Electricity Sector

The growth of U.S. electricity demand (including retail sales and direct use) slowed in each decade since the 1950s, from a 9.8% annual rate of growth from 1949 to 1959 to only 0.7% per year in the first decade of the twenty-first century. Electricity demand growth in the Reference case is slow, as increasing demand for electricity services is offset by efficiency gains from new appliance standards and investments in energy-efficient equipment. Total electricity demand grows by 28% in the projection (0.9% per year), from 3839 billion kilowatt-hours (kWh) in 2011 to 4930 billion kWh in 2040. The share of electricity generated by coal declines over the projection period by an annual average of 0.5%, primarily due to growth in generation from natural gas and renewables.

The decline in coal-fired electricity generation and the rise of natural gas-fired generation in recent years was driven primarily by two factors: (1) the huge fall in natural gas prices that occurred as U.S. shale gas resources were successfully developed and (2) the recession that began in late 2007, which contributed to a 2-year decline in electricity generation (the first time that has occurred since EIA began tracking the data). Coal absorbed most of the negative impacts of the reduction, as natural gas prices fell sharply in the period to keep volumes relatively stable.

Between 1990 and 2008, coal-fired power plants accounted for 50% or more of U.S. electricity generation each year. However, since 2008, coal's share of generation declined every year, falling to 42% in 2011. The story for natural gas is almost the complete opposite. After falling to less than 10% of total generation in 1988, natural gas's share of generation increased to nearly 25% in 2011. EIA expects the natural gas share of electricity generation to be much higher in 2012 when final data are available. While natural gas prices remain low in the early years of the projection due to the surge in tight gas production, they gradually increase over time as drilling moves into more expensive resources with lower recovery rates.

The *AEO2013* Reference case expects the share of natural gas in generation to continue growing as prices slowly increase. EIA expects coal-fired generation to recover as natural gas prices rise, but not enough to increase its market share. Partly as a result of the crowding out effect natural gas has on coal, U.S. coal exports in the *AEO2013* Reference case grow from 107 million short tons in 2011 to 159 million short tons in 2040.

Natural gas and renewables account for the largest share of the growth in domestic energy production between 2011 and 2040 (76%) and their share of total production grows over the projection, from 42% in 2011 to 49% in 2040. Non-hydro renewable generation shows rapid growth, as state and federal programs spur growth in the near term, and they become increasingly competitive in the long term.

#### **18.6.5.1 Coal**

In the *AEO2013* Reference case, coal-fired power plants continue to be the largest source of electricity generation throughout the projection period, but their market share declines from 42% in 2011 to 35% in 2040. The United States retires approximately 15% of the coal-fired capacity active in 2011 by 2040, while only 3% of total new generating capacity added by 2040 is coal-fired. Existing coal-fired units that have undergone environmental equipment retrofits continue to operate throughout the projection.

Coal production grows modestly between 2011 and 2040 even though coal consumption for power generation falls through 2016 with the retirement of over 30 GW of coal capacity. After 2016, coal consumption grows as the remaining coal capacity is used more intensely and growth in coal use in CTL production accelerates.

#### **18.6.5.2 Natural Gas**

As a result of the new outlook for natural gas production, generation from natural gas increases by an average of 1.6% per year from 2011 to 2040, and its share of total generation grows from 24% in 2011 to 30% in 2040. The relatively low cost of natural gas makes the dispatching of existing natural gas plants more competitive with coal plants and, in combination with relatively low capital costs of new natural gas units, makes plants fueled by natural gas an attractive option for new generation capacity.

### 18.6.5.3 Nuclear

Nuclear generation grows by 14% in the Reference case, due to 11 GW of additional nuclear capacity and 8 GW of updates of existing capacity offsetting over 7 GW of retirements. Nuclear's share of total U.S. electricity generation declines from 19% in 2011 to 17% in 2040, as the growth in natural gas-fired generation outpaces electricity generation from nuclear power plants (NPPs). Generation from U.S. NPPs increases by 0.5% per year on average from 2011 to 2040, with most of the growth between 2011 and 2025.

### 18.6.5.4 Renewables

In the AEO2013 Reference case, renewable generating capacity accounts for nearly one-fifth of total generating capacity (but not total generation) in 2040. Nearly all renewable capacity additions over the period consist of non-hydropower capacity, which grows by more than 150% from 2011 to 2040. Renewable capacity additions are supported by state renewable portfolio standards, the federal RFS, and federal tax credits.

Generation from renewable sources grows by 1.7% per year on average, and its share of total generation rises from 13% in 2011 to 16% in 2040 (Figure 18.8). Renewable generation increases from 524 billion kWh in 2011 to 858 billion kWh in 2040. The non-hydropower share of total renewable generation increases from 38% in 2011 to 65% in 2040. The increase in wind-powered generation from 2011 to 2040 of 134 billion kWh, or 2.6% per year, represents the largest absolute increase in renewable generation. However, generation from solar energy grows by 92 billion kWh over the same period, representing the highest annual average growth at 9.0% per year. Biomass generation increases by 95 billion kWh over the projection period, for an average annual increase of 4.5%.

**FIGURE 18.8**

Renewable electricity generation by type, including end-use generation, 2008–2040 (billion kWh).

**FIGURE 18.9**

Energy use per capita and per dollar of gross domestic product, 1980–2040 (index, 1980 = 1).

## 18.7 Energy Intensity and CO<sub>2</sub> Emissions

The potential for more energy conservation continues to receive attention as energy prices rise. The Reference case projection does not assume policy-induced conservation measures beyond those in existing legislation and regulation, nor does it assume behavioral changes beyond those experienced in the past.

Energy intensity (thousand Btu per 2005 dollars of GDP) in the United States declined by an average of 1.9% per year between 1992 and 2003, as the role of energy-intensive industries in the U.S. economy fell sharply (the share of industrial output from the energy-intensive industries declined on average by 1.3% per year from 1992 to 2003) (Figure 18.9). On a national basis, energy intensity falls by 2.1% per year from 2011 to 2040 in the Reference case.

Historically, energy use per person varies over time with the level of economic growth, weather conditions, and energy prices, among other factors. During the late 1970s and early 1980s, energy consumption per capita fell in response to high energy prices and weak economic growth. Starting in the late 1980s and lasting through the mid-1990s, energy consumption per capita increased with declining energy prices and strong economic growth. Per capita energy use declines in the Reference case projection by nearly 0.6% per year between 2011 and 2040, with growth in the demand for energy services offset by efficiency gains (Figure 18.10).

Efficiency gains in the transportation sector help to moderate the growth of CO<sub>2</sub> emissions from energy use, increasing from 5471 million metric tons in 2011 to 5501.1 million metric tons in 2025, and to 5691.1 million metric tons in 2040. The CO<sub>2</sub> emissions-intensity of the U.S. economy falls from 411 thousand metric tons per million dollars of GDP in

**FIGURE 18.10**

U.S. energy-related carbon dioxide emissions by sector and fuel, 2005 and 2040 (million metric tons).

2005 dollars in 2011 to 290 thousand metric tons per million dollars GDP in 2025. Further, they continue to drop to 209 thousand metric tons per million dollars (2005 USD) of GDP in 2040.

By sector—and including the emissions associated with the electricity consumed—CO<sub>2</sub> emissions for 2011 to 2040 remain largely unchanged in the residential sector, increase by 0.3% per year for the commercial sector, increase by 0.3% per year for the industrial sector, and decline slightly for transportation. Power sector CO<sub>2</sub> emissions grow at 0.2% per year but these are already included in the sectoral emissions listed earlier.

## Acknowledgments

We are indebted to the staff of the Office of Energy Analysis at the U.S. Energy Information Administration (EIA) for their integral part in helping to develop this projection. Credits for this effort are shared with the staff and management who produced the *Annual Energy Outlook 2013 (AEO2013)*. Like all projections, this projection represents what might occur under laws, regulations, policies, and other key assumptions of the scenarios at the time of their development. It is not a forecast of what will occur. All errors remain the sole responsibility of the authors.

### 19.1 Introduction

A viable transportation system is a crucial part of a sustainable energy future. Transportation is a complex interdisciplinary topic, which really deserves a book unto itself. However, some of the main issues related to transportation have to do with fuels and energy storage, which are the topics covered in this book. This section does not purport to be exhaustive, but examines some of the key issues related to a viable transportation future.

Gasoline and diesel not only are very convenient fuels for ground transportation, but also have a high energy density that permits storage in a relatively small volume—an important asset for automobiles. For example, these liquid fuels have a volumetric specific energy content of about 10,000 kWh/m<sup>3</sup>, compared to hydrogen compressed to 100 bar at about 300 kWh/m<sup>3</sup>. But known petroleum resources worldwide are being consumed rapidly, and future availability of these resources is bound to decline. At present, more than 97% of the fuel used for ground transportation in the United States is petroleum based. Importation of fossil fuels in the United States has recently been decreasing, primarily because of domestic exploration and production of oil and natural gas. The increase in the cost of gas and oil has become of growing concern to average citizens, and the emission from current transportation systems is a major component of CO<sub>2</sub> pollution that produces global warming.

**FIGURE 19.1**

Oil production vs. time for various recoverable amounts of petroleum. (According to Bartlett, A.A., *Math. Geol.*, 32(1), 2000. With permission.)

There is worldwide agreement among oil experts that global oil production will reach a peak sometime between 2020 and 2030. The predictions for the date of peak world oil production according to various estimates [1] are demonstrated in Figure 19.1. The oil production is shown as a function of time for three total amounts of recoverable oil that span the entire range of assumptions by experts. Although new oil fields may be discovered in the future, it is not expected that they will substantially increase the total recoverable amounts. Hence, it is believed that the total amounts lie somewhere between 3000 and 4000 billion barrels of oil (bbl). The obvious conclusion to be drawn from these predictions is that the production peak is imminent and the price of oil will continue to escalate as supplies decline. Thus, planning for a sustainable transportation system that does not depend entirely on petroleum resources is an imperative segment of a sustainable energy future.

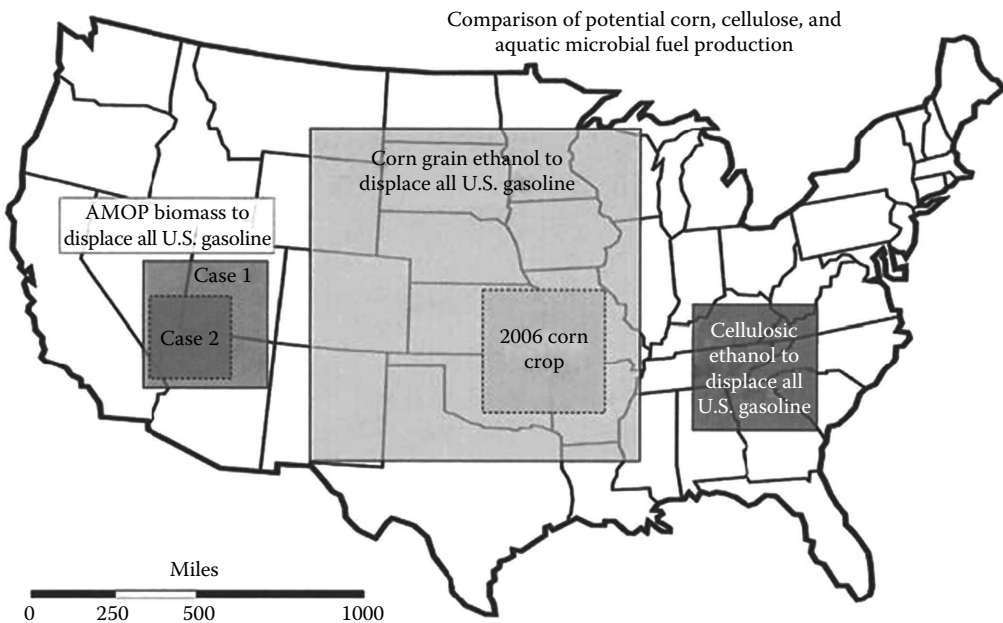

## 19.2 Alternative Fuels

Alternative fuels available to supplement oil as well as their feedstock are shown in Table 19.1 [2]. Inspection of the table shows that biodiesel, electricity, ethanol, and hydrogen (via electricity) are the fuels potentially independent of a petroleum resource such as oil or natural gas. The potential of producing liquid fuel from biomass has been treated elsewhere in this handbook. There is every reason to believe that biomass will provide an increasing percentage of the future transportation fuel, especially if ethanol can be produced from cellulosic materials such as switchgrass or bio-waste, or diesel from algae. The reason for this is that ethanol produced by traditional methods from corn kernels has only an energy return on energy investment on the order of 1.25, whereas the EROI for cellulosic ethanol is claimed to be about 6. Diesel from algae may be even better. As shown in Figure 19.2, even cellulosic ethanol would not be able to replace oil, because growing it would require too large a percentage of all the arable lands in the United States, and the

**TABLE 19.1**

Feedstocks for Alternative Fuels

Fuel	Feedstock
Propane (LPG)	Natural gas (NG), petroleum
CNG	NG
Hydrogen	NG or (water + electricity)
FT diesel	NG, coal, or algae
Methanol (M85)	NG or coal
Ethanol (E85)	Corn, sugarcane, or cellulosic biomass
Electricity	NG, coal, uranium, or renewables

**FIGURE 19.2**

Relative land area requirement for various liquid fuel biosources. (From Dismukes, C. et al., *Curr. Opin. Biotechnol.*, 19, 235, June 2008. With permission.)

production of large amounts of ethanol would compete with the production of food, which is of increasing importance for a socially sustainable energy system.

It has recently been proposed [3] to use biofuels derived from aquatic microbial oxygenic photoautotrophs (AMOPs), commonly known as algae. In this study, it was shown that AMOPs are inherently more efficient solar collectors, use less or no land, can be converted to liquid fuels using simpler technologies than cellulose, and offer secondary uses that fossil fuels do not provide. AMOPs have a 6- to 12-fold energy advantage over terrestrial plants because of their inherently higher solar energy conversion efficiency, which is claimed to be between 3% and 9%. Figure 19.2 compares the area needed for three different biomass sources. The data are for corn grain, switchgrass, mixed prairie grasses, and AMOPs. Each box superimposed on the map of the United States represents the area needed to produce a sufficient amount of biomass to generate enough liquid fuel to displace all the gasoline

**TABLE 19.2**

Comparison of Some Sources of Biodiesel

<sup>a</sup> For meeting 50% of all transport fuel needs of the United States.

<sup>b</sup> 70% oil (by wt) in biomass.

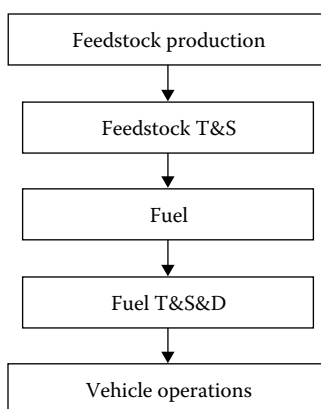

<sup>c</sup> 30% oil (by wt) in biomass.

used in the United States in the year 2007. The two boxes for AMOPs are for 30% and 70% conversion efficiency. The overall solar energy conversion to biofuels works out to about 0.05% for solar to ethanol from corn grain and roughly 0.5% from switchgrass to ethanol. Comparatively, this value is about 0.5%–1% for AMOPs to ethanol or biodiesel.

An even more favorable assessment for the potential of algae to produce biodiesel is presented in Ref. [4]. According to this study, microalgae may be a source of biodiesel that has the potential to displace fossil fuel. According to Ref. [4], microalgae grow extremely rapidly and are exceedingly rich in oil. Some microalgae double their biomass every day, and the oil content of microalgae can exceed 80% by weight. Table 19.2 shows a comparison of some sources of biodiesel that could meet 50% of all of the transportation needs in the United States. According to estimates in Ref. [4], only a small percentage of U.S. cropping areas would be necessary to supply 50% of the entire transport fuel needs in the United States. However, no full-scale commercial algae biodiesel production facility has been built and operated for a sufficient time to make reliable predictions regarding the future of algae for a sustainable transportation system.

### 19.3 Well-to-Wheel Analysis

Rather than simply looking at the efficiency of an engine or a given fuel, a more comprehensive way to determine overall efficiency when evaluating the potential of any new fuel for ground transportation is to use what is called a *well-to-wheel analysis*. The approach to a well-to-wheel analysis is shown schematically in [Figure 19.3](#) [5,14]. The well-to-wheel approach of a fuel cycle includes several sequential steps: feedstock production; feedstock transportation and storage; fuel production; transportation, storage, and distribution (T&S&D) of fuel; and finally vehicle operation. This approach is essential for a fair comparison of different options because each step entails losses. For example, whereas a fuel cell has a much higher efficiency than an internal combustion (IC) engine, for its operation, it depends on a supply of hydrogen, which must be produced by several steps from other sources. Moreover, there is no infrastructure for transporting and storing hydrogen, and this step in the overall well-to-wheel analysis has large losses and contributes to much larger energy requirements compared to a gasoline or electrically driven vehicle.

**FIGURE 19.3**  
Steps in a well-to-wheel analysis for ground transportation vehicles.

---

## 19.4 Mass Transportation

An opinion held widely among state governments and environmentalists is that the mass transportation would greatly reduce the total energy consumption for the transportation sector. However, as shown in [Table 19.3](#), based upon data collected by the U.S. Transportation Department in this country, the energy intensity of intercity rail and transit buses, that is, the energy spent per passenger-mile traveled, is virtually the same as the energy intensity of automobiles with current use. This is due to the urban sprawl in major cities that makes it difficult to reach outlying areas by a mass transport network. In other words, unless there are incentives for mass transport or disincentives to use the automobile, thereby achieving higher mass transport load factors—that is, more passengers per mile—on transit buses and light rail, the availability of mass transport systems will not materially change the overall energy use by the transportation sector. Moreover, installing new light rail is very capital-intensive and may not always be worth the energy and/or the money invested in its construction. Although passenger mass transit does not appear to offer large untapped opportunities, using ship or rail instead of air for shipment of freight and commercial goods is a source of enormous fuel reduction potential.

---

## 19.5 Hybrid Electric Vehicles

Another obvious approach to ameliorating the expected increase in price and lack of availability of petroleum fuel is to increase the mileage of the vehicles. This can be achieved by improving the efficiency of the IC engine, for instance, by using advanced diesel engines that have a higher compression ratio than spark ignition (SI) engines, or by using hybrid electric vehicles (HEVs). Increasing the efficiencies of IC or diesel engines is a highly specialized topic and is not discussed here. However, HEVs offer a near-term option for utilizing improved battery technology.

An HEV is powered by the combination of a battery pack and electric motor—like that of an electric vehicle—and a power generation unit (PGU), which is normally an IC or

diesel engine. Unlike electric vehicles, however, HEV batteries can be recharged by an onboard PGU, which can be fueled by existing fuel infrastructure.

HEVs can be configured in a parallel or a series design. The parallel design enables the HEV to be powered by both the PGU and the motor, either simultaneously or separately. The series design uses the PGU to generate electricity, which recharges the HEV battery pack and produces power via an electric motor. The key element of either design is that the battery pack, as well as the PGU, can be much smaller than those of a typical electric vehicle or a vehicle powered by an IC engine because the IC engine can be operated at its maximum efficiency nearly all the time.

Currently available HEVs, such as the Toyota Prius, use a parallel configuration, as shown in [Figure 19.4](#). A parallel HEV has two propulsion paths: one from the PGU and one from the motor, while computer chips control the output of each. A parallel-configuration HEV has a direct mechanical connection between the PGU and the wheels, as in a conventional vehicle (CV), but also has an electric motor that can drive the wheels. For example, a parallel vehicle could use the electric motor for highway cruising and the power from

**FIGURE 19.4**  
Schematic of a parallel-configuration hybrid electric vehicle.

(a)

(b)

**FIGURE 19.5**  
Fuel-efficient cars (a) 2010 Toyota Prius: Toyota's third-generation Prius is a *parallel* hybrid; the 80 hp (60 kW) electric motor and gas engine work together to produce an average 50 mpg. (b) 2010 Ford Fusion: The Fusion can travel up to 47 mph (75 kph) on electric power alone. The motor is powered by a nickel metal hydride battery pack, and the car's engine is a 2.5 L Atkinson Cycle I-4 gasoline engine. The Fusion gets 41 mpg in the city and 36 mpg highway. (Courtesy of *Solar Today*, November/December 2009.)

IC engine for accelerating. The power produced by the PGU also drives the generator, which in turn can charge the battery as needed. The system to transfer electricity from the generator to the battery pack is exactly like that of an electric vehicle, with alternating current converted to DC by the inverter. HEV parallel designs also use a regenerative braking feature that converts energy stored in the inertia of the moving vehicle into electric power during deceleration (see Figure 19.5).

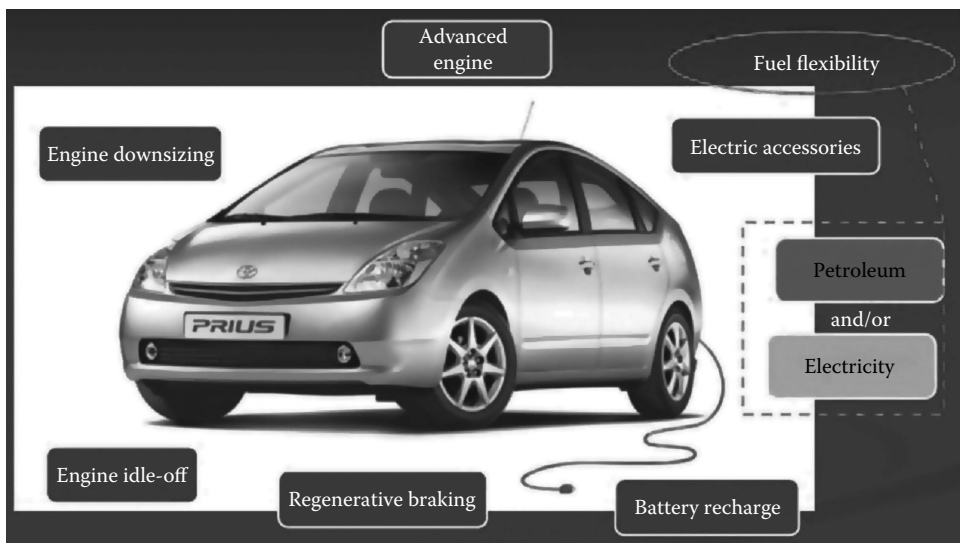

Some benefits of a parallel configuration versus a series configuration include the following:

- The vehicle has more power because both the engine and the motor provide power simultaneously.
- Parallel HEVs do not need a separate generator.
- Power is directly coupled to the road, thus operating the vehicle more efficiently.

Energy and cost savings from an HEV depend on many factors, such as the overall car design, cost of fuel, and the cost and efficiency of the batteries. Preliminary estimates indicate that over 5–8 years, the reduced size of the motor and savings in gasoline could pay for the additional cost of the batteries. Economically, an HEV would be beneficial when the price per gallon of gasoline or diesel exceeds \$3.00/gal, but the life cycle of the batteries will also have to be considered. If batteries have a life cycle of 150,000 miles, as claimed by Toyota, they will not need to be replaced during the life of an average vehicle. On the other hand, if the battery life is considerably less and battery replacement is necessary during the expected 10-year life of the car, the operation cost over the life of an HEV would be considerably higher.

## 19.6 Plug-In Hybrid Electric Vehicles

Given the current state of technology, probably the most promising near-term solution to the ground transportation crisis is the use of plug-in HEVs (PHEVs). PHEVs have the potential of making the leap to the mainstream consumer market because they require neither a new technology nor a new distribution infrastructure. Like hybrids, which are already widely available, PHEVs have a battery and an IC engine for power, but the difference is that a PHEV has a larger battery capacity and a plug-in charger with which the battery can be recharged whenever the car is parked near a 110 or 220 V outlet. A so-called series PHEV40 can travel the first 40 miles on grid-supplied electric power when fully charged. When that charge is depleted, the gas or diesel motor kicks in, and the vehicle operates like a conventional hybrid. Because most commuter trips are less than 40 miles, it is estimated that a PHEV could reduce gasoline usage by 50% or more for many U.S. drivers. Moreover, using electric energy is cheaper and cleaner than using gasoline in automobile-type ground transportation. Figure 19.6 shows a Prius with

**FIGURE 19.6**  
Plug-in hybrid electric vehicle. (Courtesy of NREL, Golden, CO)

plug-in potential added. These early plug-in additions are available as aftermarket conversions, but because they are not in mass production, their cost is high, and Toyota does not honor their warranty when plug-in features are added aftermarket. More recently, all major original equipment manufacturers (OEMs) have introduced plug-in vehicles with various battery storage capacities.

An important feature of PHEVs is that their batteries can be charged at night when utilities have excess power available. Utilities have taken notice of the potential energy charging and storage capabilities of PHEVs because off-peak charging would help utilities to use low-cost baseload generation more fully. Furthermore, more advanced vehicle-to-grid concepts would allow utilities to buy back energy from the batteries of vehicle owners during peak demand periods and thus make a fleet of PHEVs into a large distributed storage-generation network. The arrangement would also enable renewable energy storage by charging PHEVs using solar- or wind-generated excess capacity. As mentioned in the previous section on batteries, lithium-ion and lithium-polymer batteries have the potential to store large charges in a lightweight package, which would make the HEVs even more attractive than the current technology, which uses nickel metal hydride (NiMH) batteries.

The efficiency of a PHEV depends on the number of miles the vehicle travels on liquid fuel and electricity, respectively, as well as on the efficiency of the prime movers according to the following equation:

$$\eta_{\text{PHEV}} = \frac{\text{Energy to wheels}}{\text{Energy from primary source}} = f_1\eta_1\eta_2 + f_2\eta_3\eta_4 \quad (19.1)$$

where

$\eta_1$  is the efficiency from the primary energy source to electricity

$\eta_2$  is the efficiency of transmitting energy to the wheels

$f_1$  is the fraction of energy supplied by electricity

$f_2$  is the fraction of energy supplied by fuel  $= (1 - f_1)$

$\eta_3$  is the well-to-wheel efficiency

$\eta_4$  is the tank-to-wheel efficiency

PHEVs can be designed with different all-electric ranges. The distance, in miles, that a PHEV can travel on batteries alone is denoted by a number after PHEV. Thus, a PHEV20 can travel 20 miles on fully charged batteries without using the gasoline engine. According to a study by the Electric Power Research Institute (EPRI) [7], on average, one-third of the annual mileage of a PHEV20 is supplied by electricity and two-thirds by gasoline. The percentage depends, of course, on the vehicle design and the capacity of the batteries on the vehicle. A PHEV60 can travel 60 miles on batteries alone, and the percentage of electric miles will be greater as will the battery capacity and weight. The tank-to-wheel (more appropriately battery-to-wheel) efficiency for a battery all-electric vehicle according to EPRI [7] is 0.82.

Given the potentials for plug-in hybrid vehicles, the EPRI [7] conducted a large-scale analysis of the cost, the battery requirements, and the economic competitiveness of plug-in vehicles today and within the near-term future. Table 19.4 presents the net present value of life cycle costs over 10 years for a midsize IC engine vehicle such as the Ford Focus [IC], HEVs such as the Prius [HEV], and a future PHEV20 plug-in electric vehicle. The battery module cost in dollars per kWh is the cost at which the total life cycle costs of all three vehicles would be the same. According to projections for the production of NiMH battery

**TABLE 19.4**

Net Value of Life Cycle Costs over 117,000 Miles/10 Years for Conventional Gasoline (IC), HEV and PHEV20 Midsize Vehicles with Gasoline Costs at \$1.75/gal

Vehicle Type	IC	HEV	PHEV 20
Battery unit cost (\$/kWh)		385 <sup>a</sup>	316 <sup>a</sup>
Incremental vehicle cost (\$)		547	224
Battery pack cost (\$)	60	3,047	3,893
Fuel costs (\$)	5,401	3,725	2,787
Maintenance costs (\$)	5,445	4,733	4,044
Battery salvage costs (\$)		54	43
Total life cycle costs (\$)	10,906	10,904	10,905

*Source:* Extracted from EPRI, Advanced batteries for electric drive vehicles: A technology and cost-effectiveness assessment for battery electric vehicles, power assist hybrid electric vehicles and plug-in hybrid electric vehicles, EPRI Tech. Report 1009299, EPRI, Palo Alto, CA, 2004.

<sup>a</sup> Battery module price at which life cycle parity with CV occurs.

modules, a production volume of about 10,000 units per year would achieve the necessary cost reduction to make both an HEV and a PHEV20 economically competitive. The EPRI analysis was conducted in 2004 and is, therefore, extremely conservative because it assumed a gasoline cost of \$1.75/gal. A reevaluation of the analysis based upon a gasoline cost of \$2.50/gal showed that the permitted battery price at which the net present value of conventional IC vehicles and battery vehicles are equal for battery module costs \$1135 for an HEV and \$1648 for a PHEV20, respectively.

Table 19.5 shows the electric and plug-in hybrid vehicle battery requirements (module basis for the cost estimates in Table 19.4), and it is apparent that, even with the currently available NiMH batteries, the cost of owning and operating HEVs and PHEVs is competitive with that of an average IC engine vehicle.

**TABLE 19.5**

NiMH Battery Cost Assumptions for Table 19.4

Assumption	ARB 2000 Report for BEVs		EPRI Assumptions
	2003	Volume	
Module cost (\$/kWh) <sup>a</sup>	300	235	Varied <sup>b</sup>
Added cost for pack (\$/kWh)	40	20	680 + 13
Multiplier for manufacturer and dealer markup	1.15	1.15	Varies <sup>c</sup>
Battery life assumptions (years)	6	10	10

<sup>a</sup> Equivalent module costs for an HEV 0 battery is \$480 for 2003 and \$384 for volume. Equivalent module costs for a PHEV 20 battery is \$376 for 2003 and \$301 for volume. HEV 0 and PHEV 20 batteries have a higher power-to-energy ratio and are more costly. These figures are based on data shown in the biomass chapter of this handbook.

<sup>b</sup> Battery module costs were varied in this analysis to determine the effect of battery module cost on life cycle cost.

<sup>c</sup> Manufacturer and dealer mark-up for HEV 0 battery modules estimated at \$800, PHEV 20 battery modules \$850, pack hardware mark-up assumed to be 1.5. Method documented in 2001 EPRI HEV report.

A cautionary note in the expectation of future ground transportation systems is the reduction in the rate of petroleum consumption that can be expected as HEVs and PHEVs is introduced into the fleet [8]. In these estimates, a rate of new vehicle sales of 7% of the fleet per year, a retirement rate of 5% per year resulting in a net increase in total vehicles of 2% per year was assumed. This increase is in accordance with previous increase rates between 1966 and 2003. Based upon the existing mileage for IC engine, HEVs, and PHEVs, it was estimated that *even if all new cars were HEVs or PHEVs*, after 10 years, the annual gasoline savings as a percentage of the gasoline usage by an all-gasoline fleet in the same year would only be about 30% for the HEVs and 38% for the PHEVs. These relatively small reductions in the gasoline use are due to the fact that despite introduction of more efficient vehicles, it takes time to replace the existing fleet of cars, and the positive effects will not be realized for some years.

---

## 19.7 Advanced Ground Transportation with Biomass Fuel

The previous section analyzed the potential of using batteries combined with traditional engines to reduce the petroleum consumption in the transportation system. However, the scenario used for this analysis can also be extended to determine the combination of PHEVs with biofuels, particularly ethanol made from corn or cellulosic biomass. No similar analysis for using diesel from algae is available at this time.

It is important to note that in October 2010, the U.S. Environmental Protection Agency granted a partial waiver for the use of E15 (15% ethanol and 85% gasoline) for use in light-duty motor vehicles in cars newer than model year 2007. In January 2011, a second waiver was granted that allowed for use of E15 in light-duty vehicles manufactured in 2001–2006. The decision to grant the waivers was the result of testing performed by the Department of Energy (DOE) and information regarding the potential effect of 15 on vehicle emissions [9]. According to the Renewable Fuels Association, the E15 waivers pertain to over 62% of vehicles currently on the roads in the United States. If all passenger cars and pickup trucks were to switch to E15, this would represent 17.5 gal of ethanol use annually [10]. There remain some practical infrastructure barriers, as the current fuel pumps at gasoline retail stations do not support this higher blend. However, as consumers begin to demand more options in biofuels, it is likely that E15 will be made more available in the foreseeable future.

A scenario for a sustainable transportation system based on fuel from biomass has been presented in Ref. [11]. In this analysis, the following four vehicle types combined with various fuel options have been calculated. The preferred mixture in an economy based largely on ethanol (E85) would be 85% ethanol and 15% gasoline that could be used in Flex Fuel automobiles. Currently, the United States is using E10, a mixture of 90% gasoline and 10% ethanol, with ethanol produced from corn. The fuel types used in this analysis are gasoline only, E10 with ethanol made from either corn or cellulosic materials, and E85 with ethanol from either corn or cellulosic materials. The four vehicle combinations are a convention SI engine, an HEV similar to the Toyota Prius, a PHEV20, and a PHEV30. The analysis was based upon an average 2009 performance on the U.S. light vehicle fleet at approximately 20 miles per gallon (mpg), for an HEV at 45 mpg, and for a PHEV20 at 65 mpg, according to Ref. [7]. For ethanol-/gasoline-blended fuels, it was assumed that the

gasoline and ethanol are utilized with the same efficiency. That is, the mileage per unit of fuel energy is the same for gasoline and ethanol.

Based on the earlier assumption, the following parameters were calculated:

1. The miles per gallon of fuel, including the gasoline used to make ethanol (mpg).
2. The petroleum required to drive a particular distance for a case vehicle as a percentage of the petroleum required to drive the same distance by a gasoline-fueled SI vehicle.
3. The carbon dioxide emission rate for case vehicles as a percentage of that for SI gasoline only.

Using the earlier assumptions, one can calculate the mpg of fuel as

$$\begin{aligned}
 MF_{ij} &= \text{miles/gal gas} \times \left[ (\text{gal gas/gal fuel}) + (1 - \text{gal gas/gal fuel}) \right. \\
 &\quad \left. \times \frac{(\text{energy, LHV/gal ethanol})}{(\text{LHV/gal gasoline})} \right] \\
 &= MGO_i \times [FG_j + (1 - FG_j) \times (\text{LHV ratio})] \quad (19.2)
 \end{aligned}$$

where

$MF_{ij}$  is the mpg of fuel for vehicles type  $i$  and fuel type  $j$

$MGO_i$  is the mpg gasoline-only for vehicle  $i$  (see Table 19.4)

$FG_j$  is the volume fraction of gasoline in fuel type

$j(1 - FG_j)$  is the volume fraction of ethanol in fuel type  $j$

LHV ratio is the ratio of lower heating values; LHV ratio = (LHV/gal ethanol)/(LHV/gal gasoline) = 0.6625

The index  $i$  indicates the vehicle type as shown in Table 19.4, and the index  $j$  denotes the volume fraction of gasoline in an ethanol–gasoline blend as follows: for gasoline only,  $FG_1 = 1$ ; for E10 (i.e., 10 vol% ethanol and 90 vol% gasoline),  $FG_2 = 0.90$ ; and for E85 (85 vol% ethanol, 15 vol% gasoline),  $FG_3 = 0.15$ . Other ethanol concentrations could be used (Figure 19.7).

The mpg of gasoline in the fuel, including the petroleum-based fuels used in the making of the ethanol in the fuel (by counting the energy of all petroleum-based fuels as gasoline), is given by

$$\begin{aligned}
 MG_{ijk} &= \frac{MF_{ij}}{[FG_j + (1 - FG_j) \times (0.6625) \times (\text{MJ gasoline used in making 1 gal ethanol}) / \text{MJ/gal ethanol}]} \\
 &= \frac{MF_{ij}}{FG_j + (1 - FG_j) \times (0.6625) \times Rk} \quad (19.3)
 \end{aligned}$$

where  $Rk$  denotes the gallons of gasoline used to make 1 gal of ethanol. For corn-based ethanol,  $k = 1$ ,  $R1 = 0.06$ , while for cellulosic-based ethanol,  $k = 2$ ,  $R2 = 0.08$ , according to Ref. [12].

**FIGURE 19.7**

Petroleum requirement as a percentage of that for SI gasoline vehicle. (Calculated by Kreith, F. and West, R.E., *ASME J. Energy Res. Technol.*, 128(9), 236, September 2006.)

### 19.7.1 Petroleum Requirement

The petroleum required to produce an ethanol–gasoline blend, including the petroleum used to make the ethanol, is expressed as a percentage of the petroleum required for the same miles traveled by the same vehicle type using gasoline only (Figure 19.7). For a gasoline-only-fueled vehicle of any type, this percentage is 100%.

$$\text{Petroleum requirement (\%)} = 100 \times \frac{(MGO_i)}{(MG_{ijk})} \quad (19.4)$$

### 19.7.2 Carbon Dioxide Emissions

The CO<sub>2</sub> emissions, including those from making the ethanol and generating the electricity used from the grid by the vehicle, are expressed as a percentage of the emissions produced by the same type of vehicle fueled by gasoline only traveling the same number of miles (Figure 19.8).

$$\begin{aligned}
 &= 100 \times [FE_m \times (\text{kWh/miles}) \times (\text{g-carbon/kWh})] + (1/MGO_i) \times (1 - FE_m) \\
 &\quad \times [FG_j \times (\text{g-carbon/MJ gasoline}) \times (\text{MJ/gal gasoline})] + (1 - FG_j) \\
 &\quad \times \frac{[(\text{MJ/gal ethanol}) \times (\text{g-carbon/MJ ethanol})]}{[(\text{g-carbon/MJ gasoline used}) \times (\text{MJ/gal gasoline}) / (MGO_1)]} \quad (19.5)
 \end{aligned}$$

**FIGURE 19.8**

Carbon dioxide emissions as a percentage of emissions for SI gasoline vehicle.

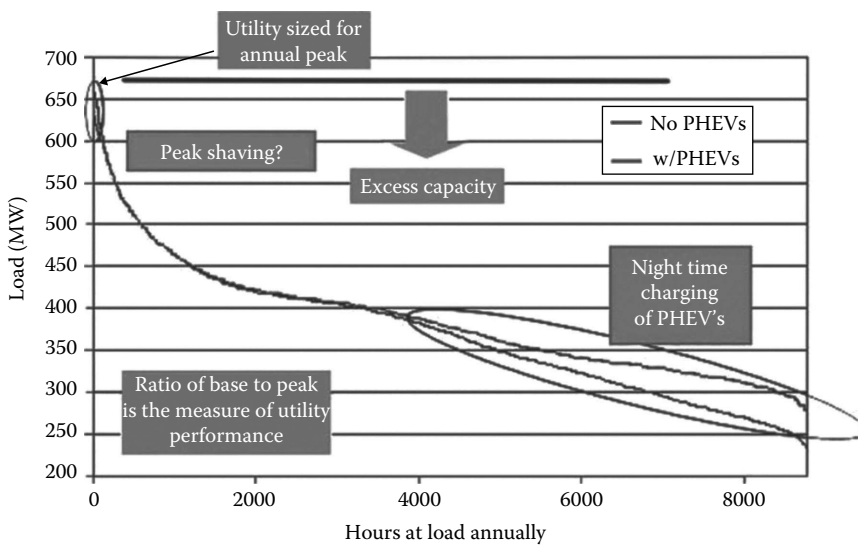

where  $FE_m$  is the fraction of the miles driven by electricity from the grid for a plug-in hybrid vehicle. For  $m = 0$ , any non-PHEV,  $FE_0 = 0$ ; for a PHEV20,  $m = 1$ , and  $FE_1 = 0.327$  [7]; and for a PHEV30,  $m = 2$ , and  $FE_2 = 0.50$  estimated by analogy with PHEV20. According to Ref. [7], the kWh/mile from the grid = 0.2853, the g-carbon emitted/kWh = 157 (146 average for all electricity generation [13] divided by 0.93, the average transmission efficiency), the g-carbon emitted/MJ gasoline = 94 [7], the MJ/gal gasoline = 121, the MJ/gal ethanol = 80.2, and  $CE_k$  the g-carbon emitted/MJ ethanol. For  $k = 1$  (corn),  $CE_1 = 87$ , and for  $k = 2$ , cellulotics,  $CE_2 = 11$ .

So

CO<sub>2</sub> production as % of that for a gasoline-only vehicle

$$100 \times \{FE_m \times (0.2853) \times (157) + (1/MF_{ij}) \times (1 - FE_m) \times [FG_j \times (94) \times 121 + (1 - FG_j) \times CE_k \times (80.2)]\} / \frac{(94) \times (121)}{21} \quad (19.6)$$

The final question to be asked in the utilization of PHEVs is whether or not the existing electricity system of the United States could handle the charging of the batteries in a PHEV-based ground transportation system. This question has recently been answered by an analysis in Ref. [14]. This analysis clearly showed that with a normal commuting scenario, which was based upon statistical information from a major city, if charging occurred during off-peak hours, no additional generational capacity or transmission requirements would be needed to charge a significant portion of the automotive fleet with PHEVs in the system, as illustrated in Figure 19.9. The analysis also showed that the off-peak charging scenario would also add to the profit of the electric utilities.

**FIGURE 19.9**  
PHEV impact on utilities' load profile. (Courtesy of NREL, Golden, CO.)

An unexpected result of the analysis was that, although the amount of  $\text{CO}_2$  emitted by the electric utility will increase from PHEV charging, if this is compared to the corresponding reduction in tailpipe emission to assess the overall environmental impact, the generation/PHEV transportation system would substantially decrease  $\text{CO}_2$  emission even if the current mix of coal, nuclear, and renewable generation facilities were unchanged. This result can be explained, however, because the average efficiency of the electric power system is on the order of 43%, whereas the average efficiency of IC engines is only on the order of 22%. Consequently, the net emission of  $\text{CO}_2$  would be reduced by a hybrid system consisting of PHEVs and electric charging during off-peak hours. Moreover, the utility generation profile would be evened out, and this would also contribute to reducing  $\text{CO}_2$  emissions, as well as the cost of producing electricity.

In summary, in a PHEV transportation system, if charging of batteries is limited to off-peak hours, this hybrid arrangement can

- Reduce the amount of petroleum consumed by the transportation sector
- Reduce the cost of driving
- Reduce  $\text{CO}_2$  emission
- Improve the load profile of electric utilities

Although no quantitative analyses are as yet available, it is believed that the availability of electric storage in the batteries of a fleet of PHEVs could also be used to reduce the peak demand on electric utilities by utilizing the vehicle's batteries as a distributed storage system. Details of such an arrangement would have to be worked out by differential charges, incentives, and taxation arranged between utilities and owners of PHEVs.

---

## 19.8 Future All-Electric System

The next step in the development of a viable transportation system could be the all-electric car. All-electric vehicles were mandated in California as part of an effort to reduce air pollution about 25 years ago by the California Air Resources Board. Initially, automakers embraced the idea, but it is likely that the acceptance by Detroit was the result of the mandate that required that at least 2% of all the cars sold in California by any one automaker had to be zero-emission vehicles. The only zero-emission vehicle available at the time was the electric car, and the mandate therefore required selling a certain number of all-electric vehicles. Battery technology at the time was nowhere near ready for commercialization, and in addition, there was no infrastructure available for charging vehicle batteries on the road. As a result, the mandate failed to achieve its objective, and as soon as the mandate was lifted, automakers ceased to make electric vehicles. In the meantime, however, battery technology has evolved to where one could potentially envision an all-electric ground transportation system. Some people propose that there should be enough charging stations built to make it possible to charge batteries anywhere in the country, whereas others propose that there should be, instead of gas stations, battery exchange stations that would simply replace batteries as they reach the end of their charge. At present, batteries take too long to be charged during a trip, and it may be necessary to combine the two ideas to evolve an all-battery transportation system sometime in the near future.

City pollution could be significantly reduced with the use of electric cars due to their zero tailpipe emissions. It is postulated that carbon dioxide emissions could be reduced by up to 40%, depending upon the country's current energy mix. The information from Electric Drive Transportation Association (EDTA) as of January 2015 ([Figure 19.10](#)) shows how the market for PHEVs and EVs are growing over time [15].

At this time, it is not possible to assess which electrified powertrain will achieve the bigger market domination over time as the price of fuel, batteries, and other infrastructure all play into that equation. The earlier summary is a snapshot at the time of preparing this text and is a continuous state of flux. The reader is encouraged to follow developments in the current literature included in the bibliography. The EDTA is an excellent source for timely developments regarding this technology.

---

## 19.9 Hydrogen for Transportation

Hydrogen was touted as a potential transportation fuel after former President George W. Bush said in his 2001 inaugural address that "a child born today will be driving a pollution-free vehicle... powered by hydrogen." This appeared to be welcome news. However, to analyze whether or not hydrogen is a sustainable technology for transportation, one must take into account all the steps necessary to make the hydrogen from a primary fuel source, get it into the fuel tank, and then power the wheels via a prime mover and a drive train. In other words, one must perform a well-to-wheel analysis, as shown in [Figure 19.3](#). There is a loss in each step, and to obtain the overall efficiency, one must multiple the efficiencies of all the steps. Using natural gas as the primary energy source, a well-to-wheel analysis [16] showed that a hybrid SI car would have a wheel-to-energy

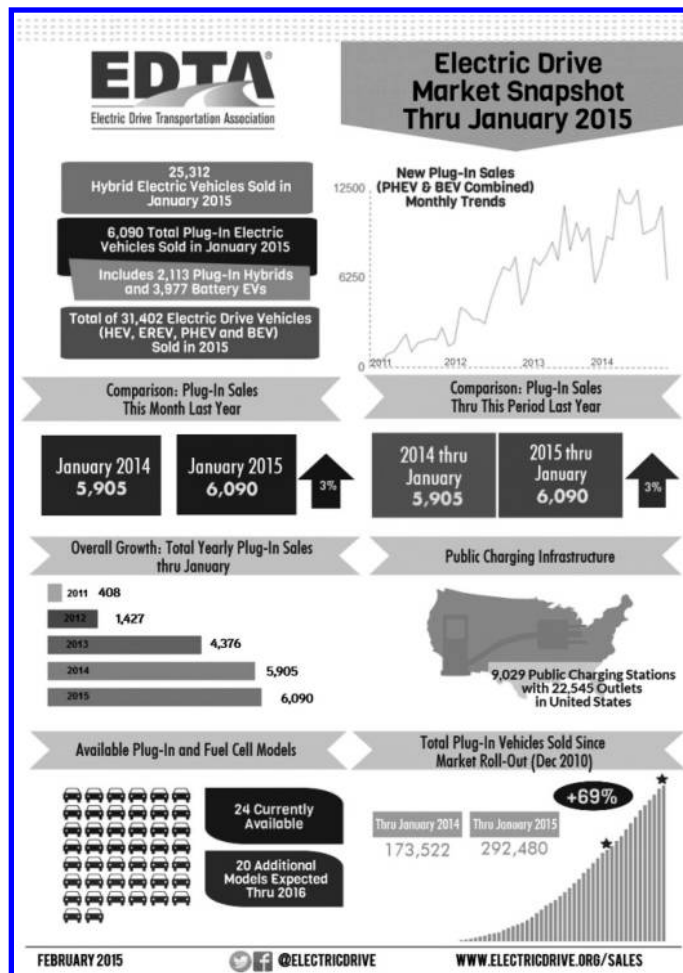

FIGURE 19.10

Growth of market for PHEVs and EVs over time.

efficiency of 32%; a hydrogen-powered fuel cell car with hydrogen made by steam reforming of natural gas would have a wheel-to-energy efficiency of 22%; a hydrogen fuel cell car with hydrogen made by electrolysis with electricity from a natural gas–combined cycle power plant with 55% efficiency would have a well-to-wheel efficiency of 12%, as shown in Table 19.6; and if the hydrogen were produced from photovoltaic cells, the well-to-wheel efficiency of the automobiles would be less than 5%. The estimates in Table 19.6 assume a fuel cell stack efficiency at a peak load of 44.5%, a part load efficiency factor of 1.1, and a transmission efficiency of 90%. For details, see [17].

In addition to the low overall efficiency of a hydrogen transportation system, as well as the high cost compared to other options, it should also be noted that before a hydrogen transportation system could be put into practice, an infrastructure for the distribution and storage of the hydrogen would have to be constructed. An extensive study of the comparative costs of fuel distribution systems conducted at Argonne National Laboratory in 2001 estimated that for a market penetration by the year 2030, 40% of hydrogen vehicles with a

**TABLE 19.6**

Well-to-Wheel Efficiency of Fuel Cell Vehicle with Hydrogen  
Produced by Electrolysis

NG feedstock production efficiency	95%
Conversion efficiency (NG to electricity)	55%
Electrolysis efficiency (electricity to H <sub>2</sub> )	63%
Storage and transmission	97%
Compression efficiency	87%
Overall efficiency of fuel production	28%
Total fuel cell well-to-wheel efficiency: $(0.28 \times 445 \times 1.1 \times 0.9)$	12%

mileage of 2.5 times that of average CVs (i.e., about 55 mpg) would minimally cost \$320 billion, but could be as high as \$600 billion. Based upon these estimates, a national transportation plan based on hydrogen with any currently available technology would be wasteful and inefficient and should not be considered as a pathway to a sustainable energy future [16]. The former U.S. DOE, secretary of Energy and Nobel Laureate, Dr. Steven Chu, concurred with this conclusion and, according to the *New York Times*, cutoff funds for development related to hydrogen fuel cell vehicles in 2009 [19]. Before he left DOE, Chu reversed his support for FCs after several meetings with OEMs, who showed their significant progress and commitment to FCVs. Although still significant infrastructure hurdles exist for hydrogen, the ability to provide a product with a range similar to conventional ICE is very compelling to OEMs, especially when they consider the cost improvement potential of the fuel cell and associated components including new and innovative packaging. Commitments by OEMs to develop hydrogen fuel-cell cars surged between 2012 and 2014. BMW, Toyota, Hyundai, Daimler, Nissan, and Honda all announced plans to commercialize the fuel cell drivetrain, in some cases through collaborative agreements in order to spread early technology risk and accomplish economies of scale.

## 19.10 Natural Gas as a Transitional Bridging Fuel

Despite its potential as a transportation fuel, except for large buses and trucks, natural gas has heretofore received relatively little attention from the U.S. automobile industry. The only major effort to use natural gas for transportation was the Freedom CAR initiative proposed by President George W. Bush in 2001. This program envisioned replacing gasoline with hydrogen, which at that time was largely produced from natural gas. More than a billion dollars was provided for R&D as well as generous tax incentives. But as shown in Table 19.6, the efficiency of a natural gas/hydrogen vehicle based on a well-to-wheel analysis is less than that of hybrid SI/natural gas vehicle (NGV), and the construction of a hydrogen distribution system would be extremely expensive. Thus, the hydrogen via natural gas effort for transportation was a failure and was terminated in 2010. However, since 2009, new supplies of natural gas have become available in the United States, primarily as a result of fracking technology for natural gas extraction from oil shale deposits. This development has heightened awareness of the potential of natural gas as a bridging fuel for transportation for an eventual zero carbon future. Within this context, MIT has conducted an interdisciplinary investigation

that addresses the question, “What is the role of natural gas in a carbon-constrained economy?” [20].

Natural gas is likely to find increased use in the transportation sector with compressed natural gas (CNG) playing an important role, particularly for high-mileage fleets. But the advantage of liquid fuel in transportation indicates that the chemical conversion of the gas into some form of liquid fuel may be a more desirable pathway for the future. It should be noted that a basic infrastructure for distributing natural gas exists, and if CNG were to be used to fuel automobiles, the only major addition at gas stations that have a natural gas outlet would be a compressor to increase the gas pressure above that in the natural gas automobile tank. However, the vast majority of natural gas supplies are delivered to markets by pipeline, and delivery costs typically represent a relatively large fraction of the total cost in the supply chain.

Natural gas vehicles have been in use for trucks and other large vehicles in many parts of the world for some time as shown in Table 19.7. With a starting price of \$26,305, a 2013 natural gas Civic costs \$8,100 more than the base gasoline model. Big trucks that burn 20,000–40,000 gal a year can easily make up that difference, but it takes far longer for regular consumers, who may use only 500 gal/year. Home fueling stations add \$4000–\$6000 to the cost.

Range is also a concern. The United States has 1100 natural gas fueling stations, but only about half are open to the public. A natural gas Civic can go around 200 miles on a tank. That’s better than an electric car, which might go 100 miles on a charge. But it’s less than the 300–350 miles a driver can go on a tank of gasoline in a regular Civic.

All those things could change, but GE is trying to develop a \$500 home fueling station, and the federal government could encourage sales with tax credits, as it has done with its \$7500 electric vehicle credit. Some states are already giving tax credits to CNG vehicle buyers, including West Virginia—which gives up to \$7,500 for smaller vehicles and \$20,000 for trucks—and Colorado, which gives up to \$6,000.

As availability of natural gas wanes, a number of renewable sources for natural gas or biomethane are available. Biomethane can be produced from any organic matter. Nature produces it naturally in landfills, but it can also be produced, as discussed in Chapter 13, in anaerobic digesters or through pyrolysis from sewage, industrial, animal, or crop wastes, or from specific energy crops. The biomethane from landfills used in NGVs reduces

**TABLE 19.7**

Top 11 NGV Countries

Country	No. of NGVs
1. Pakistan	2,850,500
2. Iran	2,070,930
3. Argentina	1,927,007
4. Brazil	1,667,038
5. India	1,100,000
6. Italy	754,659
7. China	550,000
8. Colombia	340,000
9. Thailand	238,583
10. Ukraine	200,019
11. United States	112,000

greenhouse gases by 90% according to the California Air Resources Board. After biomethane is produced, it can be injected into natural gas pipeline systems and sold to NGV station operators. A 5% or 10% blend of biomethane with natural gas would add to NGV's greenhouse gas potential. While many other alternative fuels are still in the R&D stage, NGVs are not in that category and are ready to go now.

### **20.1 Introduction**

Risk is associated with all projects and business ventures taken by individuals and organizations regardless of their sizes, their natures, and their time and place of execution and utilization. Risk is present in various forms and levels even in small domestic projects such as adding a deck to a residential house and in large multibillion-dollar projects such as developing and producing a space shuttle. These risks could result in significant budget

overruns, delivery delays, failures, financial losses, environmental damages, and even injuries and loss of life. Risks are taken even though they could lead to devastating consequences because of potential benefits, rewards, survival, and future return on investment. This chapter defines and discusses risk and its dimensions, risk analysis, risk management and control, and risk communication.

---

## 20.2 Risk Terminology

Definitions that are needed for presenting risk-based technology methods and analytical tools are presented in this section.

### 20.2.1 Hazards

A hazard is an act or phenomenon posing potential harm to some person(s) or thing(s), which is a source of harm, and its potential consequences. For example, uncontrolled fire, water, and strong wind are hazards. For the hazard to cause harm, it needs to interact with person(s) or thing(s) in a harmful manner. The magnitude of the hazard is the amount of harm that might result, including the seriousness and the exposure levels of people and the environment. Hazards need to be identified and considered in projects' life cycle analyses because they could pose threats and could lead to project failures.

The interaction between a person (or a system) and a hazard can be voluntary or involuntary. For example, exposing a marine vessel to a sea environment might lead to its interaction with extreme waves in an uncontrollable manner, that is, an involuntary manner. Although the decision of a navigator of the vessel to go through a storm system that is developing can be viewed as a voluntary act in nature, and might be needed to meet schedule constraints or other constraints, the potential rewards of delivery of shipment or avoidance of delay charges offer an incentive that warrants such an interaction. Other examples can be constructed where individuals interact with hazards for potential financial rewards, fame, and self-fulfillment and satisfaction ranging from investment undertaking to climbing cliffs.

### 20.2.2 Reliability

Reliability can be defined for a system or a component as its ability to fulfill its design functions under designated operating or environmental conditions for a specified time period. This ability is commonly measured using probabilities. Reliability is, therefore, the occurrence probability of the complementary event to failure as provided in the following expression:

$$\text{Reliability} = 1 - \text{Failure probability} \quad (20.1)$$

### 20.2.3 Event Consequences

For an event of failure, *consequences* can be defined as the degree of damage or loss from some failure. Each failure of a system has some consequence(s). A failure could cause economic damage, environmental damage, injury, loss of human life, or other possible events.

Consequences need to be quantified in terms of failure consequence severities using relative or absolute measures for various consequence types to facilitate risk analysis.

For an event of success, consequences can be defined as the degree of reward or return or benefits from success. Such an event could cause economic outcomes, environmental effects, or other possible events. Consequences need to be quantified using relative or absolute measures for various consequence types to facilitate risk analysis.

#### 20.2.4 Risk

The concept of risk can be linked to uncertainties associated with events. Within the context of projects, risk is commonly associated with an uncertain event or condition that, if it occurs, has a positive or a negative effect on the objectives of a project. Risk originates from the Latin term *risicum*, which means the challenge presented by a barrier reef to a sailor. The *Oxford Dictionary* defines risk as the chance of hazard, bad consequence, loss, etc., or risk can be defined as the chance of a negative outcome.

*Risk* is commonly associated with a system and commonly defined as the potential loss resulting from an uncertain exposure to a hazard or resulting from an uncertain event that exploits the system's vulnerability. Risk should be based on identified risk events or event scenarios.

In 2009, the International Organization of Standardizations (ISO) provided a broadly based definition of risk in its standard (ISO 31000:2009) as the "effect of uncertainty on objectives" in order to cover the following considerations as noted in the standard:

- An effect is a deviation from the expected that can be positive and/or negative.
- Objectives can have different aspects, such as financial, health and safety, and environmental goals, and can apply at different levels, such as strategic, organization-wide, project, product, and process.
- Risk is often characterized by reference to potential events and consequences, or a combination of these as provided in the commonly used definition.
- Risk is often expressed in terms of a combination of the consequences of an event, including changes in circumstances, and the associated likelihood of occurrence as provided in the commonly used definition.

Providing two definitions of risk should not cause any confusion since most of the coverage in this book focuses on the adverse domain of effects, that is, using the former definition; however, readers must become familiar and comfortable with the latter broadly based definition.

*Risk context* is the external and internal parameters or considerations to be taken into account when managing risk and setting the scope and risk criteria for the risk management policy as follows (ISO 31000:2009):

- *External*—the cultural, social, political, legal, regulatory, financial, technological, economic, natural, and competitive environment, whether international, national, regional, or local; key drivers and trends having impact on the objectives of the organization; and relationships with, and perceptions and values of, external stakeholders.
- *Internal*—governance, organizational structure, roles, and accountabilities; policies, objectives, and the strategies that are in place to achieve them; the capabilities,

understood in terms of resources and knowledge (e.g., capital, time, people, processes, systems, and technologies); information systems, information flows, and decision-making processes (both formal and informal); relationships with, and perceptions and values of, internal stakeholders; the organization's culture; standards, guidelines, and models adopted by the organization; and the form and extent of its contractual relationships.

In the context of the former risk definition, risk can be viewed to be a multidimensional quantity that includes event occurrence probability, event occurrence consequences, consequence significance, and the things at risk including populations, properties, and environmental concerns; however, it is commonly measured as a pair of the probability of occurrence of an event and the outcomes or consequences associated with the event's occurrence. Another common representation of risk is in the form of an exceedance probability function of consequences. Sometimes, risk is shown schematically as the intersection of a hazard (or a threat) defined by scenarios with a system of interest that exploit its vulnerabilities and could impact things at risk including populations, properties, and environmental concerns. Such a representation shows how each aspect of risk can be controlled or managed by countermeasures, system hardening, and mitigations as discussed in detail in later sections of this chapter.

Risk results from an event or sequence of events referred to as a *scenario*. The event or scenario can be viewed as a cause and, if it occurs, results in consequences with various severities. Sometimes, these events or scenarios are called risk factors. For example, an event or cause may be a shortage of personnel necessary to perform a task required to produce a project. The event, in this case, of a personnel shortage for the task will have consequences in regard to the project cost, schedule, and/or quality. The events can reside in the project environment, which may contribute to project success or failure through project management practices, or in external partners or subcontractors.

Risk has defining characteristics that should be recognized in a risk assessment process. Risk is a characteristic of an uncertain future and is a characteristic of neither the present nor the past. Once uncertainties are resolved and/or the future is attained, the risk becomes nonexistent; therefore, we cannot describe risks for historical events or risks for events that are currently being realized. Moreover, risks cannot be directly associated with a success. Although risk management through risk mitigation of selected events could result in project success, leading to rewards and benefits, these rewards and benefits cannot be considered as outcomes of only the nonoccurrence of events associated with the risks. The occurrence of particular events leads to adverse consequences that are clearly associated with their occurrence; however, their nonoccurrences are partial contributors to the project success that leads to rewards and benefits. The credit in the form of rewards and benefits cannot be given solely to the nonoccurrence of these events. Some risk assessment literature defines risk to include both potential losses and rewards, which should be treated separately as (1) risks leading to adverse consequences and (2) risks, if appropriately and successfully managed, contributing to benefits or rewards. Such a treatment utilizes the latter risk definition where a threat (or opportunity or a factor) could affect adversely (or favorably) the achievement of the objectives of a project and associated outcomes.

Developing an economic, analytical framework for a decision situation involving risks requires examining the economic and financial environments of a project. These environments can have significant impacts on the occurrence probabilities of events associated with risks. This added complexity might be necessary for particular projects in order to

obtain justifiable and realistic results. The role of such environments in risk analysis is discussed in subsequent sections and chapters.

Risk, as the potential of losses for a system resulting from an uncertain exposure to a hazard or resulting from an uncertain event, can be viewed to be a multidimensional quantity that includes event occurrence probability, event occurrence consequences, consequence significance, and commonly, the population at risk; however, common practices minimally define it in terms of event probability and event outcomes or consequences. This pairing can be represented by the following equation:

$$\text{Risk} \equiv [(p_1, c_1), (p_2, c_2), \dots, (p_i, c_i), \dots, (p_n, c_n)] \quad (20.2)$$

where

- $p_i$  is the occurrence probability of an outcome or event  $i$
- $c_i$  is the occurrence consequences or outcomes of the event

A generalized definition of risk is sometime expressed as

$$\text{Risk} \equiv [(l_1, o_1, u_1, cs_1, po_1), (l_2, o_2, u_2, cs_2, po_2), \dots, (l_n, o_n, u_n, cs_n, po_n)] \quad (20.3)$$

where

- $l$  is the likelihood
- $o$  is the outcome
- $u$  is the utility (or significance)
- $cs$  is a causal scenario
- $po$  is the population affected by the outcome
- $n$  is the number of outcomes

The definition provided by Equation 20.3 covers key attributes measured in risk assessment that are described in this chapter and offers a practical description of risk, starting with the causing event to the affected population and consequences. The population-size effect should be considered in risk studies as society responds differently for risks associated with a large population in comparison to a small population. For example, a fatality rate of 1 in 100,000 per event for an affected population of 10 results in an expected fatality of  $10^{-4}$  per event, whereas the same fatality rate per event for an affected population of 10,000,000 results in an expected fatality of 100 per event. Although the impact of the two scenarios might be the same on society (same expected risk value), the total number of fatalities per event or accident is a factor in risk acceptance. Plane travel may be safer than, for example, recreational boating, but 200–300 injuries per accident in the case of air travel are less acceptable to society. Therefore, the size of the population at risk and the number of fatalities per event should be considered as factors in setting acceptable risk.

The dimension of likelihood can be illusive in nature due to two of its aspects: (1) the means of quantification and (2) the effect of time. The most common means of quantification are as follows:

- *Frequency* defined as the count of an outcome of interest from a number of repeated observations of identical experiments or systems. If expressed as a fraction or percent, it is called *relative frequency*.

- *Rate* commonly defined as the count of an outcome of interest for a system occurring within a time period. The rate itself can be time dependent due to changes in the system's state, for example, due to aging. The term "frequency" is sometimes incorrectly used to mean the rate.
- *Probability* defined as a measure of chance or likelihood.

The effects of time on these three quantification means are discussed in the following, respectively:

- As for the frequency, by increasing the observation time, an estimate of the frequency tends toward a value, and for cases involving unbiased consistent estimators, the estimate tends to the true value.
- As for the rate, by increasing the observation time, an estimate of the rate tends toward a value, and for cases involving unbiased consistent estimators, the estimate tends to the true value.
- As for the probability, we are interested in the probability of an event in a time period. By increasing the length of this time period, this probability tends to 1. As long as the event is possible, it has a sure eventual occurrence; otherwise, it goes against the premise of being possible.

Risk matrices, also called heat maps, are basically tools for representing and displaying risks by defining ranges for consequence and likelihood as a 2D presentation of likelihood and consequences. According to this method, risk is characterized by categorizing probabilities and consequences on the two axes of a matrix. Risk matrices have been used extensively for the screening of various risks. They may be used alone or as a first step in a quantitative analysis. Regardless of the approach used, risk analysis should be a dynamic process—that is, a living process where risk assessments are reexamined and adjusted. Actions or inactions in one area might affect risk in another; therefore, continuous updating is necessary.

To quantify risk, we must accordingly assess its defining components and measure the chance, its negativity, and potential rewards or benefits. Estimation of risk is commonly approximated by a point estimate as the expected value resulting from the multiplication of the conditional probability of the event occurring by the consequence of the event given that it has occurred as follows with a loss in information in terms of associated dispersion or variability:

$$\text{Risk} = \text{Likelihood} \times \text{Impact} \quad (20.4)$$

In Equation 20.4, the measurement scales, as the bases for quantifying likelihood, impact, and risk, are likelihood measured on an event rate scale in units of count of events per time period of interest, for example, events per year; impact measured on a loss scale, such as monetary units or fatalities or any other units suitable for analysis or multiple units per event, for example, dollars per event; and risk is (event per unit time)  $\times$  (loss units per event) producing loss units per unit time. The likelihood in Equation 20.4 can also be expressed as a probability. Equation 20.4 presents risk as an expected value of loss per unit time or an average loss.

The product in Equation 20.4 is sometimes interpreted as the Cartesian product for scoping the space defined by the two dimensions of likelihood and impact for all underlying

events and scenarios, which is a preferred interpretation. This interpretation preserves the complete nature of risk. Ideally, the entire probability distribution of consequences should be estimated.

A plot of occurrence probabilities and consequences is a *risk profile* or a *Farmers curve*. An example Farmers curve is given in Figure 20.1a based on a nuclear case study provided herein for illustration purposes (Kumamoto and Henley 1996). It should be noted that the abscissa provides the number of fatalities, and the ordinate provides the annual

**FIGURE 20.1**  
(a) Example risk profile. (b) Example project risk profile.

**FIGURE 20.2**  
Uncertain risk profile.

frequency of exceedance for the corresponding number of fatalities. These curves are sometimes constructed using probabilities instead of rates. The curves represent average or best estimate values. Figure 20.1b shows another example representing the gross margin of an investment project covering both potential loss and profits. This figure was generated using Monte Carlo simulation and presents the results in the form of a relative frequency histogram (i.e., the bar chart) and smoothed cumulative probability distribution (i.e., the solid curve). The figure shows that the loss probability is 0.047, and the probability of profits exceeding \$200 million is 0.353.

Sometimes, bands or ranges are provided to represent uncertainty in these curves, and they represent confidence intervals for the average curve or for the risk curve. Figure 20.2 shows examples of curves with bands (Kumamoto and Henley 1996). This uncertainty is sometimes called *epistemic uncertainty* or *meta-uncertainty*.

In cases involving deliberate threats, the occurrence probability ( $p$ ) of an outcome ( $o$ ) can be decomposed into an occurrence probability of an event or a threat ( $t$ ), probability of success ( $s$ ) given a threat ( $s|t$ ), and the outcome probability given the occurrence of a successful event ( $o|t,s$ ). The occurrence probability of an outcome can be expressed as follows using conditional probability concepts discussed in Appendix A on fundamentals of probability theory and statistics:

$$p(o) = p(t)p(s|t)p(o|t,s) \quad (20.5)$$

In this context, threat is defined as a hazard or the capability and intention of an adversary to undertake actions that are detrimental to a system or an organization's interest. In this case, threat is a function of only the adversary or competitor and usually cannot be controlled by the owner of the system. The adversary's intention to exploit his capability may, however, be encouraged by the vulnerability of the system or discouraged by

an owner's countermeasures. The probability  $p(o|t)$  can be decomposed further into two components of success probability of the adversary and a conditional probability on this success of consequences. This probability  $p(o|t)$  can then be computed as the success probability of the adversary times the conditional probability of consequences given this success.

*Risk register*—is a record of information about identified risks, sometimes called *risk log*.

*Risk profile*—is a description of any set of risks that may relate to the whole organization, part of the organization, or a group of stakeholders.

*Risk aggregation*—is a combination of a number of risks into one risk to develop a more complete understanding of an overall risk, whereas *risk segregation* is the decomposition of an overall risk profile into a number of underlying risk profiles.

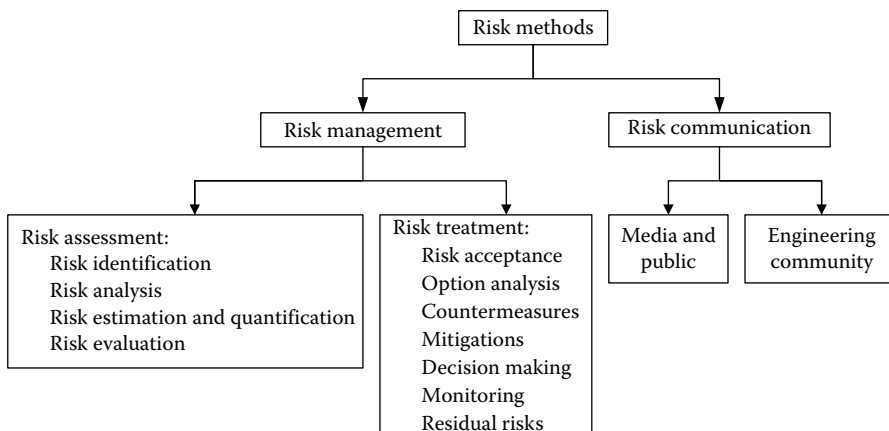

### 20.2.5 Performance

The performance of a system or component can be defined as its ability to meet functional requirements. The performance of an item can be described by various elements, including items such as speed, power, reliability, capability, efficiency, and maintainability. The design and operation of the product or system influence performance.

### 20.2.6 Risk-Based Technology

Risk-based technologies (RBT) are methods or tools and processes used to assess and manage the risks of a component or system. RBT methods can be classified into risk management that includes risk assessment/risk analysis and risk control using failure prevention and consequence mitigation, and risk communication as shown in Figure 20.3.

Risk assessment consists of hazard identification, event probability assessment, and consequence assessment. Risk control requires the definition of acceptable risk and comparative evaluation of options and/or alternatives through monitoring and decision analysis. Risk control also includes failure prevention and consequence mitigation. Risk communication involves perceptions of risk, which depends on the audience targeted, hence, classified into risk communication to the media, the public, and to the engineering community.

**FIGURE 20.3**  
Risk-based technology methods.

### 20.2.7 Safety

*Safety* can be defined as the judgment of risk acceptability for the system. Safety is a relative term since the decision of risk acceptance may vary depending on the individual making the judgment. Different people are willing to accept different risks as demonstrated by different factors such as location, method or system type, occupation, and lifestyle. The selection of these different activities demonstrates an individual's safety preference despite a wide range of risk values. Table 20.1 identifies varying annual risks for different activities based on typical exposure times for these activities. Also Figure 20.4 from the Imperial Chemical Industries, Ltd. shows the variation of risk exposure during a typical day that starts by waking up in the morning from sleep and getting ready to go to work, then commuting and working during morning hours, followed by a lunch break, then additional work hours followed by commuting back to having dinner, and round-trip on a motorcycle to a local pub. The ordinate in this figure is the fatal accident frequency rate (FAFR) with a FAFR of 1.0 corresponding to one fatality in 11,415 years, or 876 fatalities per one million years. The figure is based on an average number of deaths in  $10^8$  h of exposure to a particular activity.

Risk perceptions of safety may not reflect the actual level of risk in some activity. Table 20.2 shows the differences in risk perception by three groups of the league of women voters, college students, and experts of 29 risk items. Only the top items are listed in the table. Risk associated with nuclear power was ranked as the highest type by women voters and college students, whereas it was placed as the 20th by experts. Experts place motor vehicles as the first risk. Public perception of risk and safety varies by age, gender, education, attitudes, and culture among other factors. Individuals sometimes do not recognize uncertainties associated with risk event or activity causing an unwarranted confidence in an individual's perception of risk or safety. Rare causes of death are often overestimated and common causes of death are often underestimated. Perceived risk is often biased by the familiarity of the hazard. The significance or the

**TABLE 20.1**

Relative Risk of Different Activities

Risk of Death	Occupation	Lifestyle	Accidents/Recreation	Environmental Risk
1 in 100	Stunt person			
1 in 1,000	Race car driver, firefighter, miner	Smoking (one pack/day)	Skydiving, rock climbing, snowmobile, canoeing, automobile	
1 in 10,000	Farmer, police officer	Heavy drinking	All home accidents, frequent air travel	
1 in 100,000	Truck driver, engineer, banker, insurance agent	Using contraceptive pills, light drinking	Skiing, home fire	Substance in drinking water, living downstream of a dam
1 in 1,000,000		Diagnostic x-rays, smallpox vaccination (per occasion)	Fishing, poisoning, occasional air travel (one flight per year)	Natural background radiation, living at the boundary of a nuclear power plant
1 in 10,000,000		Eating charcoal-broiled steak (once a week)		Hurricane, tornado, lightning, animal bite or insect sting

**FIGURE 20.4**  
Daily death risk exposure for a working healthy adult.

impact of safety perceptions stems from those decisions that are often made on subjective judgments. If the judgments hold misconceptions about reality, this bias affects the decision. For example, the choice of a transportation mode—train, automobile, motorcycle, bus, bicycle, etc.—results in a decision based on many criteria including items such as cost, speed, convenience, and safety. The weight and evaluation of the decision criteria in selecting a mode of transportation rely on the individual's perception of safety that may deviate sometimes significantly from the actual values of risks. Understanding these differences in risk and safety perceptions is vital to performing risk management decisions and risk communications as provided in subsequent sections on risk management and control.

## 20.3 Risk Assessment

### 20.3.1 Risk Assessment Methodologies

Risk studies require the use of analytical methods at the system level that considers subsystems and components in assessing their failure probabilities and consequences. Systematic, quantitative, qualitative, or semiquantitative approaches for assessing the failure probabilities and consequences of engineering systems are used for this purpose.

**TABLE 20.2**

## Risk Perception

Activity or Technology	League of Women Voters	College Students	Experts

A systematic approach allows an analyst to evaluate expediently and easily complex systems for safety and risk under different operational and extreme conditions. The ability to quantitatively evaluate these systems helps cut the cost of unnecessary and often expensive redesign, repair, strengthening, or replacement of components, subsystems, and systems. The results of risk analysis can also be utilized in decision analysis methods that are based on cost–benefit trade-offs.

Risk assessment is a technical and scientific process by which the risks of a given situation for a system are modeled and quantified. Risk assessment can require and/or provide both qualitative and quantitative data to decision makers for use in risk management.

Risk assessment or risk analysis provides the process for identifying hazards, event-probability assessment, and consequence assessment. The risk assessment process answers three basic questions: (1) What can go wrong? (2) What is the likelihood that it will go wrong? (3) What are the consequences if it does go wrong? Answering these questions requires the utilization of various risk methods as discussed in this chapter.

A risk assessment process should utilize experiences gathered from project personnel including managers, other similar projects and data sources, previous risk assessment models, experiences from other industries and experts, in conjunction with analysis and damage evaluation/prediction tools. A risk assessment process is commonly a part of a risk-based or risk-informed methodology that should be constructed as a synergistic combination of decision models, advanced probabilistic reliability analysis algorithms, failure consequence assessment methods, and conventional performance assessment methodologies that have been employed in related industry for performance evaluation and management. The methodology should realistically account for the various sources and types of uncertainty involved in the decision-making process (Ayyub and McCuen 2003; Ayyub and Klir 2006).

In this section, a typical overall methodology is provided in the form of a workflow or block diagram. The various components of the methodology are described in subsequent sections. [Figure 20.5](#) provides an overall description of a methodology for risk-based management of structural systems for the purpose of demonstration. The methodology consists of the following primary steps:

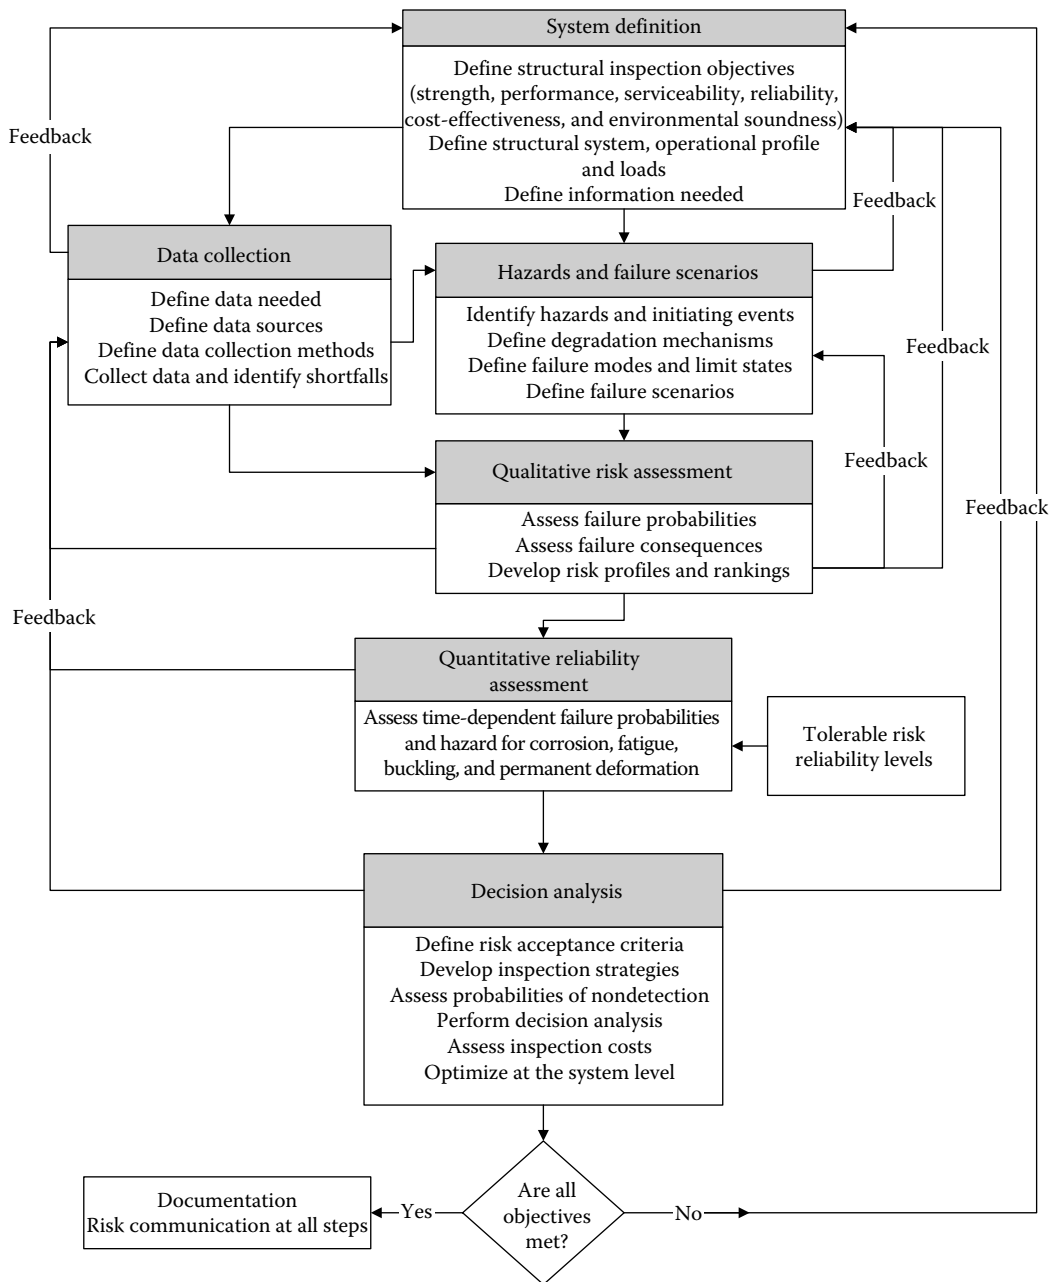

1. Definition of analysis objectives and systems
2. Hazard analysis, definition of failure scenarios, and hazardous sources and their terms
3. Collection of data in a life cycle framework
4. Qualitative risk assessment
5. Quantitative risk assessment
6. Management of system integrity through failure prevention and consequence mitigation using risk-based decision making.

These steps are briefly described in the following with additional background materials provided in subsequent sections.

The first step of the methodology is to define the system. This definition should be based on a goal that is broken down into a set of analysis objectives. A system can be defined as an assemblage or combination of elements of various levels and/or details that act together for a specific purpose. Defining the system provides the risk-based methodology with the information it needs to achieve the analysis objectives. The system definition phase of the proposed methodology has four main activities. The activities are to

1. Define the goal and objectives of the analysis
2. Define the system boundaries
3. Define the success criteria in terms of measurable performances
4. Collect information for assessing failure likelihood
5. Collect information for assessing failure consequences

For example, structural systems require a structural integrity goal that can include objectives stated in terms of strength, performance, serviceability, reliability, cost-effectiveness, and environmental soundness. The objectives can be broken down further to include other structural integrity attributes, such as alignment and water tightness in case of marine vessels. A system can be defined based on a stated set of objectives. The same system can be defined differently depending on these stated objectives. A marine

**FIGURE 20.5**

Methodology for risk-based life cycle management of structural systems.

vessel structural system can be considered to contain individual structural elements such as plates, stiffened panels, stiffeners, longitudinals, etc. These elements could be further separated into individual components and/or details. Identifying all of the elements, components, and details allows an analysis team to collect the necessary operational, maintenance, and repair information throughout the life cycle of each item so that

failure rates, repair frequencies, and failure consequences can be estimated. The system definition might need to include nonstructural subsystems and components that would be affected in case of failure. The subsystems and components are needed to assess the consequences.

To understand failure and the consequences of failure, the states of success need to be defined. For the system to be successful, it must be able to perform its designed functions by meeting measurable performance requirements. But the system may be capable of various levels of performance, all of which might not be considered a successful performance. While a marine vessel maybe able to get from point A to point B only at a reduced speed due to a fatigue failure that results in excessive vibration at the engine room, its performance would probably not be considered successful. The same concept can be applied to individual elements, components, and details. It is clear from this example that the vessel's success and failure impacts should be based on the overall vessel performance that can easily extend beyond the structural systems.

With the development of the definition of success, one can begin to assess the likelihood of occurrence and causes of failures. Most of the information required to develop an estimate of the likelihood of failure might exist in maintenance and operating histories available on the systems and equipment and based on judgment and expert opinion. This information might not be readily accessible, and its extraction from its current source might be difficult. Also, assembling it in a manner that is suitable for the risk-based methodology might be a challenge.

Operation, maintenance, engineering, and corporate information on failure history needs to be collected and analyzed for the purpose of assessing the consequences of failures. The consequence information might not be available from the same sources as the information on the failure itself. Typically, there are documentations of repair costs, reinspection or recertification costs, lost person-hours of labor, and possibly even lost opportunity costs due to system failure. Much more difficult to find and assess are costs associated with the effects on other systems, the cost of shifting resources to cover lost production, and things like environmental, safety loss, or public relations costs. These may be attained through carefully organized discussions and interviews with cognizant personnel including the use of expert-opinion elicitation.

### 20.3.2 Risk Events and Scenarios

To adequately assess all risks associated with a project, the process of identification of risk events and scenarios is an important stage in risk assessment. Risk events and scenarios can be categorized as follows:

- Technical, technological, quality, or performance risks, such as unproven or complex technology, unrealistic performance goals, and changes to the technology used or to the industry standards during the project.
- Project management risks, such as poor allocation of time and resources, inadequate quality of the project plan, and poor use of project management disciplines.
- Organizational risks, such as cost, time, and scope objectives that are internally inconsistent, lack of prioritization of projects, inadequacy or interruption of funding, resource conflicts with other projects in the organization, errors by individuals or by an organization, and inadequate expertise and experience by project personnel.

- External risks, such as shifting legal or regulatory environment, labor issues, changing owner priorities, country risk, and weather.
- Natural hazards, such as earthquakes, floods, strong wind, and waves generally require disaster recovery actions in addition to risk management. Within these categories, several risk types can be identified.

### **20.3.3 Identification of Risk Events and Scenarios**

The risk assessment process starts with the question “What can go wrong?” The identification of what can go wrong entails defining hazards, risk events, and risk scenarios. The previous section provided categories of risk events and scenarios. Risk identification involves determining which risks might affect the project and documenting their characteristics. The risk identification generally requires the participation from a project team, risk management team, subject matter experts from other parts of the company, customers, end users, other project managers, stakeholders, and outside experts on as needed basis. Risk identification can be an iterative process. The first iteration may be performed by selected members of the project team or by the risk management team. The entire project team and primary stakeholders may take a second iteration. To achieve an unbiased analysis, persons who are not involved in the project may perform the final iteration. Risk identification can be a difficult task, because it is often highly subjective, and there are no unerring procedures that may be used to identify risk events and scenarios other than relying heavily on the experience and insight of key project personnel.

The development of the scenarios for risk evaluation can be created deductively (e.g., fault tree) or inductively (e.g., failure mode and effects analysis [FMEA]) as provided in [Table 20.3](#). The table shows methods of multiple uses including likelihood or frequency estimation expressed either deterministically or probabilistically. Also, they can be used to assess varying consequence categories including items such as economic loss, loss of life, or injuries.

The risk identification process and risk assessment require the utilization of these formal methods as shown in Table 20.3. These different methods contain similar approaches to answer the basic risk assessment questions; however, some techniques may be more appropriate than others for risk analysis depending on the situation.

### **20.3.4 Risk Breakdown Structure**

Risk sources for a project can be organized and structured to provide a standard presentation that would facilitate understanding, communication, and management. The previously presented methods can be viewed as simple linear lists of potential sources of risk, providing a set of headings under which risks can be arranged. These lists are sometimes called risk taxonomy. A simple list of risk sources might not provide the richness needed for some decision situations since it only presents a single level of organization. Some applications might require a full hierarchical approach to define the risk sources, with as many levels as are required to provide the necessary understanding of risk exposure. Defining risk sources in such a hierarchical structure is called a risk breakdown structure (RBS). The RBS is defined as a source-oriented grouping of project risks organized to define the total risk exposure of a project of interest.

**TABLE 20.3**

Risk Assessment Methods

Method	Scope
Safety/review audit	Identifies equipment conditions or operating procedures that could lead to a casualty or result in property damage or environmental impacts.
Checklist What-If	Ensures that organizations are complying with standard practices.
Hazard and operability study (HAZOP)	Identifies hazards, hazardous situations, or specific accident events that could result in undesirable consequences.
Preliminary hazard analysis (PrHA)	Identifies system deviations and their causes that can lead to undesirable consequences and determine recommended actions to reduce the frequency and/or consequences of the deviations.
Probabilistic risk analysis (PRA)	Identifies and prioritizes hazards leading to undesirable consequences early in the life of a system. It determines recommended actions to reduce the frequency and/or consequences of the prioritized hazards. This is an inductive modeling approach.
Failure modes and effects analysis (FMEA)	Methodology for quantitative risk assessment developed by the nuclear engineering community for risk assessment. This comprehensive process may use a combination of risk assessment methods. Identifies the components' (equipment) failure modes and the impacts on the surrounding components and the system. This is an inductive modeling approach.
Fault tree analysis (FTA)	Identifies combinations of equipment failures and human errors that can result in an accident. This is a deductive modeling approach.
Event tree analysis (ETA)	Identifies various sequences of events, both failures and successes that can lead to an accident. This is an inductive modeling approach.
The Delphi technique	Assists to reach consensus of experts on a subject such as project risk while maintaining anonymity by soliciting ideas about the important project risks that are collected and circulated to the experts for further comment. Consensus on the main project risks may be reached in a few rounds of this process.
Interviewing	Identifies risk events by interviews of experienced project managers or subject matter experts. The interviewees identify risk events based on experience and project information.
Experience based identification	Identifies risk events based on experience including implicit assumptions.
Brainstorming	Identifies risk events using facilitated sessions with stakeholders, project team members, and infrastructure support staff.

Each descending level represents an increasingly detailed definition of risk sources for the project. The value of the RBS can be in aiding an analyst to understand the risks faced by the project.

An example RBS is provided in [Table 20.4](#). In this example, four risk levels are defined as shown in the table. The project's risks are viewed as level 0. Three types of level 1 risks are provided in the table for the purpose of demonstration. The number of risk sources in each level varies and depends on the application at hand. The subsequent level 2 risks are provided in groups that are detailed further in level 3. The RBS provides a means to systematically and completely identify all relevant risk sources for a project.

The RBS should not be treated as a list of independent risk sources since commonly they have interrelations and common risk drivers. Identifying causes behind the risk sources is a key step toward an effective risk management plan including mitigation actions. A process of risk interrelation assessment and root-cause identification can be utilized to potentially lead to identifying credible scenarios that could lead to snowball effects for risk management purposes.

**TABLE 20.4**

Risk Breakdown Structure for a Project

Level 0	Level 1	Level 2	Level 3
Project Risks	External	Corporate	History, experiences, culture, personnel Organization structure, stability, communication Finances conditions Other projects M
		Management	
		Customers and Stakeholders	History, experiences, culture, personnel Contracts and agreements Requirement definition Finances and credit M

		Performance	Technology maturity Technology limitations New technologies New hazards or threats M
		Application	Organizational experience Personnel skill sets and experience Physical resources M

### 20.3.5 System Definition for Risk Assessment

Defining the system is an important first step in performing a risk assessment. A system can be defined as a deterministic entity comprising an interacting collection of discrete elements and commonly defined using deterministic models.

The word “deterministic” implies that the system is identifiable and not uncertain in its architecture. The definition of the system is based on analyzing its functional and/or performance requirements. A description of a system may be a combination of functional and physical elements. Usually, functional descriptions are used to identify high information levels on

a system. A system may be divided into subsystems that interact. Additional detail leads to a description of the physical elements, components, and various aspects of the system.

The examination of a system needs to be made in a well-organized and repeatable fashion so that risk analysis can be consistently performed, therefore insuring that important elements of a system are defined and extraneous information omitted. The formation of system boundaries is based upon the objectives of the risk analysis.

The establishment of system boundaries can assist in developing the system definition. The decision on what the system boundary is partially based on what aspects of the system's performance are of concern.

The selection of items to include within the external boundary region is also reliant on the goal of the analysis. Beyond the established system boundary is the external environment of the system.

Boundaries beyond the physical/functional system can also be established. For example, time may also be a boundary since an overall system model may change, as a product is further along in its life cycle. The life cycle of a system is important because some potential hazards can change throughout the life cycle. For example, material failure due to corrosion or fatigue may not be a problem early in the life of a system; however, this may be an important concern later in the life cycle of the system.

Along with identifying the boundaries, it is also important to establish a resolution limit for the system. The selected resolution is important because it limits the detail of the analysis. Providing too little detail might not provide enough information for the problem. Too much information may make the analysis more difficult and costly due to the added complexity. The depth of the system model needs to be sufficient for the specific problem. Resolution is also limited by the feasibility of determining the required information for the specific problem. For failure analysis, the resolution should be to the components level where failure data are available. Further resolution is not necessary and would only complicate the analysis.

The system breakdown structure is the top-down division of a system into subsystems and components. This architecture provides internal boundaries for the system. Often the systems/subsystems are identified as functional requirements that eventually lead to the component level of detail. The functional level of a system identifies the function(s) that must be performed for the operation of the system. Further decomposition of the system into "discrete elements" leads to the physical level of a system definition identifying the hardware within the system. By organizing a system hierarchy using a top-down approach rather than fragmentation of specific systems, a rational, repeatable, and systematic approach to risk analysis can be achieved.

Further system analysis detail is addressed from modeling the system using some of the risk assessment methods described in [Table 20.3](#). These techniques develop processes that can assist in decision making about the system. The logic of modeling based on the interaction of a system's components can be divided into induction and deduction. This difference in the technique of modeling and decision making is significant. Induction logic provides the reasoning of a general conclusion from individual cases. This logic is used when analyzing the effect of a fault or condition on a systems operation. Inductive analysis answers the question, "What are the system states due to some event?" In reliability and risk studies, this "event" is some fault in the system. Several approaches using the inductive approach include preliminary hazard analysis (PrHA), FMEA, and event tree analysis (ETA). Deductive approaches provide reasoning for a specific conclusion from general conditions. For system analysis, this technique attempts to identify what modes of a system/subsystem/component failure can be used to contribute to the failure of the system. This technique answers the question,

“How a system state can occur?” Inductive reasoning provides the techniques for fault tree analysis (FTA) or its complement success tree analysis (STA).

### 20.3.6 Selected Risk Assessment Methods

*Qualitative versus quantitative risk assessment:* The risk assessment methods can be categorized according to how the risk is determined: by quantitative or qualitative analysis. Qualitative risk analysis uses judgment and sometimes “expert” opinion to evaluate the probability and consequence values. This subjective approach may be sufficient to assess the risk of a system, depending on the available resources.

Quantitative analysis relies on probabilistic and statistical methods and databases that identify numerical probability values and consequence values for risk assessment. This objective approach examines the system in greater detail to assess risks.

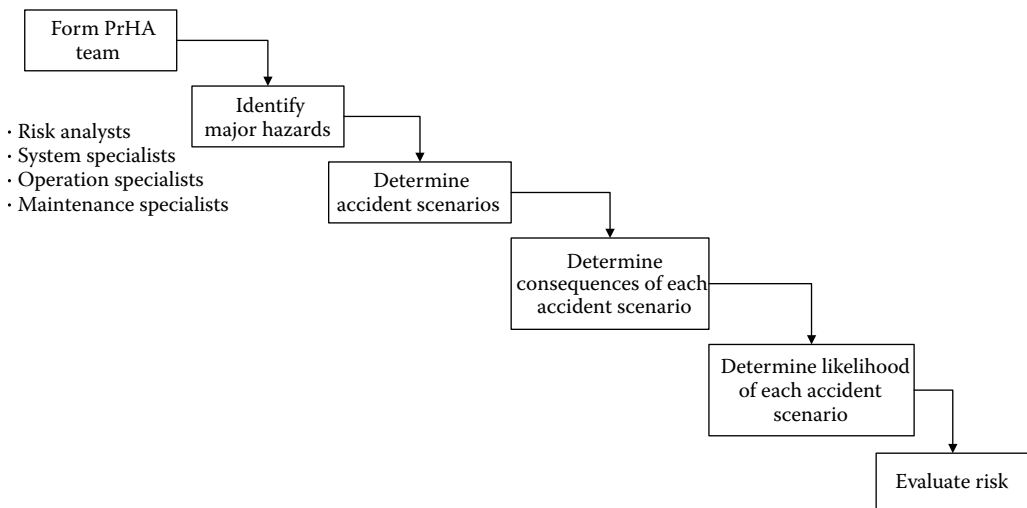

The selection of a quantitative or qualitative method depends upon the availability of data for evaluating the hazard and the level of analysis needed to make a confident decision. Qualitative methods offer analyses without detailed information, but the intuitive and subjective processes may result in differences in outcomes by those who use them. Quantitative analysis generally provides a more uniform understanding among different individuals, but requires quality data for accurate results. A combination of both qualitative and quantitative analyses can be used depending on the situation.

Risk assessment requires estimates of the failure likelihood at some identified levels of decision making. The failure likelihood can be estimated in the form of lifetime failure likelihood, annual failure likelihood, mean time between failures, or failure rate. The estimates can be in numeric or nonnumeric form. An example numeric form for an annual failure probability is 0.00015 and for a mean time between failures is 10 years. An example nonnumeric form for “an annual failure likelihood” is large and for a “mean time between failures” is medium. In the latter nonnumeric form, guidance needs to be provided regarding the meaning of terms such as large, medium, small, very large, very small, etc. The selection of the form should be based on the availability of information, the ability of the personnel providing the needed information to express it in one form or another, and the importance of having numeric versus nonnumeric information in formulating the final decisions.

The types of failure consequences that should be considered in a study need to be selected. They can include production loss, property damage, environmental damage, and safety loss in the form of human injury and death. Approximate estimates of failure consequences at the identified levels of decision making need to be determined. The estimates can be in numeric or nonnumeric form. An example numeric form for production loss is 1000 units. An example nonnumeric form for production loss is large. In the latter nonnumeric form, guidance needs to be provided regarding the meaning of terms such as large, medium, small, very large, very small, etc. The selection of the form should be based on the availability of information, the ability of the personnel providing the needed information to express it in one form or another, and the importance of having numeric versus nonnumeric information in formulating the final decisions.

Risk estimates can be determined as a pair of the likelihood and consequences and computed as the arithmetic multiplication of the respective failure likelihood and consequences for the equipment, components, and details. Alternatively, for all cases, plots of failure likelihood versus consequences can be developed. Then, approximate ranking of them as groups according to risk estimates, failure likelihood, and/or failure consequences can be developed.

*Preliminary hazard analysis:* PrHA is a common risk-based technology tool with many applications. The general process is shown in [Figure 20.6](#). This technique requires experts to

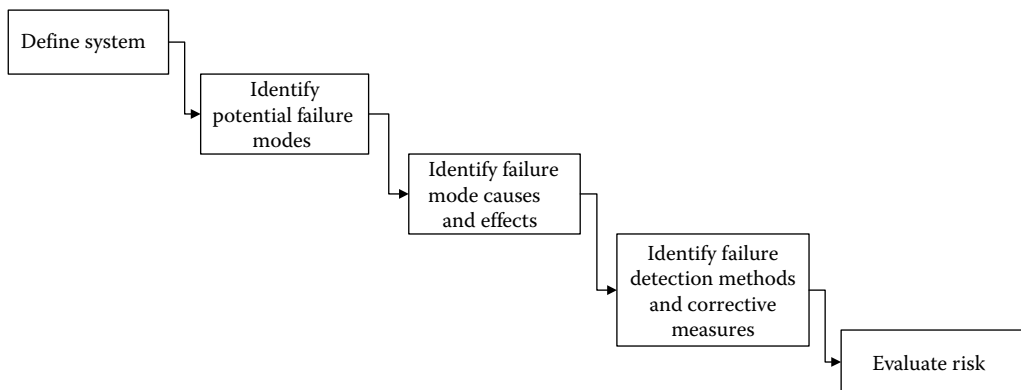

**FIGURE 20.6**

Preliminary hazard analysis (PrHA) process.

identify and rank the possible accident scenarios that may occur. It is frequently used as a preliminary method to identify and reduce the risks associated with major hazards of a system.

*Failure mode and effects analysis:* FMEA is another popular risk-based technology tool as shown in Figure 20.7. This technique has been introduced in both the national and international regulations for the aerospace (US MIL-STD-1629A), processing plant, and marine industries. The Society of Automotive Engineers, in its recommended practice, introduces two types of FMEA: design and process FMEA. This analysis tool assumes that a failure mode occurs in a system/component through some failure mechanism; the effect of this failure on other systems is then evaluated. A risk ranking can be developed for each failure mode for the effect on the overall performance of the system.

The various terms used in FMEA with examples based on the manufacturing of personal flotation devices (PFDs) are provided under subsequent headings to include

**FIGURE 20.7**

Failure mode and effects analysis (FMEA) process.

failure mode, failure effect, severity rating, causes, occurrence rating, controls, detection rating, and risk priority number.

*Risk matrices:* Risk can be assessed and presented using matrices for preliminary screening by subjectively estimating probabilities and consequences in a qualitative manner. A risk matrix is a 2D presentation of likelihood and consequences using qualitative metrics for both dimensions. According to this method, risk is characterized by categorizing probability and consequence on the two axes of a matrix. Risk matrices have been used extensively for the screening of various risks. They may be used alone or as a first step in a quantitative analysis. Regardless of the approach used, risk analysis should be a dynamic process, that is, a living process where risk assessments are reexamined and adjusted. Actions or inactions in one area can affect risk in another; therefore, continuous updating is necessary.

The likelihood metric can be constructed using the categories shown in Table 20.5, whereas the consequences metric can be constructed using the categories shown in Table 20.6 with an example provided in Table 20.7. The consequence categories of Table 20.6 focus on the health and environmental aspects of consequences. The consequence categories of Table 20.7 focus on the economic impact and should be adjusted to meet specific needs of industry and/or applications. An example risk matrix is shown in Figure 20.8. In the figure, each boxed area is shaded depending on a subjectively assessed risk level. Three risk levels are used herein for illustration purposes: low (L), medium (M), and high (H). Other risk levels may be added using a scale of five levels instead of three levels if needed. These risk levels are also called *severity factors*. The high (H) level can be considered as unacceptable risk level, the medium (M) level can be treated as either undesirable or acceptable with review, and the low (L) level can be treated as acceptable without review.

*Event modeling: event, success trees, and fault trees:* Event modeling is a systematic—and often the most complete—way to identify accident scenarios and quantify risk for

**TABLE 20.5**

Likelihood Categories for a Risk Matrix

Category	Description	Annual Probability Range
A	Likely	>0.1 (1 in 10)
B	Unlikely	>0.01 (1 in 100) but <0.1
C	Very unlikely	>0.001 (1 in 1,000) but <0.01
D	Doubtful	>0.0001 (1 in 10,000) but <0.001
E	Highly unlikely	>0.00001 (1 in 100,000) but <0.0001
F	Extremely unlikely	<0.00001 (1 in 100,000)

**TABLE 20.6**

Consequence Categories for a Risk Matrix

Category	Description	Examples
I	Catastrophic	Large number of fatalities and/or major long-term environmental impact
II	Major	Fatalities and/or major short-term environmental impact
III	Serious	Serious injuries and/or significant environmental impact
IV	Significant	Minor injuries and/or short-term environmental impact
V	Minor	First aid injuries only and/or minimal environmental impact
VI	None	No significant consequence

**TABLE 20.7**

Example Consequence Categories for a Risk Matrix in 2003 Monetary Amounts (US\$)

Category	Description	Cost
I	Catastrophic loss	>\$10,000,000,000
II	Major loss	>\$1,000,000,000 but <\$10,000,000,000
III	Serious loss	>\$100,000,000 but <\$1,000,000,000
IV	Significant loss	>\$10,000,000 but <\$100,000,000
V	Minor loss	>\$1,000,000 but <\$10,000,000
VI	Insignificant loss	<\$1,000,000

Probability category	A	L	M	M	H	H	H
	B	L	L	M	M	H	H
	C	L	L	L	M	M	H
	D	L	L	L	L	M	M
	E	L	L	L	L	L	M
	F	L	L	L	L	L	L
		VI	V	IV	III	II	I

**FIGURE 20.8**

Example risk matrix.

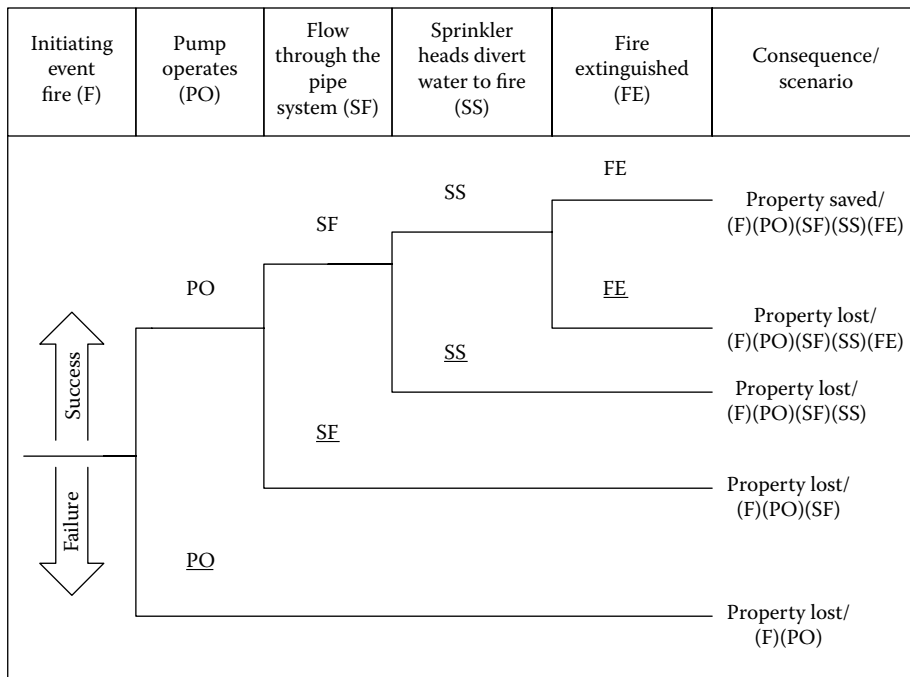

risk assessment. This risk-based technology tool provides a framework for identifying scenarios to evaluate the performance of a system or component through system modeling. The combination of ETA, STA, and FTA can provide a structured analysis to system safety.

ETA is often used if the successful operation of a component/system depends on a discrete (chronological) set of events. The initiating event is first followed by other events leading to an overall result (consequence). The ability to address a complete set of scenarios is developed because all combinations of both the success and failure of the main events are included in the analysis. The probability of occurrence of the main events of the event tree can be determined using a fault tree or its complement, the success tree. The scope of the analysis for event trees and fault trees depends on the objective of the analysis.

ETA is appropriate if the operation of some system/component depends on a successive group of events. Event trees identify the various combinations of event successes and failures as a result of an initiating event to determine all possible scenarios. The event tree starts with an initiating event followed by some reactionary event. This reaction can be either a success or a failure. If the event succeeds, the most commonly used indication is the upward movement of the path branch. A downward branch of the event tree marks the failure of an event. The remaining events are evaluated to determine the different possible scenarios. The scope of the events can be functions/systems that can provide some reduction to the possible hazards from the initiating event. The final outcome of a sequence of events identifies the overall state resulting from the scenario of events. Each path represents a failure scenario with varying levels of probability and risk. Different event trees can be created for different event initiators. [Figure 20.9](#) shows an example event tree for the basic elements of a sprinkler system that might be critical for maintaining the integrity of a marine vessel.

Based on the occurrence of an initiating event, ETA examines possible system outcomes or consequences. This analysis tool is particularly effective in showing interdependence

**FIGURE 20.9**  
Event tree example for sprinkler system.

of system components, which is important in identifying events, that at first might appear insignificant, but due to severity factors. The high (H) level can be considered as unacceptable risk level, the medium (M) level can be treated as either undesirable or acceptable with review, and the low (L) level can be treated as acceptable without review. The interdependence leads to devastating results. ETA is similar to FTA because both methods use probabilistic reliability data of the individual components and events along each path to compute the likelihood of each outcome.

A quantitative evaluation of event tree probability values can be used for each event to evaluate the probability of the overall system state. Probability values for the success or failure of the events can be used to identify the probability for a specific event tree sequence. The probabilities of the events in a sequence can be provided as an input to the model or evaluated using fault trees. These probabilities for various events in a sequence can be viewed as conditional probabilities and therefore can be multiplied to obtain the occurrence probability of the sequence. The probabilities of various sequences can be summed up to determine the overall probability of a certain outcome. The addition of consequence evaluation of a scenario allows for generation of a risk value. For example, the occurrence probability of the top branch, that is, scenario, in Figure 20.9 is computed as the product of the probabilities of the composing events to this scenario, that is,  $F \text{ fi } POH \text{ SFfi } SSfi \text{ FE}$  or  $(F)(PO)(SF)(SS)(FE)$  for short.

Complex systems are often difficult to visualize and the effect of individual components on the system as a whole is difficult to evaluate without an analytical tool. Two methods of modeling that have greatly improved the ease of assessing system reliability/risk are fault trees (FT) and success trees (ST). A fault tree is a graphical model created by deductive reasoning leading to various combinations of events that lead to the occurrence of some

top event failure. A success tree shows the combinations of successful events leading to the success of the top event. A success tree can be produced as the complement (opposite) of the fault tree as illustrated in this section. FT and ST are used to further analyze the event tree headings (the main events in an event tree) to provide further detail to understand system complexities. In constructing the FT/ST, only those failure/success events that are considered significant are modeled. This determination is assisted by defining system boundaries. For example, the event “pump operates (PO)” in [Figure 20.9](#) can be analyzed by developing a top-down logical breakdown of failure or success using fault trees or event trees, respectively.

FTA starts by defining a top event that is commonly selected as an adverse event. An engineering system can have more than one top event. For example, a ship might have the following top events for the purpose of reliability assessment: power failure, stability failure, mobility failure, or structural failure. Then, each top event needs to be examined using the following logic: in order for the top event to occur, other events must occur. As a result, a set of lower-level events is defined. Also, the form in which these lower-level events are logically connected (i.e., in parallel or in series) needs to be defined. The connectivity of these events is expressed using “AND” or “OR” gates. Lower-level events are classified into the following types:

1. Basic events: These events cannot be decomposed further into lower-level events. They are the lowest events that can be obtained. For these events, failure probabilities need to be obtained.
2. Events that can be decomposed further: These events can be decomposed further to lower levels. Therefore, they should be decomposed until the basic events are obtained.
3. Undeveloped events. These events are not basic and can be decomposed further. However, because they are not important, they are not developed further. Usually, the probabilities of these events are very small or the effect of their occurrence on the system is negligible, or can be controlled or mediated.
4. Switch (or house) events. These events are not random and can be turned on or off with full control. The symbols shown in [Figure 20.10](#) are used for these events. Also, a continuation symbol is shown that is used to break up a fault tree into several parts for the purpose of fitting it in several pages.

FTA requires the development of a tree-looking diagram for the system that shows failure paths and scenarios that can result in the occurrence of a top event. The construction of the tree should be based on the building blocks and the Boolean logic gates.

The outcome of interest from the FTA is the occurrence probability of the top event. Because the top event was decomposed into basic events, its occurrence can be stated in the form of “AND” and “OR” of the basic events. The resulting statement can be restated by replacing the “AND” with the intersection of the corresponding basic events, and the “OR” with the union of the corresponding basic events. Then, the occurrence probability of the top event can be computed by evaluating the probabilities of the unions and intersections of the basic events. The dependence between these events also affects the resulting probability of the system.

For large fault trees, the computation of the occurrence probability of the top event can be difficult because of their size. In this case, a more efficient approach is needed for assessing the reliability of a system, such as the minimal cut set approach. According to this

**FIGURE 20.10**

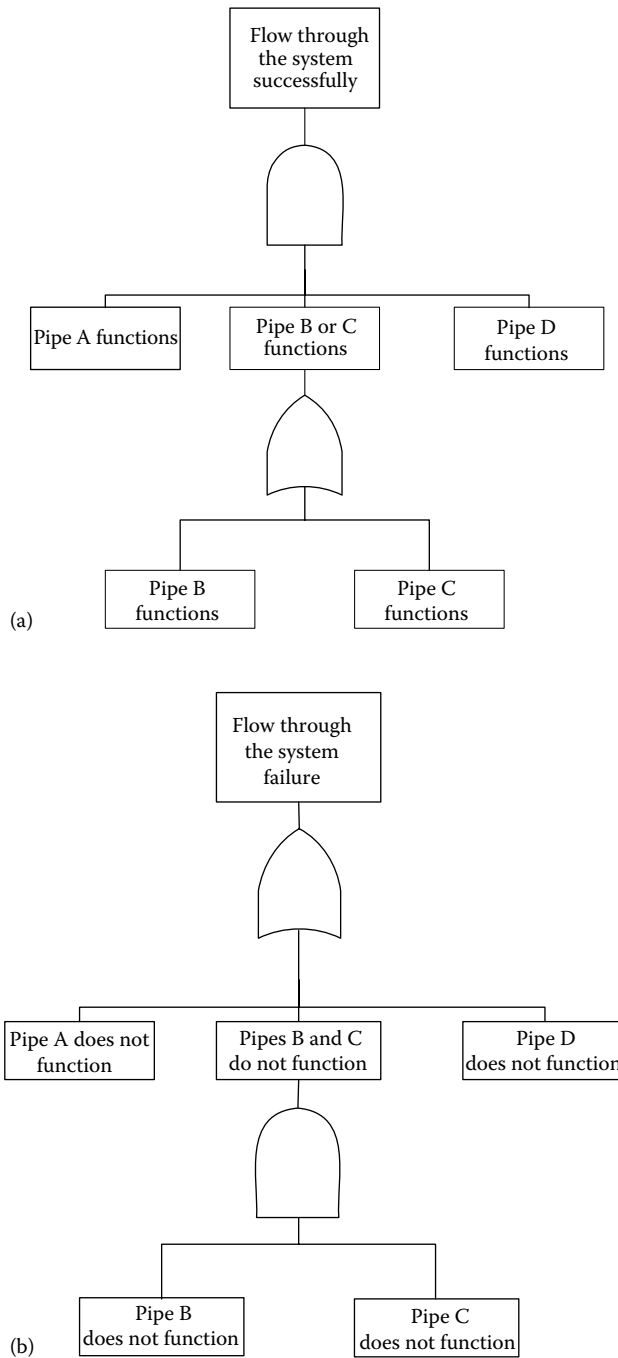

Symbols used in fault tree analysis.

approach, each cut set is defined as a set of basic events where the joint occurrence of these basic events results in the occurrence of the top event. A minimal cut set is a cut set with the condition that the nonoccurrence of any one basic event from this set results in the non-occurrence of the top event. Therefore, a minimal cut set can be viewed as a subsystem in parallel. In general, systems have more than one minimal cut set. The occurrence of the top event of the system can, therefore, be due to any one of these minimal cut sets. As a result, the system can be viewed as the union of all the minimal cut sets for the system. If probability values are assigned to the cut sets, a probability for the top event can be determined.

A simple example of this type of modeling is shown in Figure 20.11 for a pipe system using a reliability block diagram. If the goal of the system is to maintain water flow from one end of the system to the other, then the individual pipes can be related with a Boolean logic. Both pipe (a) and pipe (d) and pipe (b) or pipe (c) must function for the system to meet its goal as shown in the success tree (Figure 20.12a). The complement of the success tree

**FIGURE 20.11**

A reliability block diagram for a piping system.

**FIGURE 20.12**

(a) Success tree for the pipe system example. (b) Fault tree for the pipe system example.

is the fault tree. The goal of the fault tree model is to construct the logic for system failure as shown in [Figure 20.12b](#). After these tree elements have been defined, possible failure scenarios of a system can be defined.

As described previously, a failure path is often referred to as a *cut set*. One objective of the analysis is to determine the entire minimal cut sets, where a minimal cut set is defined as a failure combination of all essential events that can result in the failure top event. A minimal cut set includes in its combination all essential events, that is, the nonoccurrence of any of these essential events in the combination of a minimal cut set results in the nonoccurrence of the minimal cut set. These failure combinations are used to compute the failure probability of the top event. The concept of the minimal cut sets applies only to the fault trees. A similar concept can be developed in the complementary space of the success trees and is called the minimal pass set. In this case, a minimal pass set is defined as a survival (or success) combination of all essential success events that can result in success as defined by the top event of the success tree. For the piping example, the minimal cut sets are

$$A \quad (20.6a)$$

$$D \quad (20.6b)$$

$$B \text{ and } C \quad (20.6c)$$

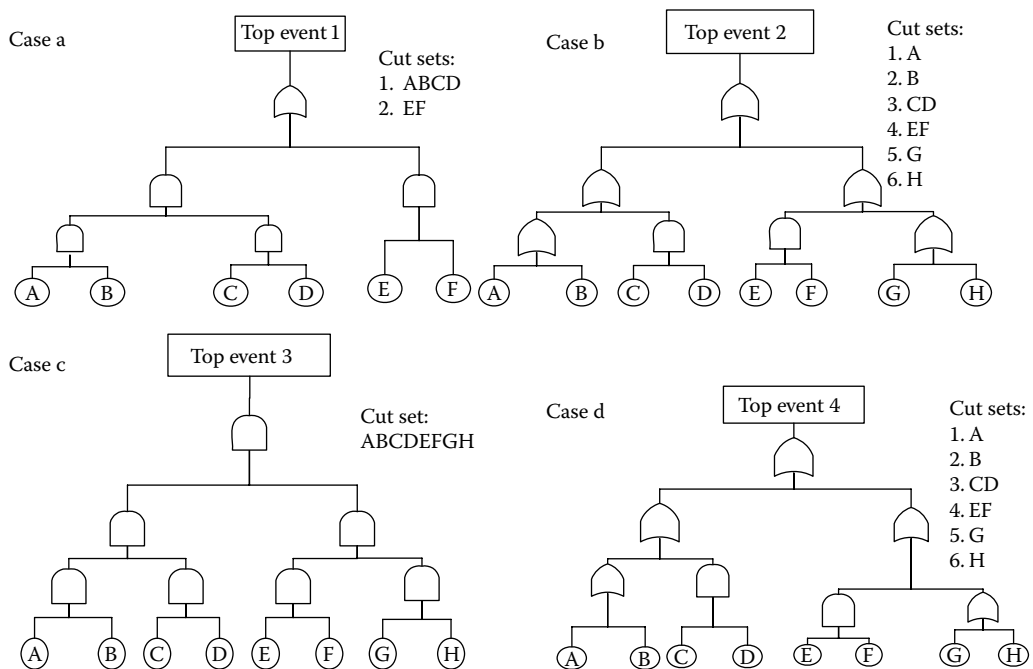

A minimal cut set includes events that are all necessary for the occurrence of the top event. For example, the following cut set is not a minimal cut set:

$$A \text{ and } B \quad (20.7)$$

### Example 20.1 Trends in Fault Tree Models and Cut Sets

This example demonstrates how the cut sets can be identified and constructed for different arrangements of OR and AND gates logically defining a top event occurrence. Generally, the number of cut sets increases by increasing the number of OR gates in the tree. For example, [Figure 20.13](#) shows this trend by comparing cases a, b, and d. On the other hand, increasing the number of AND gates results in increasing the number of events included in the cut sets as shown in case c of [Figure 20.13](#).

Common cause scenarios are events or conditions that result in the failure of seemingly separate systems or components. Common cause failures complicate the process of conducting risk analysis because a seemingly redundant system can be rendered ineffective by a common cause failure. For example, an emergency diesel generator fed by the same fuel supply as the main diesel engine will fail with the main diesel generator, if the fuel supply is the root source of the failure. The redundant emergency diesel generator is not truly redundant due to a common cause failure. Another example of common cause events is the failure of two separate but similar pieces of machinery due to a common maintenance problem, two identical pieces of equipment failing due to a common manufacturing defect, or two pieces of equipment failing due to a common environmental condition such as the flooding of a compartment or a fire in the vicinity of both pieces of machinery. A method for calculating the reliability of a system while taking into account common cause effects is the beta-factor model. Other methods include multiple Greek letter model, alpha-factor model, and beta-binomial failure-rate model.

**FIGURE 20.13**

Trends in fault tree models and cut sets. (From Maryland Emergency Management Agency (MEMA), *State of Maryland Guide for the Protection of Critical Infrastructure and Key Resources for Homeland Security, Volume 1: Critical Asset & Portfolio Risk Assessment (CAPRA) Methodology*, Office of Homeland Security, Annapolis, MD, 2006.)

Part of risk-based decision analysis is pinpointing the system components that result in high-risk scenarios. Commercial system reliability software provides this type of analysis in the form of system reliability sensitivity factors to changes in the underlying component reliability values. In performing risk analysis, it is desirable to assess the importance of events in the model, or the sensitivity of final results to changes in the input failure probabilities for the events. Several sensitivity or importance factors are available and can be used. The most commonly used factors include (1) Fussell-Vesely factor and (2) Birnbaum factor. Also, a weighted combination of these factors can be used as an overall measure.

### 20.3.7 Human-Related Risks

Risk assessment requires the performance analysis of an entire system composed of a diverse group of components. The system definition readily includes the physical components of the system; however, humans are also part of most systems and provide significant contributions to risk. It has been estimated that nearly 90% of the accidents at sea are contributed to human error. The human contribution to risk can be estimated from an understanding of behavioral sciences. Both the “hardware failure” and human error should be addressed in the risk assessment since they both contribute to risks associated with the system. After the human error probabilities are determined, human error/failures are treated in the same fashion as hardware failures in performing risk assessment quantification.

The determination of the human error contribution to risk is determined by human reliability analysis (HRA) tools. HRA is the discipline that enables the analysis and impact

of humans on the reliability and safety of systems. Important results of HRA are determining the likelihood of human error as well as ways in which human errors can be reduced. When combined with system risk analysis, HRA methods provide an assessment of the detrimental effects of humans on the performance of the system. HRA is generally considered to be composed of three basic steps: error identification, modeling, and quantification.

Other sources of human-related risks are in the form of deliberate sabotage of a system from within a system or as threat from outside the system, such as a computer hacker or a terrorist. The hazard in this case is not simply random but intelligent. The methods introduced in earlier sections might not be fully applicable for this risk type. The threat scenarios to the system in this case have a dynamic nature that are affected by the defense or risk mitigation and management scenarios that would be implemented by an analyst. The use of game theory methods might be needed in this case in combination with other risk analysis and management methods. Game theory is introduced in the last subsection herein.

*Human error identification:* Human errors are unwanted circumstances caused by humans that result in deviations from expected norms that place systems at risk. It is important to identify the relevant errors to make a complete and accurate risk assessment. Human error identification techniques should provide a comprehensive structure for determining significant human errors within a system. Quality HRA allows for accuracy in both the HRA assessment and overall system risk assessment.

Identification of human errors requires knowledge about the interactions of humans with other humans or machines (the physical world). It is the study of these interfaces that allow for the understanding of human errors. Potential sources of information for identifying human error may be determined from task analysis, expert judgment, laboratory studies, simulation, and reports. Human errors may be considered active or latent depending on the time delay between when the error occurs and when the system fails.

It is important to note the distinction between human errors and human factors. Human errors are generally considered separately from human factors that provide information about human behavior, abilities, limitations, and other characteristics to the design of tools, machines, systems tasks, jobs, and environments for productive, safe, comfortable, and effective human use. Human factors are determined from performing descriptive studies for characterizing populations and experimental research. However, human factors analysis may contribute to the HRA.

*Human error modeling:* After human errors have been identified, they must be represented in a logical and quantifiable framework along with other components that contribute to the risk of the system. This framework can be determined from the development of a risk model. Currently, there is no consensus on how to model human reliability. Many of these models utilize human event trees and fault trees to predict human reliability values. The identifications of human failure events can also be identified using failure mode and effects analysis. The human error rate estimates are often based on simulation tests, models, and expert estimation.

*Human error quantification:* Quantification of human error reliability promotes the inclusion of the human element in risk analysis. This is still a developing science requiring understanding of human performance, cognitive processing, and human perceptions. Because an exact model for human cognition has not been developed, much of the current human reliability data rely on accident databases, simulation, and other empirical approaches.

Many of the existing data sources were developed for from specific industry data such as nuclear and aviation industries. The application of these data sources for a specific problem should be thoroughly examined prior to application for a specific model. The result of the quantification of human reliability in terms of probability of occurrence is typically called a *human error probability (HEP)*. There are many techniques that have been developed to help predict the HEP values. The technique for human error rate prediction (THERP) is one of the most widely used methods for HEP. This technique is based on data gathered from the nuclear and chemical processing industries. THERP relies on HRA event tree modeling to identify the events of concern. Quantification is performed from data tables of basic HEP for specific tasks that may be modified based on the circumstances affecting performance.

The degree of human reliability is influenced by many factors often called *performance shaping factors (PSFs)*. PSFs are those factors that affect the ability of people to carry out required tasks. For example, the knowledge people have on how to don/activate a PFD will affect the performance of this task. Training (another PSF) in donning PFDs can also assist in the ability to perform this task. Another example is the training that is given to passengers on airplanes before takeoff on using seatbelts, emergency breathing devices, and flotation devices. Often, the quantitative estimates of reliability are generated from a base error rate that is then altered based on the PSFs of the particular circumstances. Internal performance shaping factors are an individual's own attributes (experience, training, skills, abilities, attitudes) that affect the ability of the person to perform certain tasks. External PSFs are the dynamic aspects of situation, tasks, and system that affect the ability to perform certain tasks. Typical external factors include environmental stress factors (such as heat, cold, noise, situational stress, time of day), management, procedures, time limitations, and quality of person-machine interface. With these PSFs, it is easy to see the dynamic nature of HEP evaluation based on the circumstances of the analysis.

*Reducing human errors:* Error reduction is concerned with lowering the likelihood for error in an attempt to reduce risk. The reduction of human errors may be achieved by human factors interventions or by engineering means. Human factors interventions include improving training or improving the human-machine interface (such as alarms, codes, etc.) based on an understanding of the causes of error. Engineering means of error reduction may include automated safety systems or interlocks. The selection of the corrective actions to take can be done through decision analysis considering cost-benefit criteria.

*Game theory for intelligent threats:* Game theory can be used to model human behavior as a threat to a system. Generally, game theory utilizes mathematics, economics, and the other social and behavioral sciences to model human behavior.

An example of intelligent threats is terrorism and sabotage as an ongoing battle between coordinated opponents representing a two-party game, where each opponent seeks to achieve their own objectives within a system. In the case of terrorism, it is a game of a well-established political system as a government versus an emerging organization that uses terrorism to achieve partial or complete dominance. Each player in this game seeks a utility, that is, benefit, that is a function of the desired state of the system. In this case, maintaining system survival is the desired state for the government, whereas the opponent seeks a utility based on the failure state of the system. The government, as an opponent, is engaged in risk mitigation whose actions seek to reduce the threat, reduce the system vulnerability, and/or mitigate the consequences of any successful attacks. The terrorists, as an opponent, can be viewed as the aggressor who strives to alter or damage their opponent's

desired system state. This game involves an intelligent threat and is dynamic. The game is ongoing until the probability of a successful disruptive attempt of the aggressor reaches an acceptable level of risk—a stage where risk is considered under control—and the game is brought to an end. Classical game theory can be used in conjunction with probabilistic risk analysis to determine optimal mitigation actions that maximize benefits.

A classical example used to introduce game theory is called the *prisoners' dilemma* and is based on two suspects that are captured near the scene of a crime and are questioned separately by authority such as the police. Each has to choose whether or not to confess and implicate the other. If neither person confesses, then both will serve, for example, 1 year on a charge of carrying a concealed weapon. If each confesses and implicates the other, both will go to prison for, say, 10 years. However, if one person confesses and implicates the other, and the other person does not confess, the one who has collaborated with the police will go free, while the other person will go to prison for, say, 20 years on the maximum penalty. The strategies in this case are as follows: confess or do not confess. The payoffs, herein *penalties*, are the sentences served. The problem can be expressed compactly in a payoff table of a kind that has become standard in game theory as provided in Table 20.8. The entries of this table mean that each prisoner chooses one of the two strategies, that is, the first suspect chooses a row and the second suspect chooses a column. The two numbers in each cell of the table provide the outcomes for the two suspects for the corresponding pair of strategies chosen by the suspects as an ordered pair. The number to the left of the comma is the payoff to the person who chooses the rows, that is, the first suspect, whereas the number to the right of the comma is the payoff to the person who chooses the columns, that is, the second suspect. Thus, reading down the first column, if they both confess, each gets 10 years, but if the second suspect confesses and the first suspect does not, the first suspect gets 20 years and second suspect goes free. This example is not a zero-sum game because the payoffs are all losses. However, many problems can be cast with losses (negative numbers) and gains (positive numbers) with a total for each cell in the payoff table. A problem with a payoff table such that the payoffs in each cell add up to zero is called a *zero-sum game*.

The solution to this problem needs to be based on identifying rational strategies that can be based on both persons wanting to minimize the time they spend in jail. One suspect might reason that “two things can happen: either the other suspect confesses or keeps quiet. Suppose the second suspect confesses, I will get 20 years if I don’t confess, 10 years if I do; therefore, in this case, it’s best to confess. On the other hand, if the other suspect doesn’t confess, and I don’t either, I get a year; but in that case, if I confess I can go free. Either way, it’s best if I confess. Therefore, I’ll confess.” But the other suspect can and presumably will reason in the same way. In this case, they both confess and go to prison for 10 years each, although if they had acted irrationally, and kept quiet, they each could have gotten off with 1 year each. The rational strategies of the two suspects have fallen

**TABLE 20.8**

Payoff Table in Years for the Prisoners’ Dilemma Game

		Second Suspect	
		Confess	Don’t Confess
First suspect	Confess	(10, 10)	(0, 20)
	Don’t confess	(20, 0)	(1, 1)

into something called *dominant strategy equilibrium*. The meaning of the term “dominant strategy equilibrium” requires defining the term “dominant strategy” that results from an individual player (the suspect, in this case) in a game evaluating separately each of the strategy combinations being faced, and, for each combination, choosing from these strategies the one that gives the greatest payoff. If the same strategy is chosen for each of the different combinations of strategies the player might face, that strategy is called a dominant strategy for that player in that game. The dominant strategy equilibrium occurs if, in a game, each player has a dominant strategy, and each player plays the dominant strategy, then that combination of (dominant) strategies and the corresponding payoffs are said to constitute the dominant strategy equilibrium for that game. In the prisoners’ dilemma game, to confess is a dominant strategy, and when both suspects confess, dominant strategy equilibrium is established. The dominant strategy equilibrium is also called *Nash equilibrium*. The definition of Nash equilibrium is a set of strategies with the property that no player can benefit by changing his/her strategy while the other players keep their strategies unchanged, then that set of strategies and the corresponding payoffs constitute the Nash equilibrium.

The prisoners’ dilemma game is based on two strategies per suspect that can be viewed as deterministic in nature, that is, nonrandom. In general, many games, especially those permitting repeatability in choosing strategies by players, can be constructed with strategies that have associated probabilities. For example, strategies can be constructed based on probabilities of 0.4 and 0.6 that sum to one. Such strategies with probabilities are called *mixed strategies* as opposed to *pure strategies* that do not involve probabilities of the prisoners’ dilemma game. A mixed strategy occurs in a game if a player chooses among two or more strategies at random according to specific probabilities.

In general, gaming could involve more than two players. In the prisoners’ dilemma game, a third player that could be identified is the authority and its strategies. The solution might change as a result of adding the strategies of this third player. The use of these concepts in risk analysis and mitigation needs further development and exploration.

*Risk methods for protecting infrastructure and key resources:* The protection of critical infrastructure and key resources (CI/KR) for homeland security requires choosing among a large set of protective, response, and recovery actions for reducing risk to an acceptable level. The selection of investment alternatives for improving asset security and increasing infrastructure resilience depends on two factors: their cost to implement and relative cost-effectiveness. To accomplish this task, the Department of Homeland Security (DHS) has identified risk methods as the primary underlying framework for system evaluations, operational assessments, technology assessments, resource and support analyses, and field operations analyses. According to the draft DHS National Infrastructure Protection Plan, cost-benefit analysis is the hallmark of critical infrastructure protection decision making. [Figure 20.14](#) shows a methodology for informing decisions relating to CI/KR protection (MEMA 2006). It is a quantitative, asset-driven framework for assessing the risk of consequential CI/KR exploitation and disruption due to a variety of plausible threat scenarios and hazard events. This process is divided into five phases as shown in [Figure 20.14](#). The results from each phase support decision making of some type, whether it be asset screening and selection based on consequences and their criticality, or countermeasure selection and evaluation based on the results from the security vulnerability assessment phase.

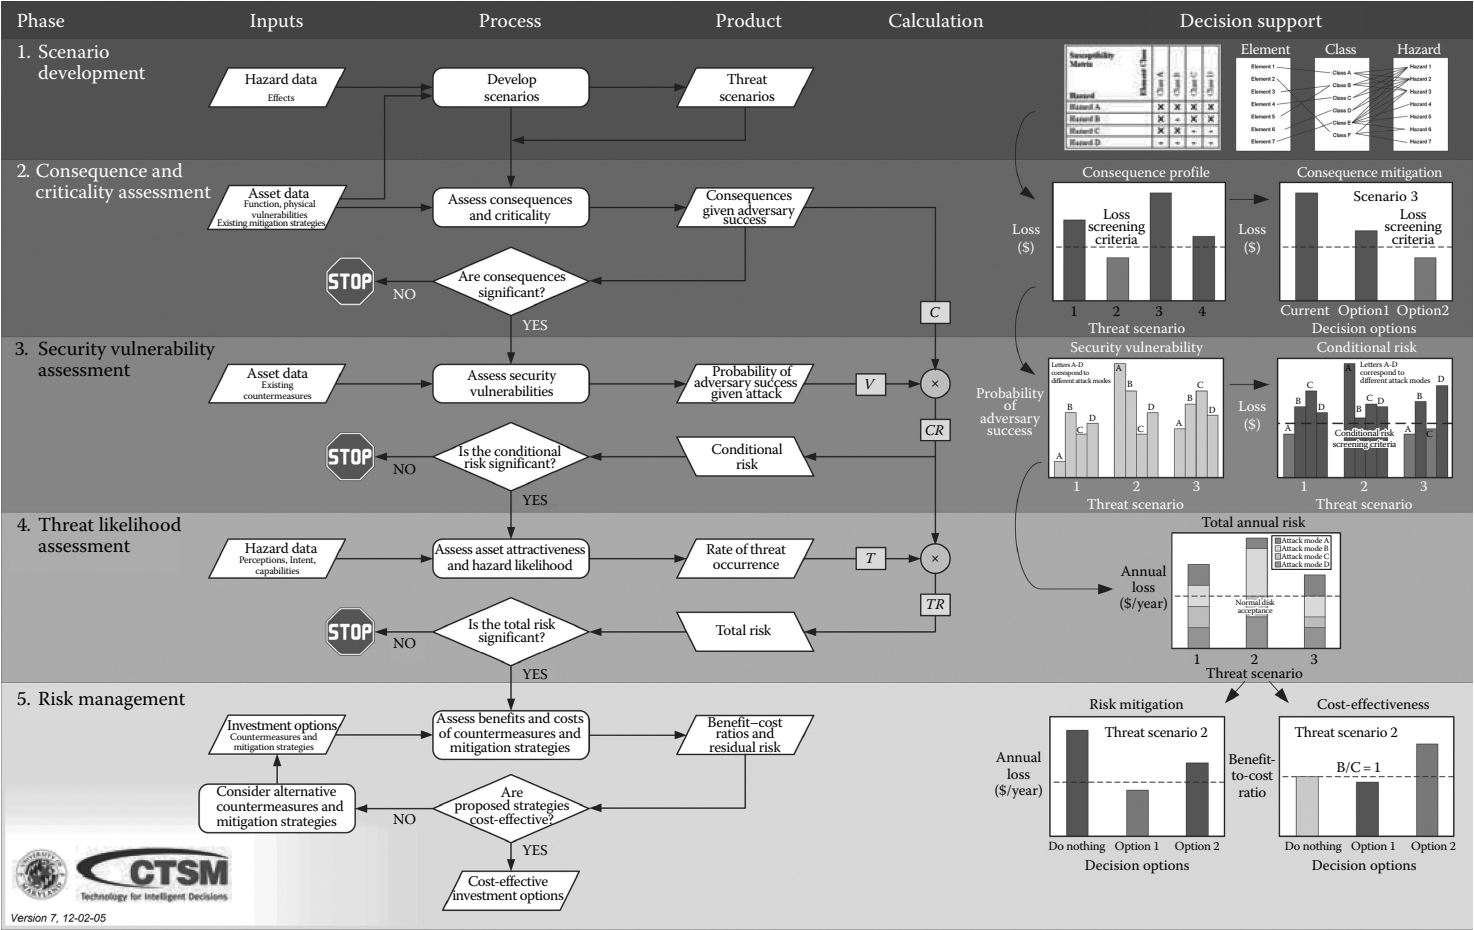

FIGURE 20.14  
Critical asset and portfolio risk analysis methodology.

### 20.3.8 Economic and Financial Risks

Economic and financial risks can be grouped into categories that include market risks, credit risks, operation risks, and reputation risks. These four categories are described in subsequent sections.

*Market risks:* Governments and corporations operate in economic and financial environments with some levels of uncertainty and instability. A primary contributor to defining this environment is interest rates. Interest rates can have significant impact on the costs of financing a project and corporate cash flows and asset values. For example, interest rates in the United States shot up in 1979 and peaked in 1981, followed by gradual decline with some fluctuations until 2002.

For projects that target global markets, exchange rate instability can be a major risk source. Exchange rates have been volatile ever since the breakdown of the Bretton Woods system to fixed exchange rates in the early 1970s. An example of a bust-up in exchange rates is the fall of the value of the British sterling and Italian lira as a result of the failure of the exchange rate mechanism in September 1992.

Many projects are dependent on the availability of venture capital and the stock performance of corporation thereby introducing another risk source related to stock market volatility. Stock prices rose significantly in the inflationary booms of the early 1970s, then fell considerably a little later. They recovered afterward and fell again in early 1981. The market rose to a peak until it crashed in 1987, followed by an increase with some swings till it reached reaching a new peak fueled by Internet technologies and finally collapsed in 2001.

Other contributing factors to economic and finance instability are commodity prices in general and energy prices in particular, primarily crude oil. The hikes in oil prices in the 1973–1974 affected commodity prices greatly and posed a series of challenges to countries and corporations.

Another contributing source to volatility is derivatives for commodities, foreign currency exchange rates, and stock prices and indices, among others. Derivatives are defined as contracts whose values or payoffs depend on those of other assets, such as the options to buy commodities in the future or options to sell commodities in the future. They offer not only opportunities for hedging positions and managing risks that can be stabilizing, but also speculative opportunities to others that can be destabilizing and a contributor to volatility.

*Credit risks:* Credit risks are associated with potential defaults on notes or bonds, as examples, by corporations, including subcontractors. Also, credit risks can be associated with market sentiments that determine a company likelihood of default that could affect its bond rating and ability to purchase money and maintain projects and operations.

*Operational risks:* Operational risks are associated with several sources that include out-of-control operations risk that could occur when a corporate branch undertakes significant risk exposure that is not accounted for by a corporate headquarters leading potentially to its collapse, an example being the British Barings Bank that collapsed primarily as a result of its failure to control the market exposure being created within a small overseas branch of the bank.

Another risk source in this category is liquidity in which a corporation needing funding more than it can arrange. Also, it could include money transfer risks and agreement breach.

Operational risks include model risks. Model risks are associated with the models and underlying assumptions used to incorrectly value financial instruments and cash flows.

*Reputation risks:* The loss of business attributable to decrease in a corporation's reputation can pose another risk source. This risk source can affect its credit rating, ability to maintain clients, workforce, etc. This risk source usually occurs at a slow attrition rate. It can be an outcome of poor management decisions and business practices.

### 20.3.9 Data Needs for Risk Assessment

In risk assessment, the methods of probability theory are used to represent engineering uncertainties. In this context, it refers to event occurrence likelihoods that occur with periodic frequency, such as weather, yet also to conditions that are existent but unknown, such as probability of an extreme wave. It applies to the magnitude of an engineering parameter, yet also to the structure of a model. By contrast, probability is a precise concept. It is a mathematical concept with an explicit definition. The mathematics of probability theory are used to represent uncertainties, despite that those uncertainties are of many forms.

The term *probability* has a precise mathematical definition, but its meaning when applied to the representation of uncertainties is subject to differing interpretations. The frequentist view holds that probability is the propensity of a physical system in a theoretically infinite number of repetitions; that is, the frequency of occurrence of an outcome in a long series of similar trials (e.g., the frequency of a coin landing heads-up in an infinite number of flips is the probability of that event). In contrast, the Bayesian view holds that probability is the rational degree of belief that one holds in the occurrence of an event or the truth of a proposition; probability is manifest in the willingness of an observer to take action upon this belief. This latter view of probability, which has gained wide acceptance in many engineering applications, permits the use of quantified professional judgment in the form of subjective probabilities. Mathematically, such subjective probabilities can be combined or operated on as any other probability.

Data are needed to perform quantitative risk assessment or provide information to support qualitative risk assessment. Information maybe available if data have been maintained on a system and components of interest. The relevant information for risk assessment included the possible failures, failure probabilities, failure rates, failure modes, possible causes, and failure consequences. In the case of a new system, data maybe used from similar systems if this information is available. Surveys are a common tool used to provide some means of data. Statistical analysis can be used to assess confidence intervals and uncertainties in estimated parameters of interest. Expert judgment may also be used as another source of data (Ayyub 2002). The uncertainty with the quality of the data should be identified to assist in the decision-making process.

Data can be classified to include generic- and project- or plant-specific types. Generic data are information from similar systems and components. This information may be the only information available in the initial stages of system design. Therefore, potential differences due to design or uncertainty may result from using generic data on a specific system. Plant-specific data are specific to the system being analyzed. This information is often developed after the operation of a system. Relevant data need to be identified and collected as data collection can be costly. The data collected can then be used to update the risk assessment. Bayesian techniques can be used to combine objective and subjective data.

Data can be classified as failure probability data and failure consequence data. The failure probability data can include failure rates, hazard functions, times between failures, results from reliability studies, and any influencing factors and their effects. Failure consequence data include loss reports, damages, litigation outcomes, repair costs, injuries, and human losses. Also included are influencing factors and

effects of failure prevention and consequence mitigation plans. Areas of deficiency in terms of data availability should be identified, and sometimes failure databases need to be constructed. Data deficiency can be used as a basis for data collection and expert-opinion elicitation.

## 20.4 Risk Management and Control

Adding risk control to risk assessment produces risk management. Risk management is the process by which system operators, managers, and owners make safety decisions, regulatory changes, and choose different system configurations based on the data generated in the risk assessment. Risk management involves using information from the previously described risk assessment stage to make educated decisions about system safety. Risk control includes failure prevention and consequence mitigation.

Risk management requires the optimal allocation of available resources in support of group goals. Therefore, it requires the definition of acceptable risk, and comparative evaluation of options and/or alternatives for decision making. The goals of risk management are to reduce risk to an acceptable level and/or prioritize resources based on comparative analysis. Risk reduction is accomplished by preventing an unfavorable scenario, reducing the frequency, and/or reducing the consequence. A graph showing the risk relationship is shown in Figure 20.15 as linear contours of constant risk, although due to risk aversion these lines are commonly estimated as nonlinear curves and should be treated as nonlinear curves. Moreover, the vertical axis is termed as probability, whereas it is commonly expressed as an annual exceedence probability or frequency as shown in Figure 20.1. In cases involving qualitative assessment, a matrix presentation can be used as shown

**FIGURE 20.15**  
Risk plot.

in Figure 20.8. The figure shows probability categories, severity categories, and risk ratings. A project's base value is commonly assumed as zero. Each risk rating value requires a different mitigation plan.

### 20.4.1 Risk Acceptance

Risk acceptance constitutes a definition of safety as discussed in previous sections. Therefore, risk acceptance is considered a complex and controversial subject that is often subject to debate. The determination of acceptable levels of risk is important to determine the risk performance a system needs to achieve to be considered safe. If a system has a risk value above the risk acceptance level, actions should be taken to address safety concerns and improve the system through risk reduction measures. One difficulty with this process is defining acceptable safety levels for activities, industries, structures, etc. Because the acceptance of risk depends upon society's perceptions, the acceptance criteria do not depend on the risk value alone. This section describes several methods that have been developed to assist in determining acceptable risk values as summarized in Table 20.9.

Risk managers make decisions based on risk assessment and other considerations including economical, political, environmental, legal, reliability, producibility, safety, and other factors. The answer to the question "How safe is safe enough?" is difficult and constantly changing due to different perceptions and understandings of risk. To determine "acceptable risk," managers need to analyze alternatives for the best choice. In some industries, an acceptable risk has been defined by consensus. For example, the U.S. Nuclear Regulatory Commission requires that reactors be designed such that the probability of a large radioactive release to the environment from a reactor incident shall be less than  $1 \times 10^{-6}$  per year. Risk levels for certain carcinogens and pollutants have also been given acceptable concentration levels based on some assessment of acceptable risk. However, risk acceptance for many other activities is not stated.

**TABLE 20.9**

Methods for Determining Risk Acceptance

Risk Acceptance Method	Summary
Risk conversion factors	This method addresses the attitudes of the public about risk through comparisons of risk categories. It also provides an estimate for converting risk acceptance values between different risk categories
Farmers curve	It provides an estimated curve for cumulative probability risk profile for certain consequences (e.g., deaths). It demonstrates graphical regions of risk acceptance/nonacceptance
Revealed preferences	Through comparisons of risk and benefit for different activities, this method categorizes society preferences for voluntary and involuntary exposure to risk.
Evaluation of magnitude of consequences	This technique compares the probability of risks to the consequence magnitude for different industries to determine acceptable risk levels based on consequence
Risk effectiveness	It provides a ratio for the comparison of cost to the magnitude of risk reduction. Using cost-benefit decision criteria, a risk reduction effort should not be pursued if the costs outweigh the benefits. This may not coincide with society values about safety
Risk comparison	The risk acceptance method provides a comparison between various activities, industries, etc., and is best suited to comparing risks of the same type

For example, qualitative implications for risk acceptance are identified in the several existing maritime regulations. The International Maritime Organization High-Speed Craft Code and the U.S. Coast Guard Navigation and Vessel Inspection Circular (NVIC) 5–93 for passenger submersible guidance both state that if the end effect is hazardous or catastrophic, a backup system and a corrective operating procedure are required. These references also state that a single failure must not result in a catastrophic event, unless the likelihood is extremely remote.

Often the level of risk acceptance with various activities is implied. Society has reacted to risks through the developed level of balance between risk and potential benefits. Measuring this balance of accepted safety levels for various risks provides a means for assessing society values. These threshold values of acceptable risk depend on a variety of issues including the activity type, industry, and users, and the society as a whole.

Target risk or reliability levels are required for developing procedures and rules for ship structures. For example, the selected reliability levels determine the probability of failure of structural components. The following three methods were used to select target reliability values:

1. Agreeing upon a reasonable value in cases of novel structures without prior history
2. Calibrating reliability levels implied in currently, successfully used design codes
3. Choosing target reliability level that minimizes total expected costs over the service life of the structure for dealing with design for which failure results in only economic losses and consequences

The first approach can be based on expert-opinion elicitation. The second approach, called *code calibration*, is the most commonly used approach as it provides the means to build on previous experiences. For example, rules provided by classification and industry societies can be used to determine the implied reliability and risk levels in respective rules and codes, then target risk levels can be set in a consistent manner, and new rules and codes can be developed to produce future designs and vessels that are of similar levels that offer reliability and/or risk consistency. The third approach can be based on economic and trade-off analysis. In subsequent sections, the methods of [Table 20.9](#) for determining risk acceptance are discussed.

*Risk conversion factors:* Analysis of risks shows that there are different taxonomies that demonstrate the different risk categories, often called *risk factors*. These categories can be used to analyze risks on a dichotomous scale comparing risks that invoke the same perceptions in society. For example, the severity category may be used to describe both ordinary and catastrophic events. Grouping events that could be classified as ordinary and comparing the distribution of risk to a similar grouping of catastrophic categories yields a ratio describing the degree of risk acceptance of ordinary events as compared to catastrophic events. The comparison of various categories determined the risk conversion values as provided in [Table 20.10](#). These factors are useful in comparing the risk acceptance for different activities, industries, etc. By computing the acceptable risk in one activity, an estimate of acceptable risk in other activities can be calculated based on the risk conversion factors. A comparison of several common risks based on origin and volition is shown in [Table 20.11](#).

*Farmers curve:* The Farmers curve is a graph of the cumulative probability versus consequence for some activity, industry, or design, as shown in [Figures 20.1](#) and [20.2](#). This curve

**TABLE 20.10**

Risk Conversion Values for Different Risk Factors

Risk Factors	Risk Conversion (RF) Factor	Computed RF Value
Origin	Natural/human made	20
Severity	Ordinary/catastrophic	30
Volition	Voluntary/involuntary	100
Effect	Delayed/immediate	30
Controllability	Controlled/uncontrolled	5–10
Familiarity	Old/new	10
Necessity	Necessary/luxury	1
Costs	Monetary/nonmonetary	NA
Origin	Industrial/regulatory	NA
Media	Low profile/high profile	NA

Note: NA, not available.

**TABLE 20.11**

Classification of Common Risks

Voluntary			Involuntary		
Source	Size	Immediate	Delayed	Immediate	Delayed
Human	Catastrophic	Aviation		Dam failure, building fire, nuclear accident	Pollution, building fire
Made	Ordinary	Sports, boating, automobiles	Smoking, occupation, carcinogens	Homicide	
Natural	Catastrophic			Earthquakes, hurricanes, tornadoes, epidemics	
	Ordinary			Lighting animal bites	Disease

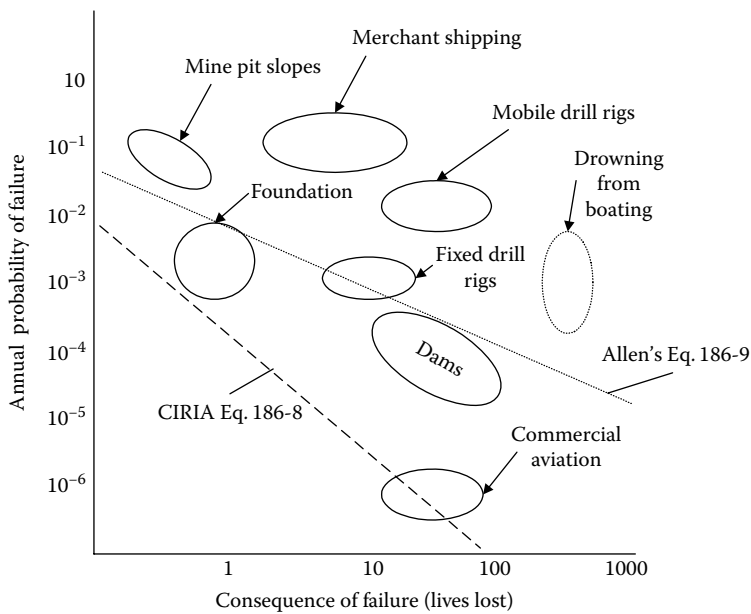

introduces a probabilistic approach in determining acceptable safety limits. Probability (or frequency) and consequence values are calculated for each level of risk generating a curve that is unique to the hazard of concern. The area to the right (outside) of the curve is generally considered unacceptable because the probability and consequence values are higher than the average value delineated by the curve. The area to the left (inside) of the curve is considered acceptable because probability and consequence values are less than the estimated value of the curve.

*Method of revealed preferences:* The method of revealed preferences provides a comparison of risk versus benefit and categorization for different risk types. The basis for this relationship is that risks are not taken unless there is some form of benefit. Benefit may be monetary or some other item of worth such as pleasure. The different risk types are for the risk category of voluntary versus involuntary actions as shown in [Figure 20.16](#).

*Magnitudes of risk consequence:* Another factor affecting the acceptance of risk is the magnitude of consequence of the event that can result from some failure. In general, the larger the consequence, the less the likelihood that this event may occur. This technique has been used in several industries to demonstrate the location of the industry within societies' risk acceptance levels based on consequence magnitude as shown in [Figure 20.17](#). Further evaluation has resulted in several estimates for the relationship between the accepted

**FIGURE 20.16**  
Accepted risk of voluntary and involuntary activities.

**FIGURE 20.17**  
Comparison of risk and control costs.

probability of failure and the magnitude of consequence for failure as provided by Allen in 1981 and called herein the CIRIA (Construction Industry Research and Information Association) equation:

$$P_f = 10^{-4} \frac{KT}{n} \quad (20.8)$$

where

$T$  is the life of the structure

$K$  is a factor regarding the redundancy of the structure

$n$  is the number of people exposed to risk

Another estimate is Allen's equation that is given by

$$P_f = 10^{-5} \frac{TA}{W\sqrt{n}} \quad (20.9)$$

where

$T$  is the life of the structure

$n$  is the number of persons exposed to risk

$A$  and  $W$  are factors regarding the type and redundancy of the structure

Equation 20.8 offers a lower bound, whereas Equation 20.9 offers a middle line.

*Risk reduction cost-effectiveness ratio:* Another measuring tool to assess risk acceptance is the determination of risk reduction effectiveness:

$$\text{Risk reduction effectiveness} = \frac{\text{Cost}}{\Delta \text{Risk}} \quad (20.10)$$

where the cost should be attributed to risk reduction and  $\Delta \text{Risk}$  is the level of risk reduction as follows:

$$\Delta \text{Risk} = (\text{Risk before mitigation action}) - (\text{Risk after mitigation action}) \quad (20.11)$$

The difference in Equation 20.11 is also called the *benefit attributed to a risk reduction action*. Risk effectiveness can be used to compare several risk reduction efforts. The initiative with the smallest risk effectiveness provides the most benefit for the cost. Therefore, this measurement may be used to help determine an acceptable level of risk. The inverse of this relationship may also be expressed as cost-effectiveness.

*Risk comparisons:* This technique uses the frequency of severe incidents to directly compare risks between various areas of interest to assist in justifying risk acceptance. Risks can be presented in different ways that can impact how the data are used for decisions. Often values of risk are manipulated in different forms for comparison reasons as demonstrated in [Table 20.12](#). Comparison of risk values should be taken in the context of the values' origin and uncertainties involved.

**TABLE 20.12****Ways to Identify Risk of Death**

<b>Ways to Identify Risk of Death</b>	<b>Summary</b>
Number of fatalities	This measure shows the impact in terms of the number of fatalities on society. Comparison of these values is cautioned since the number of persons exposed to the particular risk may vary. Also, the time spent performing the activity may vary. Different risk category types should also be considered to compare fatality rates.
Annual mortality rate/ individual	This measure shows the mortality risk normalized by the exposed population. This measure adds additional information about the number of exposed persons; however, the measure does not include the time spent on the activity.
Annual mortality	This measure provides the most complete risk value since the risk is normalized by the exposed population and the duration of the exposure.
Loss of life exposure (LLE)	This measure converts a risk into a reduction in the expected life of an individual. It provides a good means of communicating risks beyond probability values.
Odds	This measure is a layman format for communicating probability, for example, 1 in 4.

This technique is most effective for comparing risks that invoke the same human perceptions and consequence categories. Comparing risks of different categories is cautioned because the differences between risk and perceived safety may not provide an objective analysis of risk acceptance. The use of risk conversion factors may assist in transforming different risk categories. Conservative guidelines for determining risk acceptance criteria can be established for voluntary risks to the public from the involuntary risk of natural causes.

#### **20.4.1.1 Rankings Based on Risk Results**

Another tool for risk management is the development of risk ranking. The elements of a system within the objective of analysis can be analyzed for risk and consequently ranked. This relative ranking may be based on the failure probabilities, failure consequences, risks, or other alternatives with concern toward risk. Generally, risk items ranked highly should be given high levels of priority; however, risk management decisions may consider other factors such as costs, benefits, and effectiveness of risk reduction measures. The risk ranking results may be presented graphically as needed.

#### **20.4.1.2 Decision Analysis**

Decision analysis provides a means for systematically dealing with complex problems to arrive at a decision. Information is gathered in a structured manner to provide the best answer to the problem. A decision generally deals with three elements: alternatives, consequences, and preferences. The alternatives are the possible choices for consideration. The consequences are the potential outcomes of a decision. Decision analysis provides methods for quantifying preference trade-offs for performance along multiple decision attributes while taking into account risk objectives. Decision attributes are the performance scales that measure the degree to which objectives are satisfied. For example, one possible attribute is reducing the lives lost for the objective of increasing safety. Additional examples of objectives may include minimizing the cost, maximizing utility, maximizing reliability, and

maximizing profit. The decision outcomes may be affected by uncertainty; however, the goal is to choose the best alternative with the proper consideration of uncertainty. The analytical depth and rigor for decision analysis depends on the desired detail in making the decision. Cost–benefit analysis, decision trees, influence diagrams, and the analytic hierarchy process are some of the tools to assist in decision analysis. Also, decision analysis should consider constraints, such as availability of system for inspection, availability of inspectors, preference of certain inspectors, and availability of inspection equipment.

### 20.4.1.3 Cost–Benefit Analysis

Risk managers commonly weigh various factors including cost and risk. The analysis of three different alternatives is shown graphically in Figure 20.18 as an example. The graph shows that alternative (C) is the best choice because the level of risk and cost is less than alternatives (A) and (B). However, if the only alternatives were A and B, the decision would be more difficult. Alternative (A) has higher cost and lower risk than alternative (B); alternative (B) has higher risk but lower cost than alternative (A). A risk manager needs to weigh the importance of risk and cost in making this decision and availability of resources and make use of risk-based decision analysis.

Risk–benefit analysis can also be used for risk management. Economic efficiency is important to determine the most effective means of expending resources. At some point, the costs for risk reduction do not provide adequate benefit. This process compares the costs and risk to determine where the optimal risk value is on a cost basis. This optimal value occurs, as shown in Figure 20.19, when costs to control risk are equal to the risk cost due to the consequence (loss). Investing resources to reduce low risks below this equilibrium point is not providing a financial benefit. This technique may be used when cost values can be attributed to risks. This analysis might be difficult to perform for certain risks such as risk to human health and environmental risks because the monetary values are difficult to estimate for human life and the environment.

**FIGURE 20.18**

Risk benefit for three alternatives.

**FIGURE 20.19**  
Comparison of risk and control costs.

The present value of incremental costs and benefits can be assessed and compared among alternatives that are available for risk mitigation or system design. Several methods are available to determine which, if any, option is most worth pursuing. In some cases, no alternative will generate a net benefit relative to the base case. Such a finding would be used to argue for pursuit of the base case scenario. The following are the most widely used present value comparison methods: (1) NPV, (2) benefit–cost ratio, (3) internal rate of return, and (4) payback period. NPV method requires that each alternative need to meet the following criteria to warrant investment of funds: (1) having a positive NPV and (2) having the highest NPV of all alternatives considered. The first condition insures that the alternative is worth undertaking relative to the base case, for example, it contributes more in incremental benefits than it absorbs in incremental costs. The second condition insures that maximum benefits are obtained in a situation of unrestricted access to capital funds. The NPV can be calculated as follows:

$$NPV = \sum_{t=0}^k \frac{(B-C)_t}{(1+r)^t} = \sum_{t=0}^k \frac{B_t}{(1+r)^t} - \sum_{t=0}^k \frac{C_t}{(1+r)^t} \quad (20.12)$$

where

$B$  is the future annual benefit in constant dollars

$C$  is the future annual cost in constant dollars

$r$  is the annual real discount rate

$k$  is the number of years from the base year over which the project will be evaluated

$t$  is an index running from 0 to  $k$  representing the year under consideration

The benefit of a risk mitigation action can be assessed as follows:

$$\text{Benefit} = \text{Unmitigated risk} - \text{Mitigated risk.} \quad (20.13)$$

The cost in Equation 20.13 is the cost of the mitigation action. The benefit minus the cost of mitigation can be used to justify the allocation of resources. The benefit-to-cost ratio can be computed and may also be helpful in decision making. The benefit-to-cost ratio ( $B/C$ ) can be computed as

$$\text{Benefit-to-cost ratio } (B/C) = \frac{\text{Benefit}}{\text{Cost}} = \frac{\text{Unmitigated risk} - \text{Mitigated risk}}{\text{Cost of mitigated action}} \quad (20.14)$$

Cost of mitigation action ratios greater than one are desirable. In general, the larger the ratio, the better the mitigation action.

Accounting for the time value of money would require defining the benefit–cost ratio as the present value of benefits divided by the present value of costs. The benefit–cost ratio can be calculated as follows:

$$\frac{B}{C} = \frac{\sum_{t=0}^k \frac{B_t}{(1+r)^t}}{\sum_{t=0}^k \frac{C_t}{(1+r)^t}} \quad (20.15)$$

where

$B_t$  is the future annual benefit in constant dollars

$C_t$  is the future annual cost in constant dollars

$r$  is the annual real discount rate

$t$  is an index running from 0 to  $k$  representing the year under consideration

A proposed activity with a  $B/C$  ratio of discounted benefits to costs of 1 or more is expected to return at least as much in benefits as it costs to undertake, indicating that the activity is worth undertaking.

The internal rate of return ( $IRR$ ) is defined as the discount rate that makes the present value of the stream of expected benefits in excess of expected costs zero. In other words, it is the highest discount rate at which the project will not have a negative  $NPV$ . To apply the  $IRR$  criterion, it is necessary to compute the  $IRR$  and then compare it with a base rate of, say, a 7% discount rate. If the real  $IRR$  is less than 7%, the project would be worth undertaking relative to the base case. The  $IRR$  method is effective in deciding whether or not a project is superior to the base case; however, it is difficult to utilize it for ranking projects and deciding among mutually exclusive alternatives. Project rankings established by the  $IRR$  method might be inconsistent with those of the  $NPV$  criterion. Moreover, a project might have more than one  $IRR$  value, particularly when a project entails major final costs, such as cleanup costs. Solutions to these limitations exist in capital budgeting procedures and practices that are often complicated or difficult to employ in practice and present opportunities for error.

The payback period measures the number of years required for net undiscounted benefits to recover the initial investment in a project. This evaluation method favors projects with near-term and more certain benefits and fails to consider benefits beyond the payback period. The method does not provide information on whether an investment is worth undertaking in the first place.

The previous models for cost–benefit analysis presented in this section do not account for the full probabilistic characteristics of  $B$  and  $C$  in their treatment. Concepts from reliability

assessment 4 can be used for this purpose. Assuming  $B$  and  $C$  to be normally distributed, a benefit–cost index ( $f_{B/C}$ ) can be defined as follows:

$$\beta_{B/C} = \frac{\mu_B - \mu_C}{\sqrt{\sigma_B^2 + \sigma_C^2}} \quad (20.16)$$

where  $\mu/J$  and  $\sigma$  are the mean and standard deviation. The failure probability can be computed as

$$P_{f,B/C} = P(C > B) = 1 - \Phi(\beta) \quad (20.17)$$

In the case of lognormally distributed  $B$  and  $C$ , the benefit–cost index ( $f_{B/C}$ ) can be computed as

$$\beta_{B/C} = \frac{\ln \left( \frac{\mu_B}{\mu_C} \sqrt{\frac{\delta_C^2 + 1}{\delta_B^2 + 1}} \right)}{\sqrt{\ln [(\delta_B^2 + 1)(\delta_C^2 + 1)]}} \quad (20.18)$$

where  $\delta$  is the coefficient of variation. Equation 20.18 also holds for the case of lognormally distributed  $B$  and  $C$ . In the case of mixed distributions or cases involving basic random variables of  $B$  and  $C$ , the advanced second moment method or simulation method can be used. In cases where benefit is computed as revenue minus cost, benefit might be correlated with cost requiring the use of other methods.

### Example 20.2 Protection of Critical Infrastructure

This example is used to illustrate the cost of cost–benefit analysis using a simplified decision situation. As an illustration, assume that there is a 0.01 probability of an attack on a facility containing hazardous material during the next year. If the attack occurs, the probability of a serious release to the public is 0.01 with a total consequence of \$100B. The total consequence of an unsuccessful attack is negligible. The unmitigated risk can therefore be computed as

$$\text{Unmitigated risk} = 0.01(\$0.01)(100B) = \$10M.$$

If armed guards are deployed at each facility, the probability of attack can be reduced to 0.001 and the probability of serious release if an attack occurs can be reduced to 0.001. The cost of the guards for all plants is assumed to be \$100M per year. The mitigated risk can therefore be computed as

$$\text{Mitigated risk} = 0.001(0.001)(\$100B) = \$0.10M.$$

The benefit in this case is

$$\text{Benefit} = \$10M - \$0.1M \quad \text{or} \quad \sim \$10M.$$

The benefit-to-cost ratio is about 0.1. Therefore, the \$100M cost might be difficult to justify.

### 20.4.2 Risk Mitigation

A risk mitigation strategy can be presented from a financial point of view. Risk mitigation in this context can be defined as an action to either reduce the probability of an adverse event occurring or reduce the adverse consequences if it does occur. This definition captures the essence of an effective management process of risk. If implemented correctly a successful risk mitigation strategy should reduce any adverse (or downside) variations in the financial returns from a project, which are usually measured by either (1) the NPV defined as the difference between the present value of the cash flows generated by a project and its capital cost and calculated as part of the process of assessing and appraising investments or (2) the IRR defined as the return that can be earned on the capital invested in the project, that is, the discount rate that gives an NPV of zero, in the form of the rate that is equivalent to the yield on the investment.

Risk mitigation involves direct costs like increased capital expenditure or the payment of insurance premiums, hence it might reduce the average overall financial returns from a project. This reduction is often a perfectly acceptable outcome, given the risk aversion of many investors and lenders. A risk mitigation strategy is the replacement of an uncertain and volatile future with one where there is less exposure to adverse risks and so less variability in the return, although the expected NPV or IRR may be reduced. These two aspects are not necessarily mutually exclusive. Increasing risk efficiency by simultaneously improving the expected NPV or IRR and simultaneously reducing the adverse volatility is sometimes possible and should be sought. Risk mitigation should cover all phases of a project from inception to closedown or disposal.

Four primary ways are available to deal with risk within the context of a risk management strategy as follows:

- Risk reduction or elimination
- Risk transfer, for example, to a contractor or an insurance company
- Risk avoidance
- Risk absorbance or pooling

These four methods are described in subsequent sections.

*Risk reduction or elimination:* Risk reduction or elimination is often the most fruitful form for exploration. For example, could a design of a system be amended so as to reduce or eliminate either the probability of occurrence of a particular risk event or the adverse consequences if it occurs? Alternatively, could the risks be reduced or eliminated by retaining the same design but using different materials or a different method of assembly? Other possible risk mitigation options in this category include as examples: a better labor relations policy to minimize the risk of stoppages, training of staff to avoid hazards, better site security to avoid theft and vandalism, a preliminary investigation of possible site pollution, advance ordering of key components, noise abatement measures, good signposting, and liaisons with the local community.

*Risk transfer:* A general principle of an effective risk management strategy is that commercial risks in projects and other business ventures should be borne wherever possible by the party that is best able to manage them, and thus mitigate the risks. Contracts and financial agreements are the principal forms to transfer risks. Companies specializing in risk transfer can be consulted that could appropriately meet the needs of a project. Risks can be transferred alternately to an insurance company which, in return for a payment

(i.e., premium) linked to the probability of occurrence and severity associated with the risk, is obliged by the contract to offer compensation to the party affected by the risk. Insurance coverage can range from straight insurance for expensive risks with a low probability, such as fire, through performance bonds, which ensure that the project will be completed if the contractor defaults, to sophisticated financial derivatives such as hedge contracts to avoid risks such as unanticipated losses in foreign exchange markets.

*Risk avoidance:* A most intuitive way of avoiding a risk is to avoid undertaking the project in a way that involves that risk. For example, if the objective is to generate electricity but a nuclear power source, although cost efficient, is considered to have a high risk due to potentially catastrophic consequences, even after taking all reasonable precautions, the practical solution is to turn to other forms of fuel to avoid that risk. Another example would be the risk that a particularly small contractor would go bankrupt. In this case, the risk could be avoided by using a well-established contractor for that particular job.

*Risk absorbance and pooling:* Cases where risks cannot, or cannot economically, be eliminated, transferred, or avoided, they must be absorbed if the project is to proceed. Normally, a sufficient margin in the project's finances needs to be created to cover the risk event should it occur. However, it is not always essential for one party alone to bear all these absorbed risks. Risks can be reduced through pooling possibly through participation in a consortium of contractors, when two or more parties are able to exercise partial control over the incidence and impact of risk. Joint ventures and partnerships are other examples of organizational forms for pooling risks.

*Uncertainty characterization:* Risk can be mitigated through proper uncertainty characterization. The presence of improperly characterized uncertainty could lead to higher adverse event occurrence likelihood and consequences. Also, it could result in increasing estimated cost margins as a means of compensation. Therefore, risk can be reduced by a proper characterization of uncertainty. The uncertainty characterization can be achieved through data collection and knowledge construction.

---

## 20.5 Risk Communication

*Risk communication* can be defined as an interactive process of exchange of information and opinion among stakeholders such as individuals, groups, and institutions. It often involves multiple messages about the nature of risk or expressing concerns, opinions, or reactions to risk managers or to legal and institutional arrangements for risk management. Risk communication greatly affects risk acceptance and defines the acceptance criteria for safety.

Risk communication provides the vital link between the risk assessors, risk managers, and the public to understand risk. However, this does not necessarily mean that risk communication will always lead to agreement among different parties. An accurate perception of risk provides for rational decision making. The Titanic was deemed an unsinkable ship, yet was lost on its maiden voyage. Space shuttle flights were perceived to be safe enough for civilian travel until the Space Shuttle Challenger disaster. These disasters obviously had risks that were not perceived as significant until after the disaster. Risk communication is a dynamic process that must be considered prior to management decisions.

The communication process deals with technical information about controversial issues. Therefore, it needs to be skillfully performed by risk managers and communicators who might be viewed as adversaries to the public. Risk communication between risk assessors and risk managers is necessary to effectively apply risk assessments in decision making. Risk managers must participate in determining the criteria for determining what risk is acceptable and unacceptable. This communication between the risk managers and risk assessors is necessary for a better understanding of risk analysis in making decisions.

Risk communication also provides the means for risk managers to gain acceptance and understanding by the public. Risk managers need to go beyond the risk assessment results and consider other factors in making decisions. One of these concerns is politics, which is largely influenced by the public. Risk managers often fail to convince the public that risks can be kept to acceptable levels. Problems with this are shown by the public's perception of toxic waste disposal and nuclear power plant operation safety. As a result of the public's perceived fear, risk managers may make decisions that are conservative to appease the public.

The value of risk calculated from risk assessment is not the only consideration for risk managers. All risks are not created equal and society has established risk preferences based on public preferences. Decision makers should take these preferences into consideration when making decisions concerning risk.

To establish a means of comparing risks based on the society preferences, risk conversion factor (RCF) may be used. The RCF expresses the relative importance of different attributes concerning risk. An example of possible risk conversion factors is shown in [Table 20.10](#). These values were determined by inferences of public preferences from statistical data with the consequence of death considered.

For example, the voluntary and involuntary classification depends on whether the events leading to the risk are under the control of the persons at risk or not, respectively. Society, in general, accepts a higher level of voluntary risk than involuntary risk by an estimated factor of 100. Therefore, an individual will accept a voluntary risk that is 100 times greater than an involuntary risk.

The process of risk communication can be enhanced and improved in three aspects: (1) the process, (2) the message, and (3) the consumers. The risk assessment and management process needs to have clear goals with openness, balance, and competence. The contents of the message should account for audience orientation and uncertainty, provide risk comparison, and be complete. There is a need for consumer's guides that introduce risks associated with a specific technology, the process of risk assessment and management, acceptable risk, decision making, uncertainty, costs and benefits, and feedback mechanisms. Improving risk literacy of consumers is an essential component of the risk communication process.

The USACE has a 1992 Engineering Pamphlet (EP) on risk communication (EP 1110-2-8). The following are the guiding considerations in communicating risk:

- Risk communication must be free of jargon
- Consensus of expert needs to be established
- Materials must be cited and their sources must be credible
- Materials must be tailored to audience
- The information must be personalized to the extent possible
- Motivation discussion should stress a positive approach and the likelihood of success
- Risk data must be presented in a meaningful manner

## 21.1 Introduction

The North American power network may be considered the largest and most complex machine in the world—its transmission lines connect all the electric generation and distribution on the continent. In that respect, it exemplifies many of the complexities of electric power infrastructure and how technological innovation combined with efficient markets and policies can address them. This network represents an enormous investment, including over 15,000 generators in 10,000 power plants, and hundreds of thousands of miles of transmission lines and distribution networks, whose estimated worth is over U.S. \$800 billion. In 2000, transmission and distribution cables alone were valued at U.S. \$358 billion [9–16]. The National Academy of Engineering classified North American electric power grid as the greatest engineering achievement of the twentieth century. Today, the North American electric power grid is a network of approximately 10,000 power plants, 450,000 miles of high-voltage (>100 kV) transmission lines, over 6 million miles of lower voltage distribution lines in the United States, and more than 15,000 substations. The transmission system is an interstate grid whose primary purpose is to connect generating plants with electrical load centers like cities and with high demand commercial and industrial facilities. In turn, the local distribution system provides for service to residential, commercial, and small business customers.

Through the North American electricity infrastructure every user, producer, distributor, and broker of electricity buys and sells, competes, and cooperates in an *electric enterprise*. Every industry, every business, every store, and every home is a participant, active or passive, in this continent-scale conglomerate. Over the last decade and during the next few years, the electric enterprise will undergo dramatic transformation as its key participants—the traditional electric utilities—respond to deregulation, competition, renewable energy portfolio standards, tightening environmental/land-use restrictions, and other global trends.

Most of the systems currently in place were built by and for the regulated monopoly utility industry and are not fully prepared to handle the increasingly larger and faster changes in markets and technologies on both the supply and consumer side. It is essential to assume that these changes will continue and the infrastructure must become more flexible and adaptable to deal with them. Our long-term vision is to tie generation, transmission, distribution, and end use into a coherent network with ubiquitous secure data, information, and knowledge to enable best decisions for each stakeholder.

In addition, this network has evolved without formal analysis of the system-wide implications of this evolution, including its diminished transmission and generation

shock-absorber capacity under the forces of deregulation, the digital economy, and interaction with other infrastructures. Only recently, with the advent of deregulation, unbundling, and competition in the electric power industry, has the possibility of power delivery beyond neighboring areas become a key design and engineering consideration. Yet we still expect the existing grid to handle a growing volume and variety of long-distance, bulk power transfers. To meet the needs of a pervasively digital world that relies on microprocessor-based devices in vehicles, homes, offices, and industrial facilities, grid congestion and atypical power flows are increasing, as are customer reliability expectations.

In the months after Hurricane Sandy and over a decade after the massive power outages in 2003 in the United States, Canada, the United Kingdom, and Italy, the electric infrastructure's vulnerabilities were increasingly apparent [1–11]. Since then, progress, however slow, is being made to mitigate risks.

Much of the current federal effort is focused on transmission. Yet, it is essential that market design and grid expansion programs for both the transmission and distribution systems work together to maintain adequate levels of grid reliability and to provide customers with the services they demand. At the minimum, the system must support the addition of both conventional and renewable generators along with demand response and enable implementation of technologies like electric vehicles and solar on the distribution system. Much of the renewable energy and natural gas potential in the United States is located in areas that are remote from population centers, lack high demand for energy, and are not well connected to our national infrastructure for transmission of bulk electric power. The recent expansion of natural gas production in the United States has also affected the development of the grid. To achieve public policy objectives, sufficient transmission capacity must link new natural gas-generating plants, onshore or offshore wind farms, solar plants, and other renewables to customers in order to serve the energy needs of homes and businesses and have the potential to replace significant portions of the oil used today in vehicle transportation.

New transmission will play a critical role in the transformation of the electric grid to enable public policy objectives, accommodate the retirement of older generation resources, increase transfer capability to obtain greater market efficiency for the benefit of consumers, and continue to meet evolving national, regional, and local reliability standards. To optimize the use of these natural gas sites and renewable energy resources, the necessary electric infrastructure must be installed, requiring both significant financial investments and cooperation at all levels on politically challenging items such as the siting of facilities and the routing of new transmission lines.

### **21.1.1 What Is the Problem?**

It is fair to ask: why should we make significant, ongoing investments in upgrading the electric grid?

Hurricane Sandy's widespread damage and the resulting extended outages certainly put a fine point on the answer, but the context is much broader than investing to withstand the occasional horrific superstorm. Simply put, if the United States is to remain economically competitive on a global scale, it must modernize its grid just as other nations are doing.

Currently, outages from all sources cost the U.S. economy somewhere between \$80 and \$188 billion annually. A 2011 competitiveness report by the World Economic Forum ranked

U.S. infrastructure below 20th among the world's nations in most of nine categories and below 30th for the quality of our air transport and electric power sectors. Clearly, the United States needs to invest in grid modernization simply to catch up with its global rivals.

### 21.1.2 What Is Needed to Speed Up Restoration?

In the months since Hurricane Sandy struck the East Coast with unprecedented fury, much discussion has focused on questions about power restoration in the Northeast: *Did* the smart grid help? Or *would* a smart grid have helped?

The questions are valid, and the short answer is unsatisfying: it depends. A longer answer is more helpful, because it allows us to consider the drivers of grid modernization, the concepts governing a *self-healing* grid, and what we need to do to maximize the benefits of future investments.

Detailed, postevent analysis will be needed to ascertain whether smart grid technology did in fact soften Sandy's impact or speed up power restoration. Meanwhile, let's place the storm and its impacts in context.

First, it needs to be understood that a massive, physical assault on the scale of the October 2012 superstorm is bound to overwhelm the power infrastructure, at least temporarily. No amount of money or technology can guarantee uninterrupted electric service under such circumstances.

Second, the power industry in the United States is just beginning to adapt to a wider spectrum of risk. It is noteworthy that both the number and frequency of annual, weather-caused, major outages have increased since the 1950s. Between the 1950s and 1980s, those outages increased from 2 to 5 each year. In the period 2008–2012, those outages increased to between 70 and 130 per year. In that 5-year period, weather-related outages accounted for 66% of power disruptions, which affected up to 178 million customers (meters).

This adaptation process continues as we implement strategies, technologies, and practices that will harden the grid and improve restoration performance after a physical disturbance. The investments so far in advanced metering infrastructure and the coming wave of investment in distribution automation (DA) are but the beginning of a multidecade, multibillion-dollar effort to achieve an end-to-end, intelligent, secure, resilient, and self-healing system.

Third, cost-effective investments to harden the grid and support resilience will vary by region, by utility, by the legacy equipment involved, and even by the function and location of equipment within a utility's service territory.

In Sandy's case, coastal areas were subject to storm surges and flooding, while inland, high winds and lashing rain produced the most damage. Improved hardening and resilience for distribution systems in those different environments would take different forms. Underground substations along the coasts may have to be rebuilt on the surface, while it might be cost-effective to perform *selective undergrounding* for some overhead lines further inland.

The one generalization we can make, however, is that the pursuit of an intelligent, self-healing grid has some common characteristics that will make the grid highly reliable in most circumstances—certainly in cases where disruptions are less catastrophic than Hurricane Sandy. Additional, location-specific steps based on rational risk assessment also can be taken by utilities and customers.

The economic benefits of a modernized grid will accrue as investments are made. Indeed, in my view, our twenty-first-century digital economy depends on us making these investments, regardless of the prognosis for more extreme weather to come as our climate changes.

In this chapter, the security, agility, and robustness/survivability of large-scale power delivery infrastructure facing new threats and unanticipated conditions is presented. In addition, we focus in part on challenges associated with development of a smart self-healing electric power grid for enhanced system security, reliability, efficiency, and quality.

---

## 21.2 Electricity Enterprise: Today and Tomorrow

### 21.2.1 Where Are We?

The existing power delivery system is vulnerable to natural disasters and intentional attack. Regarding the latter, a successful terrorist attempt to disrupt the power delivery system could have adverse effects on national security, the economy, and the lives of every citizen.

Both the importance and difficulty of protecting power systems have long been recognized. In 1990, the Office of Technology Assessment (OTA) of the U.S. Congress issued a detailed report, *Physical Vulnerability of the Electric System to Natural Disasters and Sabotage*, concluding: “Terrorists could emulate acts of sabotage in several other countries and destroy critical [power system] components, incapacitating large segments of a transmission network for months. Some of these components are vulnerable to saboteurs with explosives or just high-powered rifles.” The report also documented the potential cost of widespread outages, estimating them to be in the range of \$1–\$5 per kW h of disrupted service, depending on the length of outage, the types of customers affected, and a variety of other factors. In the New York City outage of 1977, for example, damage from looting and arson alone totaled about \$155 million—roughly half of the total cost.

The reality of a coordinated attack has raised the issue of security to be considered along with power systems’ reliability, which posits more random and independent failures. The system’s vulnerability to natural disasters and physical attacks has long been recognized, but this vulnerability has significantly increased in recent years, in part because the system is operating closer to its capacity and in part because terrorist attacks are no longer hypothetical.

The situation has become even more complex because accounting for all critical assets includes thousands of transformer, line reactors, series capacitors, and transmission lines. Protection of *all* the widely diverse and dispersed assets is impractical because there are so many involved:

- Over 450,000 miles of HV lines (100 kV and above)
- Over 6644 transformers in the Eastern Interconnection
- Over 6000 HV transformers in the North American Interconnection (of which <300 are critical assets)
- Control centers
- Interdependence with gas pipelines
- Compressor stations
- Dams
- Rail lines
- Telecommunication equipment (monitoring and control of the system)

As an example, trends show that worldwide cyber attacks are on the rise; the number of documented attacks and intrusions has been rising very rapidly in recent years. Due to

the increasingly sophisticated nature and speed of some malicious code, intrusions, and denial-of-service attacks, human response may be inadequate. Relatively little infrastructure (especially transmission lines) has been added to handle increased demand with an adequate safety cushion.\* Some trends and documented nonsensitive modes of attack are shown in Figures 21.1 and 21.2.

**FIGURE 21.1**

Attack trends: Documented network intrusion attempts (\*\*, from CERT) and infection attempts (\*, analysis by Symantec Security Response using data from Symantec, IDC, and ICSA).

**FIGURE 21.2**

Malicious codes' threat evolution: increased sophistication and much faster than a few years ago.

\* NERC (2001), Reliability Assessment 2001–2010.

Secure and reliable operation of these systems is fundamental to national and international economy, security, and quality of life. Their very interconnectedness makes them more vulnerable to global disruption, initiated locally by material failure, natural calamities, intentional attack, or human error.

In addition to the security problems associated with electric transmission systems, additional concerns arise with nuclear power systems. Nuclear power serves the United States as well as many countries around the world as a fairly reliable source of electricity that will not contribute to global warming producing carbon dioxide. In that sense, it is a *clean* source of electricity. But there are ways in which nuclear power can be a hazardous technology.

There are two pressing safety concerns with nuclear power in this age of terrorism. The first has to do with the spent fuel storage areas located outside and near the reactors. These spent fuel *swimming pools* are laden with a far higher inventory of radioactive material than is present in the reactor itself and are far less protected from attack than the reactor. If a 9/11 plane had hit the Indian Point nuclear plant spent fuel storage area (about 35 miles from New York City), it is possible that millions of people would have had to be evacuated to escape radiation and that parts of New York would have had to be abandoned. There might of course be solutions to avoid this catastrophic scenario, but they would add to the cost of nuclear power.

The other long-term safety concern is the eventual transportation of thousands of high-level nuclear waste canisters across open roads of the United States (through 43 states) on their way to a final resting place, for example, Yucca Mountain. These shipments would be enticing targets for terrorists. Technology may be able to ameliorate this type of accident, but it is currently not in place.

North American power network's transmission lines connect all generation and distribution on the continent to form a vertically integrated hierarchical network. The question is raised as to whether there is a unifying paradigm for the simulation, analysis, and optimization of time-critical operations (both financial transactions and actual physical control) in these multiscale, multicomponent, and distributed systems. In addition, mathematical models of interactive networks are typically vague (or may not even exist); moreover, existing and classical methods of solution are either unavailable, or are not sufficiently powerful. For the most part, no present methodologies are suitable for understanding their behavior.

Another important dimension is the effect of deregulation and economic factors on a particular infrastructure. While other and more populous countries, such as China and India, will have greater potential electricity markets and demands, the United States has the largest national market for electric power. Its electric utilities have been mostly privately owned, vertically integrated, and locally regulated. National regulations in areas of safety, pollution, and network reliability also constrain their operations to a degree, but local regulatory bodies, mostly at the state level, have set their prices and their return on investment (ROI) and have controlled their investment decisions while protecting them from outside competition. That situation is now rapidly changing, state regulators are moving toward permitting and encouraging a competitive market in electric power.

The electric power grid was historically operated by separate utilities, each independent in its own control area and regulated by local bodies, to deliver bulk power from generation to load areas reliably and economically—as a noncompetitive, regulated monopoly,

**FIGURE 21.3**

Since the *crossover* point in about 1995, utility construction expenditures have lagged behind asset depreciation. This has resulted in a mode of operation of the system analogous to *harvesting the farm far more rapidly than planting new seeds*. *Utility construction expenditures and depreciation/amortization expense*: In recent years, the investor-owned utility industry's annual depreciation expenses have exceeded construction expenditures. The industry is now generally in a *harvest the assets* mode rather than an *invest in the future of the business* mode. (Data provided by EEL, *Historical Statistics of the Electric Utility Industry* and *EEI Statistical Yearbook*, © 2003, EPRI Inc., Palo Alto, CA. All rights reserved; Graph courtesy of EPRI, Palo Alto, CA.)

emphasis was on reliability (and security) at the expense of economy. Competition and deregulation have created multiple energy producers that must share the same regulated energy delivery network. Traditionally, new delivery capacity would be added to handle load increases, but because of the current difficulty in obtaining permits and the uncertainty about achieving an adequate rate of ROI, total circuit miles added annually are declining while total demand for delivery resources continues to grow. In recent years, the *shock absorbers* have been shrinking; for example, during the 1990s, actual demand in the United States increased some 35%, while capacity has increased only 18%, the most visible parts of a larger and growing U.S. energy crisis that is the result of years of inadequate investments in the infrastructure. According to Electric Power Research Institute (EPRI) analyses, since 1995 to the present, the amortization/depreciation rate exceeds utility construction expenditures (Figure 21.3).

As a result of these *diminished shock absorbers*, the network is becoming increasingly stressed, and whether the carrying capacity or safety margin will exist to support anticipated demand is in question. The complex systems used to relieve bottlenecks and clear disturbances during periods of peak demand are at great risk to serious disruption, creating a critical need for technological improvements.

### **NORTH AMERICAN ELECTRICITY INFRASTRUCTURE VULNERABILITIES AND COST OF CASCADING FAILURES**

Attention to the grid has gradually increased after several cascading failures. The August 10, 1996, blackout cost was over \$1.5 billion and included all aspects of interconnected infrastructures and even the environment. Most recently, the August 13, 2003, outage is estimated to have a cost in the range of \$6–\$10 billions. Past disturbances in both the power grid give you some idea of how cascading failures work:

- November 1965—A cascaded system collapse blackout in 10 states in the Northeast United States affected about 30 million people.
- 1967—The Pennsylvania–New Jersey–Maryland (PJM) blackout occurred.
- May 1977—15,000 square miles and one million customers in Miami lost electricity.
- July 1977—In New York’s suburbs, lightning caused overvoltages and faulty protection devices, which caused 10 million people to lose power for over 24 h, resulting in widespread looting, over 4000 arrests, and ultimately, the ouster of New York City’s mayor.
- December 1978—Blackout in part of France due to voltage collapse.
- January 1981—1.5 million customers in Idaho, Utah, and Wyoming were without power for 7 h.
- March 1982—Over 900,000 lost power for 1.5 h due to high-voltage line failure in Oregon.
- December 1994—two million customers from Arizona to Washington state lost power.
- July 1996—A high-voltage line touched a tree branch in Idaho and fell. The resulting short circuit caused blackouts for two million customers in 14 states for approximately 6 h.
- August 1996—Following the July 2 blackout, two high-voltage lines fell in Oregon and caused cascading outages affecting over seven million customers in 11 Western states and two Canadian provinces.
- January 1998—Ice storms caused over three million people to lose power in Canada, New York, and New England.
- December 1998—San Francisco, California Bay Area blackout.
- July 1999—New York City blackout caused 300,000 people to be without power for 19 h.
- 1998–2001—Summer price spikes affect customers (infrastructure’s inadequacy affecting markets).
- Industry-wide Y2K readiness program identified telecommunication failure as the biggest source of risk of the lights going out on rollover to 2000.
- Western states’ suffered power crises in summer 2001 and its aftermath.
- Eastern United States and Canada face cascading outages on August 14, 2003.

### 21.3 Reliability Issues

Several cascading failures during the past 40 years spotlighted our need to understand the complex phenomena associated with power network systems and the development of emergency controls and restoration. Widespread outages and huge price spikes during the past few years raised public concern about grid reliability at the national level [6–10,16]. According to data from the North American Electric Reliability Corporation (NERC) and analyses from the EPRI, average outages from 1984 to the present have affected nearly 700,000 customers per event annually. Smaller outages occur much more frequently and affect tens to hundreds of thousands of customers every few weeks or months, while larger outages occur every 2–9 years and affect millions. Much larger outages affect seven million or more customers per event each decade. These analyses are based on data collected for the U.S. Department of Energy (DOE), which requires electric utilities to report system emergencies that include electric service interruptions, voltage reductions, acts of sabotage, unusual occurrences that can affect the reliability of bulk power delivery systems, and fuel problems [1,3–5,9,10,16,22].

Coupling these analyses with diminished infrastructure investments, and noting that the crossover point for the utility construction investment versus depreciation occurred in 1995 (Figure 21.3), we analyzed the number and frequency of major outages along with the number of customers affected during the decade 1991–2000, splitting it into the two time periods 1991–1995 and 1996–2000 (Figure 21.4a and b). Based on EPRI's analyses [1,14] of data in NERC's Disturbance Analysis Working Group (DAWG) database [1,9,10], 41% more outages affected 50,000 or more consumers in the second half of the 1990s than in the first half (58 outages in 1996–2000 versus 41 outages in 1991–1995). The average outage affected 15% more consumers from 1996 to 2000 than from 1991 to 1995 (average size per event was 409,854 customers affected in the second half of the decade versus 355,204 in the first half of the decade). In addition, there were 76 outages of size 100 megawatts (MW) or more in the second half of the decade, compared to 66 such occurrences in the first half. During the same period, the average lost load caused by an outage increased by 34%, from 798 MW during 1991–1995 to 1067 MW during 1996–2000 (Figure 21.4) [1,9,10,14].

Furthermore, there were 41% more outages affecting 50,000 or more consumers in the second half of the 1990s than in the first half (58 outages in 1996–2000 versus 41 outages in 1991–1995). In addition, between 1996 and 2000, outages affected 15% more consumers than they did between 1991 and 1995 (the average size per event was 409,854 customers affected in the second half of the decade versus 355,204 in the first half of the decade). Similar results were determined for a multitude of additional statistics such as the kilowatt magnitude of the outage and average load lost. These trends have persisted in this decade. NERC data show that during 2001–2005, we had 140 occurrences of over 100 MW dropped, and 92 occurrences of over 50,000 or more consumers affected.

The U.S. electric grid has been plagued by ever more and ever worse blackouts over the past 15 years. In an average year, outages total 92 min/year in the Midwest and 214 min in the Northeast. Japan, by contrast, averages only 4 min of interrupted service each year. The outage data exclude interruptions caused by extraordinary events such as fires or extreme weather.

We analyzed two sets of data, one from the U.S. DOE's EIA and the other from the NERC. Generally, the EIA database contains more events, and the NERC database gives more information about the events, including the date and time of an outage, the utility

**FIGURE 21.4**

(a) Power outages have steadily increased in the most recent decade, increasing the frequency and size of U.S. power outages 100 MW or more, affecting 50,000 or more consumers per event. (From Amin, M., U.S. electrical grid gets less reliable, *IEEE Spectrum*, 80, January 2011, <http://spectrum.ieee.org/energy/policy/us-electrical-grid-gets-less-reliable>.) Generally, a relatively small number of U.S. consumers experience a large number of outages; conversely, outages that affect a large number of consumers are quite rare; however, this plot could also indicate that the number of larger outages could be rising. (Data courtesy of NERC's DAWG database.) (b) U.S. electric power outages over 100 MW and affecting over 50,000 consumers during 2000–2009, adjusted for 0.9% annual increase in load and adjusted for change in reporting in 2003. (Using all the data from 2000 to 2009 and only counting the outages that met the less stringent requirements of the EIA-417R form used during 2000–2002.)

involved, the region affected, the quantity of load dropped, the number of customers affected, the duration of the outage, and some information about the nature of the event.

These two datasets each contain events not listed in the other dataset. In general, the EIA database contains more events, and the NERC database gives more information about the events. The narrative data in the NERC (and also the EIA) databases are sufficient to identify factors such as equipment failure or severe weather (or a combination of both!) that may have contributed to an outage. Establishment of precise cause is beyond the scope of most of the narratives. Both databases are extremely valuable sources of information and insight.

In both databases, a report of a single event may be missing certain data elements such as the amount of load dropped or the number of customers affected. In the NERC database, the amount of load dropped is given for the majority of the reported events, whereas the number of customers affected is given for less than half the reported events. In the EIA database, the number of customers affected is reported more frequently than the amount of load dropped.

In both sets, each 5-year period was worse than the preceding one: according to data assembled by the U.S. EIA for most of the past decade, there were 156 outages of 100 MW or more during 2000–2004; such outages increased to 264 during 2005–2009. The number of U.S. power outages affecting 50,000 or more consumers increased from 149 during 2000–2004 to 349 during 2005–2009, according to EIA (Figure 21.2).

In 2003, EIA changed their reporting form from EIA-417R to OE-417. Both forms were attached with descriptions of reporting requirements (pp. 3 and 6, respectively). In all, the reporting requirements are very similar, with OE-417 being a little more stringent. The main change in the requirement affecting the aforementioned figures is that all outages greater than 50,000 customers for 1 h or more be reported in OE-417, where it was only required for 3 h or more in EIA-417R prior to 2003. Adjusting for the change in reporting in 2003 (using all the data from 2000 to 2009 and only counting the outages that met the less stringent requirements of the EIA-417R form used from 2000 to 2002): there were 152 outages of 100 MW or more during 2000–2004; such outages increased to 248 during 2005–2009. The number of U.S. power outages affecting 50,000 or more consumers increased from 130 during 2000–2004 to 272 during 2005–2009 (Figure 21.4b).

In summary, the number of outages adjusted for 0.9% annual increase in load and adjusted for change in reporting in 2003 is shown in the following table:

	Occurrences of 100 MW or More	Occurrences of 50,000 or More Consumers
2000–2004	152	130
2005–2009	248	272

As an energy professional and electrical engineer, I cannot imagine how anyone could believe that in the United States, we should learn to *cope* with these increasing blackouts—and that we don't have the technical know-how, the political will, or the money to bring our power grid up to twenty-first-century standards. Coping as a primary strategy is ultimately defeatist.

### 21.3.1 Electricity Infrastructure: Interdependencies with Cyber and Digital Infrastructures

As the world grows more interconnected, we are becoming surrounded by complex networked systems. These systems consist of numerous components interlinked in

complicated webs. As a result of the number of components and their intricate interconnections, complex networked systems are extremely difficult to design, analyze, control, and protect. Despite these challenges, understanding complex networked systems is becoming critical. Many of our nation's critical infrastructures are complex interdependent/networked dynamical system of systems, including

- Electric power grids with overlays of sensor/communications/control systems and markets
- Fuel supply networks together with energy/oil/gas pipelines
- Telecommunications and satellite systems
- The Internet, computer networks, and the *cyber infrastructure*
- Transportation systems
- Energy markets, banking, and finance systems
- Environmental, consumer, societal, and policy macrosystems
- State and local water supply, emergency, and other services

Secure and reliable operation of complex increasingly interdependent infrastructure systems such as these is fundamental to our economy, security, and quality of life. Of particular importance is the uninterrupted availability of inexpensive, high-quality electric power and reliable, high-performance communication networks.

Electric power utilities typically own and operate at least parts of their own telecommunications systems that often consist of backbone fiber-optic or microwave connecting major substations, with spurs to smaller sites. Increased use of electronic automation raises significant issues regarding the adequacy of operational security. As is true of other critical infrastructures, increased use of automated technologies raises significant security issues, however:

- Reduced personnel at remote sites makes the sites more vulnerable to hostile threats.
- Interconnecting automation and control systems with public data networks makes them accessible to individuals and organizations, from any worldwide location using an inexpensive computer and a modem.
- Use of networked electronic systems for metering, scheduling, trading, or e-commerce imposes numerous financial risks associated with network failures.

In what follows we shall provide a brief overview of some key areas and present selected security aspects of operational systems, without discussing potentially sensitive material; these aspects include the following:

- Operational systems rely very heavily on the exchange of information among disparate systems.
- Utilities rely on very extensive private and leased telecommunication systems.
- Networking of these systems is expanding rapidly.
- This networking is expanding beyond utility doors, to encompass other utilities, corporations, and customers.

- Standard communication protocols and integration techniques are a *must*, despite the increased security risks.
- Increased security concerns in the aftermath of tragic events of September 11, 2001.
- Deregulation is increasing the incentives for unauthorized access to information.

As the power grids become heavily loaded with long-distance transfers, the already complex system dynamics becomes even more important. The potential for rare events but high-impact cascading phenomena represents just a few of many new science and technology concepts that are under development. Analysis and modeling of interdependent infrastructures (e.g., the electric power grid, together with protection systems, telecommunications, oil/gas pipelines, and energy markets) is especially pertinent. Regarding the latter, during the past four decades, much effort has been committed to better understand the dynamics of large-scale power systems in order to enhance security, quality, reliability, and availability (SQRA) of the overall system.

Specific attributes of SQRA are needed for electricity to meet the needs of the evolving digital society. Reliability and uninterruptability are practical necessities in digital enterprises. The digital society is expected (and designed) to be continuously operational, without interruption or denial of service. The interface between digital systems, processes, and enterprises and electric power delivery must support this reliability, with innovations spanning from the generation sources to the microchip. Similarly, availability of power is also a necessity. While higher reliability is nearly always a key objective for electric power suppliers, availability is the parameter with which users of sensitive digital equipment and processes are most concerned. Other concepts considered in our ongoing work include the following:

- *Self-healing and redundant*: Digital communications use a network of high-capacity nodes to route data efficiently and expeditiously. The interface between digital systems, processes, and enterprises and electric power delivery needs the same capability. A parallel or self-healing system may actually be less reliable (i.e., suffering more individual component failures) but still provide higher availability of power to critical loads.
- *Massive customization*: The digital revolution has revealed an inexhaustible appetite for instant and user-specific customization of service and support. The interface between digital systems, processes, and enterprises and electric power delivery must have this capability to support this revolution.
- *Rapid reconfiguration*: The digital world has demonstrated its ability to rapidly adjust to changing requirements. For example, the Internet evolved from a simple document-exchange system just a few years ago to the now familiar capabilities of e-mail, online transactions, and data presentation. Even newer technologies are now being implemented, such as video conferencing, voice-over IP, and civic systems such as web-based voting. The interface between digital systems, processes, and enterprises and electric power delivery must be able to emulate this rapid adaptive behavior to support the ongoing evolution of the digital society.

Today's accepted industry practice for power system performance measurements is the starting point for introducing new and more integrated performance metrics. The challenge is to bridge between independent mathematical models and performance metrics that are used at different levels of the power system. In some cases, the models

and these independent metrics may conflict with each other to the extent that improving performance in one area may detract from others. This independence stems from several distinct performance areas such as distribution customer availability or outage reporting, grid operating contingencies, monitoring of power quality variations, and measurements of transmission reliability. The way that each of these performance elements had been applied in the past depended on the area of interest in the power system. In addition, utility industry performance measurement practices and standards evolved via groups that represented their interests in either one of end use, distribution, transmission, or generation.

### 21.3.2 Electric Power Grids

Electric infrastructure, increasingly linked with other critical and tightly coupled interdependencies noted earlier, is becoming increasingly interconnected and complex, thus posing new challenges for its secure, reliable, and efficient operation. The infrastructure is a complex dynamic network, geographically dispersed, nonlinear, and interacting both among itself with communication systems, fuel supplies, and markets and with its human owners, operators, and users. No single entity has complete control over its operation, nor does any such entity have the ability to evaluate, monitor, and manage it in real time. In fact, the conventional mathematical methodologies that underpin today's modeling, simulation, and control paradigms are unable to handle the complexity in its dynamics, and its increasing interconnectedness.

At its most fundamental level, the network's transmission lines form a vertically integrated hierarchical network consisting of the generation layer and then three network levels [17]:

- The first level is the transmission network, which is a meshed network combining extrahigh voltage (above 300 kV) and high voltage (100–300 kV) connected to large generation units, very large customers, and neighboring transmission networks and to the subtransmission level via tie-lines.
- The second level is the subtransmission, which consists of a radial or weakly coupled network including some high voltage (100–300 kV) but typically 5–15 kV that is connected to large customers and medium-sized generators.
- The third level is distribution, which is typically a radial network including low voltage (110–115 or 220–240 V) and medium voltage (1–100 kV) connected to small generators, medium-sized customers, and local low-voltage networks for small customers.

Several pertinent theories on power system operating conditions have been provided in the literature; these contributions not only provide mathematical foundations but also include some guidance on how to measure and adapt to disturbances.

The varying nature and types of extreme disturbances coupled with their anticipated infrequent occurrences makes it desirable to take automated actions to stabilize the system, which may include system separation in a controlled and coordinated manner. Inadequacy of a well-coordinated overall defense plan makes it more difficult to prevent spreading of the disturbance.

As a subset, disturbance classification lends itself to quick reaction or even the ability to predict events. At the very least, a *snapshot* of the event will have been taken. This will mean that no event will go unnoticed. In the past, events have gone unnoticed.

Furthermore, the ability to predict and react would indicate that problems could be detected and mitigated much sooner. A system operator could be trained accordingly, while taking into account both communication delays and computer server status.

Besides these many operational, spatial, and energy levels, power systems are also multiscaled in the time domain, from nanoseconds to decades. The relative time of action for different types of events, from normal to extreme, varies depending on the nature and speed of the disturbance, and the need for coordination. The aforementioned system is multiscale in time, operational space, and its dynamics. The timescale of actions and operations within the power grid (often continental in scale) ranges from microseconds to milliseconds for wave effects and fast dynamics (such as lightning); milliseconds for switching overvoltages; 100 ms or a few cycles for fault protection; 1–10 s for tie-line load frequency control; 10 s to 1 h for economic load dispatch; 1 h to a day or longer for load management, load forecasting, and generation scheduling; and several years to a decade for new transmission or generation planning and integration.

---

## 21.4 Infrastructures under Threat

The recent natural disasters and the terrorist attacks of September 11 have exposed critical vulnerabilities in America's essential infrastructures: never again can the security of these fundamental systems be taken for granted. Electric power systems constitute *the* fundamental infrastructure of modern society. A successful terrorist attempt to disrupt electricity supplies could have devastating effects on the national security, the economy, and the lives of every citizen. Yet power systems have widely dispersed assets that can never be absolutely defended against a determined attack.

Because critical infrastructures touch all of us, the growing potential for infrastructure problems stems from multiple sources. These sources include system complexity, deregulation, economic effects, power-market impacts, terrorism, and human error. The existing power system is also vulnerable to natural disasters and intentional attacks. Ongoing efforts at NERC, DOE, and EPRI—including EPRI's Enterprise Information Security Program and Infrastructure Security Initiative—have highlighted utility-specific threats and the technologies to counteract them. Regarding the latter, a November 2001 EPRI assessment developed in response to the September 11, 2001, attacks highlights three different kinds of potential threats to the U.S. electricity infrastructure [1–3,12]:

- *Attacks upon the power system:* In this case, the electricity infrastructure itself is the primary target—with ripple effects, in terms of outages, extending into the customer base. The point of attack could be a single component, such as a critical substation, or a transmission tower. However, there could also be a simultaneous, multipronged attack intended to bring down the entire grid in a region of the United States. Similarly, the attack could target electricity markets, which because of their transitional status is highly vulnerable.
- *Attacks by the power system:* In this case, the ultimate target is the population, using parts of the electricity infrastructure as a weapon. Power plant cooling towers, for example, could be used to disperse chemical or biological agents.

- *Attacks through the power system:* In this case, the target is the civil infrastructure. Utility networks include multiple conduits for attack, including lines, pipes, underground cables, tunnels, and sewers. An electromagnetic pulse, for example, could be coupled through the grid to with the intention of damaging computer and/or telecommunications infrastructure.

Protection against all three modes of attack thus represents a potentially critical *showstopper* for realizing a digital economy and enabling customer-managed service networks. Indeed, if infrastructure security is not ensured, even maintaining current levels of productivity and service will be jeopardized. Conversely, deploying some of the advanced technologies needed to enhance security will have a positive effect on efforts to improve grid reliability and coordinate power system operations with those of other infrastructures.

Therefore, the imperative for enhancing security in the electric power system has reached a new level that demands industry attention. In order to address this imperative in a logical and deliberate way, we need to understand what is involved and how to measure the current and future levels of secure performance.

The technologies that support the operational control of electric networks range from energy management systems (EMSs) to remote field devices. Critical systems include the following.

#### **21.4.1 Energy Management System**

The objective of the EMS is to manage the production, purchasing, transmission, distribution, and sale of electric energy in the power system at a minimal cost with respect to safety and reliability. Management of the real-time operation of an electric power system is a complex task requiring interaction of human operators, computer systems, communications networks, and real-time data-gathering devices in power plants and substations. An EMS consists of computers, display devices, software, communication channels, and remote terminal units (RTUs) that are connected to other RTUs, control actuators, and transducers in power plants and substations. The main tasks that an EMS performs have to do with generator control and scheduling, network analysis, and operator training. Control of generation requires that the EMS maintain system frequency and tie-line flows while economically dispatching each generating unit. The management of the transmission network requires that the EMS monitor up to thousands of telemetered values, estimate the electrical state of the network, and inform the operator of the best strategy to handle potential outages that could result in an overload or voltage-limit violation. EMSs can have real-time two-way communication links between substations, power plants, independent system operators, and other utility EMSs.

#### **21.4.2 Supervisory Control and Data Acquisition System**

A supervisory control and data acquisition (SCADA) system supports operator control of remote (or local) equipment, such as opening or closing a breaker. A SCADA system provides three critical functions in the operation of an electric power system: data acquisition, supervisory control, and alarm display. It consists of one or more computers with appropriate applications software connected by a communications system to a number of RTUs placed at various locations to collect data, perform intelligent control of electrical system devices, and report results back to an EMS. SCADAs can also be used for

similar applications in natural gas pipeline transmission and distribution applications. A SCADA can have real-time communication links with one or more EMSs and hundreds of substations.

### 21.4.3 Remote Terminal Unit

RTUs are special-purpose microprocessor-based computers that contain analog-to-digital converters (ADCs) and digital-to-analog converters (DACs), digital inputs for status, and digital output for control. There are transmission substation RTUs and DA RTUs. Transmission substation RTUs are deployed at substation and generation facilities, where a large number of status and control points are required. DA RTUs are used to

- Control air switches and Var-compensation capacitor banks on utility poles
- Control pad-mounted switches
- Monitor and automate feeders
- Monitor and control underground networks
- Monitor, control, and automate smaller distribution substations

RTUs can also be used as indicated earlier in natural gas transmission and distribution. RTUs can be configured and interrogated using telecommunication technologies. They can have hundreds of real-time communication links with other substations, EMSs, and power plants.

### 21.4.4 Programmable Logic Controller

Programmable logic controllers (PLCs) have been used extensively in manufacturing and process industries for many years and are now being used to implement relay and control systems in substations. PLCs have extended I/O systems similar to transmission substation RTUs. The control outputs can be controlled by software residing in the PLC and via remote commands from a SCADA system. The PLC user can make changes in the software stored in EEPROM without making any major hardware or software changes. In some applications, PLCs with RTU-reporting capability may have advantages over conventional RTUs. PLCs are also used in many power plant and refinery applications. They were originally designed for use in discrete applications like coal handling. They are now being used in continuous control applications such as feed-water control. PLCs can have many real-time communication links inside and outside substations or plants.

### 21.4.5 Protective Relays

Protective relays are designed to respond to system faults and short circuits. When faults occur, the relays must signal the appropriate circuit breakers to trip and isolate the faulted equipment. Distribution system relaying must be coordinated with fuses and reclosures for faults while ignoring cold-load pickup, capacitor-bank switching, and transformer energization. Transmission-line relaying must locate and isolate a fault with sufficient speed to preserve stability, reduce fault damage, and minimize the impact on the power system. Certain types of *smart* protective relays can be configured and interrogated using telecommunication technologies.

#### 21.4.6 Automated Metering

Automated metering is designed to upload residential and/or commercial gas and/or electric meter data. These data can then be automatically downloaded to a PC or other device and transmitted to a central collection point. With this technology, real-time communication links exist outside the utility infrastructure.

#### 21.4.7 Plant-Distributed Control Systems

Plant-distributed control systems (DCSs) are plant-wide control systems that can be used for control and/or data acquisition. The I/O count can be higher than 20,000 data points. Often, the DCS is used as the plant data highway for communication to and from intelligent field devices, other control systems (such as PLCs), RTUs, and even the corporate data network for enterprise resource planning (ERP) applications. The DCS traditionally has used a proprietary operating system. Newer versions are moving toward open systems such as Windows NT and Sun Solaris. DCS technology has been developed with operating efficiency and user configurability as drivers, rather than system security. Additionally, technologies have been developed that allow remote access, usually via PC, to view and potentially reconfigure the operating parameters.

#### 21.4.8 Field Devices

Examples of field devices are process instrumentation such as pressure and temperature sensors and chemical analyzers. Other standard types of field devices include electric actuators. Intelligent field devices include electronics to enable field configuration and upload calibration data. These devices can be configured off-line. They also can have real-time communication links between plant control systems, maintenance management systems, stand-alone PCs, and other devices inside and outside the facility.

Security of these cyber and communication networks is fundamental to the reliable operation of the grid. As power systems rely more heavily on computerized communications and control, system security has become increasingly dependent on protecting the integrity of the associated information systems. Part of the problem is that existing control systems, which were originally designed for use with proprietary, stand-alone communication networks, were later connected to the Internet (because of its productivity advantages and lower costs), but without adding the technology needed to make them secure. Communication of critical business information and controlled sharing of that information are essential parts of all business operations and processes.

As the deregulation of the energy industry unfolds, information security will become more important. For the energy-related industries, the need to balance the apparently mutually exclusive goals of operating system flexibility with the need for security will need to be addressed from a business perspective. Key electric energy operational systems depend on real-time communication links (both internal and external to the enterprise). The functional diversity of these organizations has resulted in a need for these key systems to be designed with a focus on open systems that are user configurable to enable integration with other systems (both internal and external to the enterprise). In many cases, these systems can be reconfigured using telecommunication technologies. In nearly all cases, the systems dynamically exchange data in real time. This results in a need for highly reliable, secure control and information-management systems.

Power plant DCSs produce information necessary for dispatch and control. This requires real-time information flow between the power plant and the utility's control center, system

dispatch center, regulatory authorities, and so on. A power plant operating as part of a large wholesale power network may have links to an independent system operator, a power pool, and so on. As the generation business moves furthermore into market-driven competitive operation, both data integrity and confidentiality will become major concerns for the operating organizations.

Any telecommunication link that is even partially outside the control of the organization that owns and operates power plants, SCADA systems, or EMSs represents a potentially insecure pathway into the business operations of the company as well as a threat to the grid itself. The interdependency analyses done by most companies during Y2K preparations have identified these links and the system's vulnerability to their failures. Thus, they provide an excellent reference point for a cyber-vulnerability analysis.

In particular, monitoring and control of the overall grid system is a major challenge. Existing communication and information system architectures lack coordination among various operational components, which usually is the cause for the unchecked development of problems and delayed system restoration. Like any complex dynamic infrastructure system, the electricity grid has many layers and is vulnerable to many different types of disturbances. While strong centralized control is essential to reliable operations, this requires multiple, high-data-rate, two-way communication links, a powerful central computing facility, and an elaborate operation-control center, all of which are especially vulnerable when they are needed most—during serious system stresses or power disruptions. For deeper protection, intelligent-distributed control is also required, which would enable parts of the network to remain operational and even automatically reconfigure in the event of local failures or threats of failure.

---

## 21.5 The Dilemma: Security and Quality Needs

The specter of terrorism raises a profound dilemma for the electric power industry: How to make the electricity infrastructure more secure without compromising the productivity advantages inherent in today's complex, highly interconnected electric networks? Resolving this dilemma will require both short-term and long-term technology development and deployment, affecting some of the fundamental characteristics of today's power systems:

- *Centralization/decentralization of control:* For several years, there has been a trend toward centralizing control of electric power systems. Emergence of regional transmission organizations (RTOs) as agents of wide-area control, for example, offers the promise of greatly increased efficiency and improved customer service. But if terrorists can exploit the weaknesses of centralized control, security would seem to demand that smaller, local systems become the system configuration of choice. In fact, strength and resilience in the face of attack will increasingly rely upon the ability to bridge simultaneous top-down and bottom-up decision making in real time.
- *Increasing complexity:* The North American electric power system has been called the *most complex machine ever built*. System integration helps move power more efficiently over long distances and provides redundancy to ensure reliable service, and it also makes the system more complex and harder to operate. In response,

new mathematical approaches are needed to simplify the operation of complex power systems and to make them more robust in the face of natural or man-made interruptions.

- *Dependence on Internet communications:* Today's power systems could not operate without tightly knit communications capability—ranging from high-speed data transfer among control centers to interpretation of intermittent signals from remote sensors. Because of the vulnerability of Internet communications, however, protection of the electricity supply system requires new technology to enhance the security of power system command, control, and communications, including both hardware and software.
- *Accessibility and vulnerability:* Because power systems are so widely dispersed and relatively accessible, they are particularly vulnerable to attack. Although *hardening* of some key components, such as power plants and critical substations, is certainly desirable, it is simply not feasible or economic to provide comprehensive physical protection to all components. Probabilistic assessments can offer strategic guidance on where and how to deploy security resources to greatest advantage.

A survey of electric utilities revealed real concerns about grid and communications security. Figure 21.5 ranks the perceived threats to utility control centers. The most likely threats were bypassing controls, integrity violations, and authorization violations. Concern about the potential threats generally increased as the size of the utility (peak load) increased.

The system's equipment and facilities are dispersed throughout the North American continent, which complicates protection of the system from a determined terrorist attack. In addition, we must consider another complexity—the power delivery systems' physical

**FIGURE 21.5**

Threats to power supply control. (From EPRI 2000, *Communication Security Assessment for the United States Electric Utility Infrastructure*, EPRI Report 1001174, pp. 4–11, December 2000.)

vulnerabilities and susceptibility to disruptions in computer networks and communication systems. For example, terrorists might exploit the increasingly centralized control of the power delivery system to magnify the effects of a localized attack. Because many consumers have become more dependent on electronic systems that are sensitive to power disturbances, an attack that leads to even a momentary interruption of power can be costly. A 20 min outage at an integrated circuit fabrication plant, for example, could cost U.S. \$30 million.

Despite increasing concerns in these areas as well as the continuing erosion of reserve margins, the infrastructures of today do generally function well. The electricity is on, the phones work, and traffic flows nearly all of the time. But more and more, the traditional level of performance is no longer good enough; more robust infrastructures are needed for the *digital society* envisioned for tomorrow. For example, in the electric power area, there is a need for an increase in reliability from today's average of about 99.9% (approximately 8 h of outage/year) to 99.9999% (about 32 s outage/year) or even 99.9999999% (one outage lasting less than a single AC cycle/year). Such near-perfect power is needed today for error-free operation of the microprocessor chips finding their way into just about everything, including billions of embedded applications.

Fortunately, the core technologies needed to strategically enhance system security are the same as those needed to resolve other areas of system vulnerability, as identified in the *Electricity Technology Roadmap*. These result from open access, exponential growth in power transactions, and the reliability needed to serve a digital society.

The North American electric power system needs a comprehensive strategy to prepare for the diverse threats posed by terrorism. Such a strategy should both increase protection of vital industry assets and ensure the public that they are well protected. A number of actions will need to be considered in formulating an overall security strategy:

- The grid must be made secure from cascading damage.
- Pathways for environmental attack must be sealed off.
- Conduits for attack must be monitored, sealed off, and *sectionalized* under attack conditions.
- Critical controls and communications must be made secure from penetration by hackers and terrorists.
- Greater intelligence must be built into the grid to provide flexibility and adaptability under attack conditions, including automatic reconfiguration.
- Ongoing security assessments, including the use of game theory to develop potential attack scenarios, will be needed to ensure that the power industry can stay ahead of changing vulnerabilities.

The dispersed nature of the power delivery system's equipment and facilities complicates the protection of the system from a determined attack. Furthermore, both physical vulnerabilities and susceptibility of power delivery systems to disruptions in computer networks and communication systems must be considered. For example, terrorists might exploit the increasingly centralized control of the power delivery system to magnify the effects of a localized attack. Because many consumers have become more dependent on electronic systems that are sensitive to power disturbances, an attack that leads to even a momentary interruption of power can be costly.

In summary, the existing end-to-end energy and power delivery system is vulnerable to natural disasters and intentional cyber attacks. Regarding the latter, a successful attempt

to disrupt the power delivery system could have adverse effects on national security, the economy, and the lives of every citizen. For decades, our industry has been dedicated to the secure and reliable operation of the electric system that is fundamental to the national and international economy, security, and quality of life. Challenges to the security of the electric infrastructure include the following:

- *Physical security:* The size and complexity of the North American electric power grid makes it impossible both financially and logistically to physically protect the entire end-to-end and interdependent infrastructure. There currently exist over 450,000 miles of 100 kV or higher transmission lines and many more thousands of miles of lower voltage lines. As an increasing amount of electricity is generated from distributed renewable sources, the problem will be only be exacerbated.
- *Cybersecurity:* Threats from cyberspace to our electric grid are rapidly increasing and evolving. While there have been no publicly known major power disruptions due to cyber attacks, public disclosures of vulnerabilities are making these systems more attractive as targets.

Due to the increasingly sophisticated nature and speed of some malicious code, intrusions, and denial-of-service attacks, human response may be inadequate. Furthermore, currently more than 90% of successful intrusions and cyber attacks take advantage of known vulnerabilities and misconfigured operating systems, servers, and network devices. Technological advances targeting system awareness, cryptography, trust management, and access controls are underway, and continued attention is needed on these key technological solutions.

Security of cyber and communication networks is fundamental to the reliable operations of the grid. As power systems rely more heavily on computerized communication and control, system security has become increasingly dependent on protecting the integrity of the associated information systems. As an example, any utility system connected directly or indirectly to the public Internet is disputed territory and is vulnerable to cyber intrusions and impersonating field devices to spoof bad data into control centers.

Cyber has *weakest link* issues. Awareness, education, and pragmatic tool developments in this vital area also continue to remain challenges. Educating stakeholders and colleagues in the cyber-physical interdependencies has often been difficult, as those who are distinguished members of the community and understand power systems well, but not the cyber threats, routinely minimize emphasis on these persisting novel threats.

Cyber threats are dynamic, evolving quickly and often combined with lack of training and awareness: cyber connectivity has increased the complexity of the control system and facilities it is intended to safely and reliably control. Thus, in order to defend electric infrastructure against the impacts of cyber-physical attacks, significant challenges must be overcome before extensive deployment and implementation of smart grid technologies can begin. Cybersecurity and interoperability are two of the key challenges of the smart grid transformation. As for security, it must be built in as part of its design and *not* glued on as afterthought.

One important constraint on regulatory oversight of security protection is the split jurisdiction over the grid. The bulk electric system is under federal regulation, but the distribution grid, metering, electric vehicles, and other aspects of the grid are regulated by individual states. As a result, the oversight of cybersecurity is split along with other regulatory functions.

---

## 21.6 Human Performance

Since humans interact with these infrastructures as managers, operators, and users, human performance plays an important role in their efficiency and security. In many complex networks, the human participants themselves are both the most susceptible to failure and the most adaptable in the management of recovery. Modeling and simulating these networks, especially their economic and financial aspects, will require modeling the bounded rationality of actual human thinking, unlike that of a hypothetical *expert* human as in most applications of artificial intelligence (AI). Even more directly, most of these networks require some human intervention for their routine control and especially when they are exhibiting anomalous behavior that may suggest actual or incipient failure.

Operators and maintenance personnel are obviously *inside* these networks and can have direct, real-time effects on them. But the users of a telecommunication, transportation, electric power, or pipeline system also affect the behavior of those systems, often without conscious intent. The amounts, and often the nature, of the demands put on the network can be the immediate cause of conflict, diminished performance, and even collapse. Reflected harmonics from one user's machinery degrade power quality for all. Long transmissions from a few users create Internet congestion. Simultaneous lawn watering drops the water pressure for everyone. In a very real sense, no one is *outside* the infrastructure.

Given that there is some automatic way to detect actual or immanent local failures, the obvious next step is to warn the operators. Unfortunately, the operators are usually busy with other tasks, sometimes even responding to previous warnings. In the worst case, the detected failure sets off a multitude of almost simultaneous alarms as it begins to cascade through the system, and, before the operators can determine the real source of the problem, the whole network has shut itself down automatically.

Unfortunately, humans have cognitive limitations that can cause them to make serious mistakes when they are interrupted. In recent years, a number of systems have been designed that allow users to delegate tasks to intelligent software assistants (*softbots*) that operate in the background, handling routine tasks and informing the operators in accordance with some protocol that establishes the level of their delegated authority to act independently. In this arrangement, the operator becomes a supervisor, who must either cede almost all authority to subordinates or be subject to interruption by them. At present, we have very limited understanding of how to design user interfaces to accommodate interruption.

---

## 21.7 Broader Technical Issues

In response to the aforementioned challenges, several enabling technologies and advances are/will be available that can provide necessary capabilities when combined in an overall system design. Among them are the following:

- Flexible AC transmission system (FACTS) devices, which are high-voltage thyristor-based electronic controllers that increase the power capacity of transmission lines and have already been deployed in several high-value applications. At peak demand, up to 50% more power can be controlled through existing lines.

- Fault current limiters (FCLs), which absorb the shock of short circuits for a few cycles to provide adequate time for a breaker to trip. It is noteworthy that preliminary results of post–August 14 outage show that FCLs could have served as large electrical *shock absorbers* to limit the size of blackouts.
- Wide-area measurement systems (WAMSs), which integrate advanced sensors with satellite communication and time stamping using global positioning systems (GPSs) to detect and report angle swings and other transmission system changes.
- Innovations in materials science and processing, including high-temperature superconducting (HTS) cables, oxide-powder-in-tube technology for HTS wire, and advanced silicon devices and wide-bandgap semiconductors for power electronics.
- Distributed resources such as small combustion turbines, solid oxide and other fuel cells, photovoltaics, superconducting magnetic energy storage (SMES), and transportable battery energy storage systems (TBESSs).
- Information systems and online data processing tools such as the Open Access Same-Time Information System (OASIS) and Transfer Capability Evaluation (TRACE) software, which determines the total transfer capability for each transmission path posted on the OASIS network while taking into account the thermal, voltage, and interface limits.
- *Monitoring and use of IT:* WAMSs, OASIS, SCADA systems, and EMSs.
- *Analysis tools:* Several software systems for dynamic security assessment of large/wide-area networks augmented with market/risk assessment.
- *Control:* FACTS; FCL.
- Intelligent electronic devices (IEDs) with security provisions built in combining sensors, computers, telecommunication units, and actuators; integrated sensor; two-way communication; *intelligent agent* functions (assessment, decision, learning); and actuation, enabled by advances in several areas including semiconductors and resource-constrained encryption.

However, if most of the aforementioned technologies are developed, still the overall systems' control will remain a major challenge. This is a rich area for research and development (R&D) of such tools, as well as to address systems and infrastructure integration issues of their deployment in the overall network—especially now because of increased competition, the demand for advanced technology to gain an advantage, and the challenge of providing the reliability and quality consumers demand.

---

## 21.8 Western States Power Crises: A Brief Overview of Lessons Learned

An example of *urgent* opportunities is within the now seemingly calm California energy markets; the undercurrents that led to huge price spikes and considerable customer pain in recent years are yet to be fully addressed and alleviated. Such *perfect storms* may appear once again during another cycle of California economic recovery and growth. The California power crisis in 2000 was only the most visible parts of a larger and growing U.S. energy crisis that is the result of years of inadequate investments in the infrastructure.

For example, at the root of the California crisis was declining investment in infrastructure components that led to a fundamental imbalance between growing demand for power and an almost stagnant supply. The imbalance had been brewing for many years and is prevalent throughout the nation (see EPRI's Western States Power Crises white paper; [www.epri.com/WesternStatesPowerCrisisSynthesis.pdf](http://www.epri.com/WesternStatesPowerCrisisSynthesis.pdf)).

California is a good downside example of a societal test bed for the ways that seemingly *good* theories can fail in the real world. For example, inefficient markets provide inadequate incentives for infrastructure investment:

- Boom-bust cycle may be taking shape in generation investment
- Transmission investment running at one-half of 1975 level
- Congestion in transmission network is rising, as indicated by an increased number of transmission loading reliefs (TLRs) during the last 3 years

Cost of market failure can be also very high, as indicated by the exercise of market power in California during the summer of 2000 that cost consumers \$4 billion initially, while the ongoing intermediate loss to businesses may well be considerably higher.

More specifically regarding the electricity under investments and persisting undercurrents, very specific *investments* by the state were made, on the order of \$10 billion, paid to subsidize (hold down) electricity prices and to bail out bankrupt companies through long-term noncompetitive contracts that did not address the undercurrents and shortcomings of the earlier policies.

To address these issues, there are both tactical and strategic needs: for example, the so-called low-hanging fruits to improve transmission networks include the following:

- Deploy existing technologies to improve use of already in place transmission assets (e.g., FACTS, dynamic thermal circuit rating, and energy storage–peak shaving technologies): for example, through the integration of load management technologies saving nearly 5000 MW, which amounts to about 10% of total demand, combined with a more precise control enabled by the use of FACTS devices, which enable nearly 50% more transfer capability over existing transmission lines.
- Develop and deploy new technologies to improve transmission reliability and throughput (e.g., low-sag composite conductors, HTS cables, extrahigh-voltage AC and DC transmission systems, hierarchical control systems).
- Improve real-time control of network via monitoring and data analysis of dynamic transmission conditions.
- Develop and deploy self-healing grid tools to adaptively respond to overload and emergency conditions.
- Digital control of the power delivery network (reliability, security, and power quality).
- Integrated electricity and communications for the user.
- Transformation of the meter into a two-way energy/information portal.
- Integration of distributed energy resource (DER) into the network.
- The complex grid can operate successfully *if* technology is deployed and operated in an integrated manner (there is no *silver bullet*!).

In addition, longer term strategic considerations must be addressed:

- Greater fuel diversity including renewable energy technologies—regional and national priorities.
- Risk assessment of long-term U.S. reliance—analysis of the value of risk management through fuel diversity.
- Introduce time-varying prices and competitive market dynamics for all customers.
- Create a planning process and in silico testing of designs, devices, and power markets.
- Model market efficiencies, environmental constraints, and renewables.
- Develop advanced EM threat detection, shielding, and surge-suppression capabilities.
- Develop the tools/procedures to ensure a robust and secure marketplace for electricity.
- Develop the portfolio of advanced power generation technologies to assure energy security.
- Transmission network expansion and RTOs: for example, would an RTO complement a competitive wholesale power market and result in a sustainable and robust system? How large should they be?
- Comprehensive architecture for power supply and delivery infrastructure that anticipates rapidly escalating demands of digital society.
- Enable self-healing power delivery infrastructure.
- Significant investment in R&D, transmission, generation, and conservation resources is needed.
- Incentives for technology innovation and accountability for R&D.
- Revitalize the national public/private electricity infrastructure partnership needed to fund the *self-healing grid* deployment.
- The *law of unintended consequences* should be considered in crafting any solution.

Having discussed the aforementioned technology-intensive *push*, we must also consider the fact that adoption of new technologies often creates equally new markets. For example, wireless communication creates the market of spectrum, and broadband technologies create the market of bandwidth. Reduced regulation of major industries has required new markets wherever the infrastructure is congested: airlines compete for landing rights, power generators for transmission rights, and oil and gas producers for pipeline capacity.

From a national perspective, a key grand challenge is how to redesign, retrofit, and upgrade the nearly 200,000 miles of electromechanically controlled system into a smart self-healing grid that is driven by a well-designed market approach.

In addressing this challenge, as technology progresses, and the economy becomes increasingly dependent on markets, infrastructures such as electric power, oil/gas/water pipelines, telecommunications, and financial and transportation networks become increasingly critical and complex. In particular, since it began in 1882, electric power has grown to become a major industry essential to a modern economy.

Over the past two decades, governments around the globe have introduced increasing amounts of competition into network industries. With the advent of restructuring in the

electric power industry, we are witnessing the onset of a historical transformation of the energy infrastructure in the context of global trends:

- Increasing electricity demand as a consequence of economic and population growth
- Technological innovations in power generation, delivery, control, and communications
- Increasing public acceptance of market mechanisms
- Growing public concerns about environmental quality and depletion of exhaustible resources

Services previously supplied by vertically integrated, regulated monopolies are now provided by multiple firms. The transition to competition has fundamentally altered important aspects of the engineering and economics of production. This presents unique opportunities and challenges. Clearly, this change will have far-reaching implications for the future development of the electricity industry. More fundamentally, as we look beyond the horizon, this change will further power the information revolution and increasing global interdependence. The long-term socioeconomic impacts of such a transformation will be huge, and the tasks are just as daunting, going well beyond the boundary of existing knowledge.

To meet such a challenge, collaborative research between engineers and economists is critical to providing a holistic and robust basis that will support the design and management of complex technological and economic systems in the long-term. The electric power industry offers an immediate opportunity for launching such research, as new ways are being sought to improve the efficiency of electricity markets while maintaining the reliability of the network. Complexity of the electric power grid combined with even more intricate interactions with markets offers a plethora of new and exciting research opportunities. In what follows we provide our vision and approach to enabling a smart self-healing electric power system that can respond to a broad array of destabilizers.

### **21.8.1 Complex System Failure**

Beyond the human dimension, there is a strategic need to understand the societal consequences of infrastructure failure risks along with benefits of various tiers of increased reliability. From an infrastructure interdependency perspective, power, telecommunications, banking and finance, transportation and distribution, and other infrastructures are becoming more and more congested, and are increasingly vulnerable to failures cascading through and between them. A key concern is the avoidance of widespread network failure due to cascading and interactive effects. Moreover, interdependence is only one of several characteristics that challenge the control and reliable operation of these networks. Other factors that place increased stress on the power grid include dependencies on adjacent power grids (increasing because of deregulation), telecommunications, markets, and computer networks. Furthermore, reliable electric service is critically dependent on the whole grid's ability to respond to changed conditions instantaneously.

More specifically, secure and reliable operation of critical infrastructures poses significant theoretical and practical challenges in analysis, modeling, simulation, prediction, control, and optimization. To address these challenges, a research initiative—the EPRI/DOD Complex Interactive Networks/Systems Initiative (CIN/SI)—was undertaken during

1998–2001 to enable critical infrastructures to adapt to a broad array of potential disturbances, including terrorist attacks, natural disasters, and equipment failures.

The CIN/SI overcame the long-standing problems of complexity, analysis, and management for large interconnected systems—and systems of systems—by opening up new concepts and techniques. Dynamical systems, statistical physics, information and communication science, and computational complexity were extended to provide practical tools for measuring and modeling the power grid, cell phone networks, Internet, and other complex systems. For the first time, global dynamics for such systems can be understood fundamentally (Figure 21.6).

As an example, related to numerous major outages, narrowly programmed protection devices have contributed to worsening the severity and impact of the outage—typically performing a simple on/off logic that locally acts as preprogrammed while destabilizing a larger regional interconnection.

From a broader perspective, any critical national infrastructure typically has many layers and decision-making units and is vulnerable to various types of disturbances. Effective, intelligent, distributed control is required that would enable parts of the constituent networks to remain operational and even automatically reconfigure in the event of local failures or threats of failure. In any situation subject to rapid changes, completely centralized control requires multiple, high-data-rate, two-way communication links, a powerful central computing facility, and an elaborate operations control center. But all of these are liable to disruption at the very time when they are most needed (i.e., when the system is stressed by natural disasters, purposeful attack, or unusually high demand).

When failures occur at various locations in such a network, the whole system breaks into isolated *islands*, each of which must then fend for itself. With the intelligence distributed,

**FIGURE 21.6**

*Understanding complex systems and global dynamics.* Economic losses from disasters were found to follow a power law distribution—for hurricanes, floods, earthquakes, and even electrical outages. Fundamental power law distributions also were found for forest fires, Internet congestion, and other systems. CIN/SI results such as these translate in new approaches for optimizing complex systems in terms of productivity and robustness to disaster. (From the EPRI/DOD CIN/SI. Our goal is to move the power outage curve down toward the origin, that is, to make outages less frequent and with smaller impact on customers.)

and the components acting as independent agents, those in each island have the ability to reorganize themselves and make efficient use of whatever local resources remain to them in ways consonant with the established global goals to minimize adverse impact on the overall network. Local controllers will guide the isolated areas to operate independently while preparing them to rejoin the network, without creating unacceptable local conditions either during or after the transition. A network of local controllers can act as a parallel, distributed computer, communicating via microwaves, optical cables, or the power lines themselves, and intelligently limiting their messages to only that information necessary to achieve global optimization and facilitate recovery after failure.

### 21.8.2 How to Make an Electric Power System Smart

To add intelligence to an electric power transmission system, independent processors in each component and each substation and power plant are needed. These processors must have a robust operating system and be able to act as independent agents that can communicate with and cooperate with other systems, forming a large distributed computing platform. Each agent must be connected to sensors associated with its own component or its own substation so that it can assess its own operating conditions and report them to its neighboring agents via the communications paths. Thus, for example, a processor associated with a circuit breaker would have the ability to communicate with sensors built into the breaker and communicate those sensor values using high-bandwidth fiber communications connected to other such processor agents.

Adding and utilizing existing intelligence—sensors, communications, monitors, optimal controls, and computers—to our electric grid can substantially improve its efficiency and reliability through increased situational awareness, reduced outage propagation, and improved response to disturbances and disruptions. This so-called smart grid can also enable transparent pricing of electricity that will allow consumers to manage their energy costs and facilitate distributed generation and redundancy, opening the door to wider use of variable renewable generation sources and supporting expanded use of electric vehicles.

The federal government recognized this potential by implementing the Energy Independence and Security Act (EISA) of 2007. Title XIII of the act mandates a smart grid that is focused on modernizing and improving the information and control infrastructure of the electric power system. Among the areas being addressed in the smart grid are transmission, distribution, home to grid, industry to grid, building to grid, vehicle to grid, integration of renewable resources and DERs (such as wind and solar), and demand response.

### 21.8.3 Value Proposition

Because of the fundamental importance of the mission and the costs involved, we have to take a critical approach to the enormous investments needed to improve reliability and resiliency and enable economic competitiveness. One metric is *payback*, or ROI.

Having studied this in depth each \$1 invested garners a return of \$2.80–\$6 to the broader economy. The ROI begins immediately with job creation and economic stimulus. To reach these numbers, we used a very narrow definition of *smart grid*. If the definition is broadened, the benefits increase.

The cost of a smarter grid would depend on how much instrumentation you actually put in, such as the communications backbone, enhanced security, and increased resilience.

The total price tag ranges around \$340–\$480 billion, which, over a 20-year period, would be something like \$20–\$25 billion/year. But right off the bat, the benefits are \$70 billion/year in reduced costs from outages, and on a year where there are lots of hurricanes, lots of ice storms, and other disturbances, that benefit even goes further. Currently, outages from all sources cost the U.S. economy somewhere between \$80 and \$188 billion annually. Costs of outages reduced by about \$49 billion/year, and reduced CO<sub>2</sub> emissions by 12%–18% by 2030. In addition, it would increase system efficiency by over 4%—that's another \$20.4 billion a year.

The costs cover a wide variety of enhancements to bring the power delivery system to the performance levels required for a smart grid. They include the infrastructure to integrate DERs and achieve full customer connectivity but exclude the cost of generation, the cost of transmission expansion to add renewables and to meet load growth, and a category of customer costs for smart-grid-ready appliances and devices. Despite the costs of implementation, investing in the grid would pay for itself, to a great extent.

But this is also about (1) increased cyber/IT security, and overall energy security, with security built in the design as part of a layered defense system architecture and (2) job creation and an economic benefit. With the actual investment, for every dollar, the return is about \$2.80–\$6 to the broader economy. And this figure is very conservative.

#### **21.8.4 What Are the Economic Benefits of Upgrading the Grid?**

The economic benefits of a modernized grid will accrue as investments are made. Indeed, in my view, our twenty-first-century digital economy depends on us making these investments, regardless of the prognosis for more extreme weather to come as our climate changes.

Yet the economic argument is clear: the payback of smart grid technologies in the United States is three to six times greater than the money invested, and grows with each sequence of grid improvement. For example, the 2009 government stimulus plan funding and matching support from utilities and the private sector in the Smart Grid Investment Grant (SGIG) and Smart Grid Demonstration Project (SGDP) programs generated a significant impact on the U.S. economy:

- As of March 2012, the total invested value of \$2.96 billion to support smart grid projects generated at least \$6.8 billion in total economic output.
- Smart grid deployment positively impacted employment and labor income throughout the economy. Overall, about 47,000 full-time equivalent jobs were supported by investments. Among smart grid vendors—an ecosystem of manufacturers, information technology, and technical services providers—about 12,000 direct jobs were supported, with the remaining jobs being in those companies' respective supply chains and induced by the money spent throughout the broader economy.
- Investment in core smart grid industries supports high-paying jobs. Industrial sectors that benefit directly include computer systems' design, technical and scientific services and consulting, and electrical/wireless equipment and component manufacturing. Industrial sectors that experience indirect and induced benefits include real estate, wholesale trade, financial services, restaurants, and health care. The U.S. DOE smart grid American Recovery and Reinvestment Act (ARRA) investments also supported employment in personal service sectors such as health

care, financial services, real estate, and food/restaurants through indirect and induced impacts.

- The smart grid gross domestic product (GDP) multiplier is higher than many forms of government investment. For every \$1 million of direct spending, which includes both government ARRA funds and private sector matching, the GDP increased by \$2.5–\$2.6 million, depending on the scenario being evaluated, which compares favorably against other potential government investments in general spending or other types of infrastructure.

### **21.8.5 What Role Does Renewable Energy Play in the Smart Grid and What Needs to Be Done to Access Sustainable Energy Resources?**

Much of the renewable energy and natural gas potential in the United States is located in areas that are remote from population centers, lack high demand for energy, and are not well connected to our national infrastructure for the transmission of bulk electric power. The recent expansion of natural gas production in the United States has also affected the development of the grid. To achieve public policy objectives, sufficient transmission capacity must link new natural gas generating plants, onshore or offshore wind farms, solar plants, and other renewables to customers if those resources are to serve the energy needs of homes and businesses and have the potential to replace significant portions of the oil used today in vehicle transportation.

New transmission will play a critical role in the transformation of the electric grid to enable public policy objectives, accommodate the retirement of older generation resources, increase transfer capability to obtain greater market efficiency for the benefit of consumers, and continue to meet evolving national, regional, and local reliability standards. With a stronger and smart grid, 40% of our electricity in the United States can come from wind by 2030.

Much of the renewable energy and natural gas potential in the United States is located in areas that are remote from population centers, lack high demand for energy, and are not well connected to our national infrastructure for transmission of bulk electric power. The recent expansion of natural gas production in the United States has also affected development of the grid. To achieve public policy objectives, sufficient transmission capacity must link new natural gas generating plants, onshore or offshore wind farms, solar plants, and other renewables to customers if those resources are to serve the energy needs of homes and businesses, and have the potential to replace significant portions of the oil used today in vehicle transportation.

New transmission will play a critical role in the transformation of the electric grid to enable public policy objectives; accommodate the retirement of older generation resources, increase transfer capability to obtain greater market efficiency for the benefit of consumers, and continue to meet evolving national, regional, and local reliability standards.

New types of generation and new uses of electricity are creating both challenges and opportunities. Examples of new generation types include wind and solar, both of which vary in output and predictability. While most wind installations are grid-scale generation sources, many solar, and a few wind, sources are also in place in distribution grids, presenting additional challenges, which are discussed in the following. An example of a technology that serves both as an electricity use (load) and as an electricity source is energy storage, affording the opportunity to compensate for varying grid conditions by providing or absorbing energy to help correct system voltage or frequency. Placing an energy storage device in the distribution grid to serve both as a load and as a DER also offers new

integration challenges and opportunities for increased reliability: the electric vehicle, for example, presents challenges in minimizing the grid impact of its charging and also in the opportunity for its use as a DER.

Another technology that has received renewed interest is direct current (DC), especially in localized grids called *microgrids*. For example, solar photovoltaic produces DC, batteries store DC, and loads such as computer equipment and variable speed motors operate on DC. The grid operates mainly on alternating current (AC), and conversions need to take place between AC and DC to interconnect DC generation or loads to the AC grid. Efficiency considerations suggest minimizing the number of such individual conversions, leading to exploration of new concepts for managing electricity at locations involving these generation sources, storage methods, and loads. Local electricity generation and storage and distribution systems should be improved next, to increase the self-sufficiency of end users. Longer term, flow-directing technologies would be added to address fluctuations and differences between energy supply and demand. Electricity might be redirected at times of peak load, for instance.

Cost-effective solutions will vary by region, utility, equipment, and threats involved. In Hurricane Sandy's case, coastal areas that were subject to storm surges and flooding might need underground substations rebuilding on the surface. Inland, where high winds and lashing rain produced the most damage, overhead lines could be buried.

Customer demand combined with sound policies supportive of this modernization along with innovation-based new business opportunities will drive the market for these generation, storage, and distribution technologies. Consumers, as surveys show, are increasingly driven by an interest in energy efficiency, digital demand, and awareness of the cost of energy disruptions. Utilities will have to fix their networks once people question why power cuts are preventing them from working on their computers, for instance.

Manufacturers in turn must integrate customer feedback into their R&D roadmaps and improve coordination of standards, R&D, and funding to drive down costs and broaden the market. Related, enabling technologies will be needed, including EMS and communication technologies.

### 21.8.6 Self-Healing Power Grid

*Smart grid* is not a very precise term. I prefer smart *self-healing* grid, because it more precisely describes the desired outcome of the investments I advocate for grid modernization.

A self-healing grid uses digital components and real-time communications technologies installed throughout a grid to monitor the grid's electrical characteristics at all times and constantly tune itself so that it operates at an optimum state. It has the intelligence to constantly look for potential problems caused by storms, catastrophes, human error, or even sabotage. It will react to real or potential abnormalities within a fraction of a second, just as a military fighter jet reconfigures itself to stay aloft after it is damaged. The self-healing grid isolates problems immediately as they occur, before they snowball into major black-outs, and reorganizes the grid and reroutes energy transmissions so that services continue for all customers while the problem is physically repaired by line crews.

A self-healing smart grid can provide a number of benefits that lend to a more stable and efficient system. Three of its primary functions include the following:

- *Real-time monitoring and reaction*, which allows the system to constantly tune itself to an optimal state. Real-time monitoring can alert grid operators to the precursors or signatures of impending faults, based on probabilistic analysis.

Real-time monitoring has been enabled by a leap from traditional SCADA systems to phasor measurement units (PMUs), aka synchrophasors. This technology improves the resolution of data polled from field devices from  $2\times\text{--}4\times$  per s with SCADA to  $20\times\text{--}50\times$  per s with PMUs. PMUs also provide precise, GPS-based time stamping so that events on the system can be analyzed accurately and chronologically in a WAMS. This allows operators to see *how the dominoes fell in the dark*.

- *Anticipation*, which enables the system to automatically look for problems that could trigger larger disturbances. Real-time monitoring enables operators to react swiftly to restore balance to the system or to program field devices to respond automatically. This allows constant tuning of the grid's many components to achieve an optimal, highly efficient state.
- *Rapid isolation*, which allows the system to isolate parts of the network that experience failure from the rest of the system to avoid the spread of disruption and enables a more rapid restoration.

As a result of these functions, a self-healing smart grid system is able to reduce power outages and minimize their length when they do occur. The smart grid is able to detect abnormal signals, make adaptive reconfigurations, and isolate disturbances, eliminating or minimizing electrical disturbances during storms or other catastrophes. And, because the system is self-healing, it has an end-to-end resilience that detects and overrides human errors that result in some of the power outages, such as when a worker error left millions of California residents without electricity in September 2011.

### 21.8.7 End-to-End Technologies

An end-to-end system that anticipates problems, supports operator decisions, or reacts automatically has a few elements worthy of emphasis.

At the customer end are the interval meters that provide usage data, serve as end-of-line sensors for voltage conservation, and emit *last gasps* as they (and the customer) lose power. Upstream of the meters, but downstream of the operators, we will see a proliferation of advanced sensors (IEDs) that facilitate real-time monitoring and control of critical assets. Advanced protective relays, for instance, provide improved isolation of faults. All of the technologies discussed in this chapter are supported by two-way communication networks that bring the real-time monitoring data back to operators and allow the latter to send commands back to assets in the field. Finally, visualization tools such as dashboards convert data into color-coded graphics and automated alerts that provide decision support.

### 21.8.8 Three-Tiered Intelligence

The self-healing grid can be thought of as having three tiers of intelligence.

The bottom layer, closest to devices in the field, is distributed intelligence. It is akin to the reptilian brain, with simple responses to environmental stimuli. At a substation, for instance, an intelligent device monitors the health of the asset and communicates that to the middle layer, where the validation of incoming data and coordination of various functions takes place in milliseconds. This is somewhat akin to a mammalian neocortex that can strategize, act, and be upgraded through experience to higher functionality. The top layer contains the centralized command-and-control functions directed by human operators.

### 21.8.9 Why Do We Need a Smart Self-Healing Grid?

Grid modernization is a global phenomenon, but in any day in the United States, about a half million people are without power for 2 or more hours. The number of weather-caused, major outages in the United States has risen since the 1950s, from between 2 and 5 each year by the 1980s to 70–130 between 2008 and 2012. Two-thirds of weather-related power disruptions have occurred in the past 5 years, affecting up to 178 million customers (meters), as changing weather patterns impact aging infrastructure.

The U.S. electric power system still relies on 1960s and 1970s technology. The sector is second from the bottom of major industries in terms of research and development (R&D) spending as a fraction of revenue; only pulp and paper is worse. Electricity R&D received just 0.17% of net sales from between 2001 and 2006, and has not risen since.

Meanwhile, electricity needs are changing and growing fast. Tweeting, and the devices and infrastructure needed to operate the underpinning communication network, data centers, and storage alone, adds more than 2500 megawatt hours (MW h) of demand globally per year that did not exist 5 years ago. Kilowatt hour (kW h) is commonly used by power companies for billing, since the monthly energy consumption of a typical residential customer ranges from a few hundred to a few thousand kilowatt hours. One MW h is equal to 1000 kW of electricity used continuously for 1 h. One MW h is the amount of electricity used by approximately 330 homes in 1 h. On average, 2500 MW h is equivalent to the electricity used by about 825,000 homes. Factor in Internet TV, video streaming, online gaming and the digitization of medical records, and the world's electricity supply will need to triple by 2050 to keep up.

### 21.8.10 How Does a Smart Self-Healing Grid Benefit Consumers?

Beyond managing power disturbances, a smart grid system has the ability to measure how and when consumers use the most power. This information allows utility providers to charge consumers variable rates for energy based upon supply and demand. Ultimately, this variable rate will incentivize consumers to shift their heavy use of electricity to times of the day when demand is low and will contribute to a healthier environment by helping consumers better manage and more efficiently use energy.

### 21.8.11 What Is Involved in Creating a Smart Self-Healing Grid?

To transform our current infrastructure into a self-healing smart grid, several technologies must be deployed and integrated.

The ideal smart grid system consists of microgrids, which are small, mostly self-sufficient power systems, and a stronger, smarter high-voltage power grid, which serves as the backbone to the overall system.

Upgrading the grid infrastructure for self-healing capabilities requires replacing traditional analog technologies with digital components, software processors, and power electronics technologies. These must be installed throughout a system so that it can be digitally controlled, which is the key ingredient to a grid that is self-monitoring and self-healing.

Much of the technology and systems thinking behind self-healing power grids comes from the military aviation sector, where I worked for 14 years on damage-adaptive flight systems for F-15 aircraft, optimizing logistics and studying the survival of squadrons and mission effectiveness. In January 1998, when I joined the EPRI, I helped bring these concepts to electricity power systems and other critical infrastructure networks, including energy,

water, telecommunications, and finance ([http://massoud-amin.umn.edu/publications/Amin\\_Computer\\_Aug\\_00.pdf](http://massoud-amin.umn.edu/publications/Amin_Computer_Aug_00.pdf)). Following the September 11, 2001, terrorist attacks, resilience and security has become even more important.

Today in the United States, 16 programs on smart grids are ongoing, amounting to several billions per year, at EPRI, NSF, DHS, DOE, and DOD. Over 100 public and private projects, many on smart meters, address the electricity system in piecemeal fashion. There is no coordinated national decision-making body.

Jurisdiction over the grid is split: the bulk electric system is under federal regulation; the distribution grid is under the purview of state public utility commissions. Local regulations essentially kill the motivation for any utility to lead a regional or nationwide effort. Government policies shift with election cycles, variously championing energy independence, clean energy, environmental protection, jobs, and so on.

#### **21.8.12 Is the Smart Grid Secure, Private, and Safe?**

It is noteworthy that smart grid is modernization of the entire end-to-end system, from fuel source to smart homes. At the end use, a smart meter, which is a sensor node, is a digital upgrade to the decades-old mechanical meters used in homes and businesses. Some smart meters use wireless technologies that transmit radio frequencies (RFs) to provide two-way secure communication of the aggregate data on the electricity usage to the electric company through remote communication technologies.

This means electric companies will no longer need to send meter readers to read our meters on a monthly basis, and instead as consumers, we receive the information as we choose, on an hourly, daily, weekly, or monthly basis, rather than receiving the bill at the end of the month with no ability to adjust our usage.

Some consumers have expressed concerns about security/confidentiality of their information (important to note that as customers we own our own data/information):

- Cybersecurity threats can cause disruptions in the flow of power and other problems if cyber intruders send computer signals to the electronic controls used in some electric generation and transmission infrastructure. The electric power industry takes cybersecurity threats very seriously. In fact, electric companies must meet mandatory cybersecurity standards that require companies to implement training, physical security, and asset recovery plans to protect against the threat of cyber attacks.
- As the smart grid is built, electric companies are incorporating cybersecurity protections into both the grid architecture and the new smart grid technologies. The electric power industry is working closely with vendors, manufacturers, and government agencies to ensure that the smart grid is secure. These measures also help to ensure that customer data remain protected from cybersecurity threats.

#### **21.8.13 Are There Potential Health Impacts of the Radiofrequency Signal Emitted by Wireless Smart Meters?**

The RF exposure levels from smart meters are far below the levels permitted by the U.S. Federal Communications Commission (FCC), which sets health standards for RF exposure, based on extensive reviews of the biological and health literature. All scientific studies, including a request by the California State Assembly for a study conducted by the *California Council on Science and Technology* (CCST) on potential health impacts from smart meters.

No causations or correlations and no health impacts were found, based both on the lack of scientific evidence of harmful effects from RF signal and on the observation that the RF exposure of people in their homes to smart meters is likely to be minuscule compared to RF exposure to items such as cell phones, microwave ovens, baby monitors, wireless routers, televisions, and laptop computers, which most of us already have in our homes [28].

According to the EPRI, the *relatively weak* strength of the RF signals generated by smart meters means that any impact of RF exposure would be minimal—similar to the levels of the exposure from televisions and radios [29].

- RF exposure from a smart meter is far below—and more infrequent—than other common electric devices. In fact, smart meters typically broadcast their signal for less than a minute at a time and usually less than a total of 15 min each day. The communication is usually from outside the customer's home, so exposure to radio waves is minimal. In addition, the electric panel and wall behind the meter actually block much of the radio signal from entering the home.
- RF is measured in units of microwatts per square centimeter. A microwatt is very small—it's one-millionth of a watt.
- Held at your ear, a cell phone's RF signal would be 1000–5000  $\mu\text{W}/\text{cm}^2$ .
- Standing 2 ft from a microwave oven, the RF signal would be 50–200  $\mu\text{W}/\text{cm}^2$ .
- Standing 10 ft from a smart meter, the RF signal would be 4  $\mu\text{W}/\text{cm}^2$ .

In summary, the RF signal emitted by a smart meter is one order of magnitude less than proximity to the microwave oven, and 1000-fold less than cell phones held to our ears.

#### **21.8.14 What Will It Take to Address Concerns That Communications Linked to Energy Services Will Invade Consumers' Privacy?**

Customer concerns are of vital importance. When it comes right down to it, what would the power supply or power grid be without consumers? If there is any compromise of the privacy or security of the service, it will undermine everything. An incident would not only create a breach of confidentiality for the information that has been compromised, but it might also compromise the potential future markets the technology might have been able to create if the service had been secure.

The bottom line is that security cannot be added to a system as an afterthought. We need to start from scratch, at the very beginning of any microgrid project, and consider privacy and security in all design criteria. Strategic consideration of these issues will make a huge difference in the confidence and protection that the overall system provides. This is necessary whether the design effort is focusing on silicon chips, network components, end user devices, the architecture, or the system as whole.

In our work, we have proposed and tested several different layers of technologies that monitor and support the privacy of customer information. Security technologies are employed for traffic analyzers, signal analyzers, and agents that monitor voltages, frequency, current (along with their rates of changes), and user behavior. Each component is secured independently and locally so the security precautions cannot be reverse engineered.

This is not a hierarchical system that can be destroyed or taken down. If one or two layers fail, the system does not fail. It's essentially a self-reconfiguring, self-healing architecture. If anybody attacks it or tries to compromise one part of it, the system reconfigures to not only protect itself but to localize and fend off such attacks.

### **21.8.15 Risk Assessment**

The initial step, before implementing these strategies and technologies, is risk assessment. Risk is dynamic, local, and specific. National policies will help, but achieving hardening and resiliency on the ground will be specific to a utility's customers' needs, its legacy systems, location, and technology roadmap.

A dynamic risk landscape requires annual updating to ensure protection of the right assets. How has the risk portfolio or the spectrum of risk changed? With climate change, the variability of weather events has increased. We are going to see more and more extreme events that have never happened before and we'll see them with greater frequency. Hurricane Sandy appears to be an example of this challenge.

So, a clear sense of dynamic risk should guide our investments in hardening and resilience, based on evidence and data. We need a new set of tools and a fresh set of approaches to system upgrades in order to be more dynamic and more adaptive to achieve resiliency and security.

### **21.8.16 Conclusions: Toward a Secure, Resilient, and Efficient Infrastructure**

How to control a heterogeneous, widely dispersed, yet globally interconnected system is a serious technological problem in any case. It is even more complex and difficult to control it for optimal efficiency and maximum benefit to the ultimate consumers while still allowing all its business components to compete fairly and freely. A similar need exists for other infrastructures, where future advanced systems are predicated on the near-perfect functioning of today's electricity, communications, transportation, and financial services.

From a strategic R&D viewpoint, agility and robustness/survivability of large-scale dynamic networks that face new and unanticipated operating conditions will be presented. A major challenge is posed by the lack of a unified mathematical framework with robust tools for modeling, simulation, control, and optimization of time-critical operations in complex multicomponent and multiscaled networks.

Our immediate and critical goal is to avoid widespread network failure, but the longer-term vision is to enable adaptive and robust infrastructure. Achieving this vision and sustaining infrastructure reliability, robustness, and efficiency are critical long-term issues that require strategic investments in research and development.

However, three factors hinder improvements to the U.S. system. First, investment is too low. Since 2010, President Obama's stimulus plan has channeled \$3.4 billion toward a U.S. smart grid; industry has added another \$4.3 billion. The full cost will be around \$400 billion, or \$25–\$30 billion a year for 20 years. Second, technological challenges for matching supply and demand remain. And third, fragmentation of the U.S. electricity system and projects across states and funding agencies requires a national strategy.

Smart grid systems must interact across centralized and decentralized electric networks and support advanced services (such as net metering, load aggregation, and real-time energy monitoring). They must meet the evolving needs of a dynamic digital future. To enable this transition, a systemic, sound, and sustainable policy framework for the regulatory oversight of grid modernization and security will be needed to provide incentives for collaboration between state utilities and federal agencies. I am often asked: "Government can't do it alone and the industry, which owns over 90% of the infrastructure, is unable to do alone; what are we to do?" A key enabler is creation of National Infrastructure Banks, which are focused on addressing both the much needed repairs today (to modernize existing aging infrastructure) *and* to bridge to more advanced, smarter, more secure, and sustainable lifeline infrastructures envisioned for the next 10–20 years. Created as

public/private partnership enterprises, these banks would lend money on a sustainable basis with clear cost/benefit, performance metrics and include fees for quality of services provided by the modernized infrastructures.

In summary, a balanced, cost-effective approach to investments and use of technology can make a sizable difference in mitigating the risk. Electricity shall prevail at the quality, efficiency, and reliability that customers demand and are willing to pay for. On the one hand, the question is, *Who provides it?*; on the other hand, it is important to note that achieving the grid performance, security, and reliability is a profitable national investment, not a cost burden on the taxpayer. The economic payback is three to six times greater than the money invested. Further, the payback starts with the completion of each sequence of grid improvement. The issue is not merely who invests money, because that is ultimately the public, but whether it's invested through taxes or kWh rates. Considering the impact of regulatory agencies, they should be capable of inducing the electricity producers to plan and fund the process; this may be the most efficient way to get it in operation. The current absence of a coordinated national decision-making body is a major obstacle. State's rights and state PUC regulators have removed the individual state's utility motivation for a national plan.

One important constraint on regulatory oversight of the reliability-centered upgrades and security protection is the split jurisdiction over the grid. The bulk electric system is under federal regulation, but the distribution grid, metering, and other aspects of the grid are regulated by individual states. And those local regulations essentially kill the motivation for any utility or utility group to lead a regional or nationwide effort. We therefore need a policy framework to provide incentives for collaboration in grid modernization—making the system smarter and stronger—and for R&D. In addition, as a result the oversight of cybersecurity is split along with other regulatory functions. Going forward, we must bridge the jurisdictional gap between federal/NERC and the state commissions on much needed grid modernization and the associated cybersecurity.

Because of the hefty budget and long timescales involved, the main investment for this infrastructure will have to come from the public purse. The regulatory agencies would need to decide whether it is best invested through taxes or power usage rates and induce the electricity producers to plan and cofund the process.

When the United States has made such strategic commitments in the past, the payoffs have been huge. Think of the interstate highway system, the lunar landing project, the Internet. Meeting each of those challenges has produced world-leading economic growth by enabling commerce and technology development and producing a highly skilled workforce in the process. The electricity smart grid could do the same. In my view, the U.S.'s twenty-first-century digital economy depends on these investments. Given the economic, societal, and quality-of-life challenges and the ever-increasing interdependencies among infrastructures we have today, we must decide whether to build electric power and energy infrastructures that support a twenty-first century's digital society, or be left behind as a twentieth-century industrial relic.

---

## Acknowledgments

I developed some of the foundational parts of the material and findings presented here while I was at the EPRI in Palo Alto, CA. I am most grateful for EPRI's support and feedback from numerous colleagues at EPRI, universities, industry, and government agencies.

## 22.1 Principal Electricity Uses in Buildings

### 22.1.1 Introduction: The Importance of Energy Efficiency in Buildings

A typical building is designed for a 40-year economic life. This implies that the existing inventory of buildings—with all their good and bad features—is turned over very slowly. Today we know it is cost-effective to design a high degree of energy efficiency into new buildings, because the savings on operating and maintenance costs will repay the initial investment many times over. Many technological advances have occurred in the last few decades, resulting in striking reductions in the energy usage required to operate buildings safely and comfortably. Added benefits of these developments are reductions in air pollution and greenhouse gas emissions, which have occurred as a result of generating less electricity.

There are hundreds of building types, and buildings can be categorized in many ways—by use, type of construction, size, or thermal characteristics, to name a few. For simplicity, two designations will be used here: residential and commercial. Industrial facilities are not included here, but are discussed in Chapter 29.

The residential category includes features common to single family dwellings, condominiums and townhouses, and multifamily apartments. In 2012, there were approximately 115 million occupied housing units in the United States (U.S. Census Bureau 2012). The commercial category includes a major emphasis on office buildings, as well as a less detailed discussion of features common to retail stores, hospitals, restaurants, and laundries. The extension to other types is either obvious or can be pursued by referring to the literature. There are roughly five million commercial buildings in the United States, estimated to total 83 billion square feet in 2012 (EIA 2013a). Three-quarters of these buildings are 25 or more years old, and the average building age is about 50 years (SMR Research Corporation 2011). Most of this space is contained in buildings larger than 10,000 ft<sup>2</sup>.

Total energy consumption in the two sectors has evolved over time and since the previous three editions of this book (see Table 22.1):

There has been a remarkable shift in the energy sources used by the residential and commercial sectors in the decades since 1975. Natural gas, which increased rapidly in these sectors prior to 1975, flattened out and has remained more or less constant. The use of petroleum has decreased. The big change has been the dramatic increase in electricity sales to the residential and commercial sectors, more than doubling from 1980 to 2011 and increasing by 2.6 times since 1975.

**TABLE 22.1**

Total Energy Consumption Trends, Quadrillion BTU

	Year						
	1955	1965	1975	1985	1995	2005	2011
Residential	7.3	10.6	14.8	16.0	18.5	21.6	21.6
Commercial	3.9	5.8	9.5	11.5	14.7	17.9	18.0
Total	11.2	16.5	24.3	27.5	33.2	39.5	39.6

Source: EIA, Annual energy review 2011. DOE/EIA-0384(2011), U.S. Energy Information Administration, Washington, DC, 2012, <http://www.eia.gov/totalenergy/data/annual/pdf/aer.pdf>.

The approach taken in this chapter is to list two categories of specific strategies that are cost-effective methods for using electricity efficiently. The first category includes those measures that can be implemented at low capital cost using existing facilities and equipment in an essentially unmodified state. The second category includes technologies that require retrofitting, modification of existing equipment, or new equipment or processes. Generally, moderate to substantial capital investments are also required.

### 22.1.2 Electricity Use in Residential and Commercial Buildings

Figures 22.1 and 22.2 illustrate estimated breakdowns of purchased electricity by major end use for the residential and commercial sectors, respectively. The data are from the Energy Information Administration's (EIA's) most recent estimates (EIA 2013a,b).

The single most significant residential end use of electricity is space cooling (19%), followed by lighting (13%), water heating (9%), refrigeration (8%), televisions and related equipment (6%), and space heating (6%). The combination of other uses such as clothes washers and dryers, personal computers, dishwashers, fans, pumps, etc. is also substantial, accounting for nearly 40% of residential electricity use.

In the commercial sector, space conditioning—that is, the combination of heating, ventilating, and air conditioning (HVAC)—is the top user of electricity, accounting for 28%. When HVAC equipment are considered as separated end uses, lighting rises to the top as the largest single end use of electricity in the commercial sector at 21%. Refrigeration (8%), non-personal computer (non-PC) office equipment (5%), and PC office equipment (5%) are also significant end uses of electricity. In addition, other end uses such as water heating, transformers, medical equipment, elevators and escalators, fume hoods, etc. account for the remaining third of electricity use in commercial buildings.

**FIGURE 22.1**

Breakdown of residential electricity end use, 2011, 1424 billion kWh. (From EIA, Annual energy outlook 2013 with projections to 2040. Residential sector key indicators and consumption. DOE/EIA-0383(2013), U.S. Energy Information Administration, Washington, DC, 2013b, <http://www.eia.gov/oiaf/aeo/tablebrowser/>)

**FIGURE 22.2**

Breakdown of commercial electricity end use, 2011, 1319 billion kWh. (From EIA, Annual energy outlook 2013 with projections to 2040. Commercial sector key indicators and consumption. DOE/EIA-0383(2013), U.S. Energy Information Administration, Washington, DC, 2013a, <http://www.eia.gov/oiaf/aeo/tablebrowser/>.)

### 22.1.2.1 Residential Electricity Use

Space conditioning (including both space cooling and heating and associated fans and pumps) is the most significant end use of electricity in residential buildings, accounting for more than one-quarter of total electricity purchases today. EIA projects space conditioning's share of total residential electricity use will continue to be substantial with the possibility of increases in demand in the absence of greater efficiency improvements. Electricity is used in space heating and cooling to drive fans and compressors, to provide a direct source of heat (resistance heating), to provide an indirect source of heat or *cool* (heat pumps),\* and for controls.

At 13% in 2011, residential lighting electricity use is up from 9% in 2001, due in part to a smaller share of electricity being consumed by other end uses. However, EIA expects lighting electricity use to decline considerably over the next decade both in terms of absolute quantity of electricity delivered to homes to power lights (35% reduction between 2011 and 2023) and in terms of lighting's relative share of residential end use (down to 8% in 2023). These projected reductions are due to the Energy Independence and Security Act (EISA) of 2007, which as of January 1, 2013, has been phasing in standards to replace incandescent lamps with more efficient compact fluorescent (CFL) and light-emitting diode (LED) lamps.

The share of residential electricity use by water heating has stayed relatively constant at 9% during the last decade. EIA projects the total electricity delivered to water heating systems will increase by 15% over the next decade and water heating's relative share of electricity use will rise to over 10% by 2023. Electricity use for this purpose currently occurs in electric storage tank water heaters, tankless electric water heaters,

\* Heat pumps are discussed in detail in Chapter 27 of this handbook.

and heat pump water heaters. Solar water heating (discussed in Chapters 40–42) is another alternative that is used on a limited basis.

Refrigerators are another important energy end use in the residential sector, accounting for 8% of residential electricity consumption in 2011, down from 14% in 2001. EIA projects refrigeration's share of residential electricity use as well as the absolute quantity of electricity delivered to refrigerators will maintain roughly constant between now and 2023. For the last half century, virtually every home in the United States has had a refrigerator. Therefore, refrigerators have fully penetrated the residential sector for some time. However, significant changes related to energy use have occurred during this period as new standards have been implemented. For one, the average size of refrigerators has more than doubled from less than 10 ft<sup>3</sup> in 1947 to over 20 ft<sup>3</sup> today. Meanwhile, the efficiency of refrigerators has increased dramatically. The net result is that current refrigerators use about one-quarter as much energy (~450 kWh/year in 2011) as smaller units did 40 years ago (~1800 kWh/year in 1972), according to data from the Association of Home Appliance Manufacturers. Furthermore, when new efficiency standards take effect in Fall 2014, new refrigerators will use about one-fifth of the energy use of those in the early 1970s.

TVs, computers, and related equipment collectively account for over 9% of residential electricity use. These types of electronic systems have proliferated in homes during the last few decades. Clothes washers and dryers, cooking, dishwashers, and freezers account for another 11%, while *other* uses (including small electric devices, heating elements, and motors not included earlier) make up the balance (22%) of electricity use in the residential sector.

### 22.1.2.2 Commercial Electricity Use

For the commercial sector as a whole, HVAC dominates electricity use, with space cooling, space heating, and ventilation systems accounting for over one-quarter of electricity use. This trend is also true for most types of commercial buildings where space conditioning is used. There are exceptions of course—in energy-intensive facilities such as laundries, the process energy will be most important. Electricity is used in space conditioning to run fans, pumps, chillers, cooling towers, and heat pumps. Other uses include electric resistance heating (e.g., in terminal reheat systems) or electric boilers.

Commercial lighting is generally next in importance to HVAC for total use of electricity, except in those facilities with energy-intensive processes. Interior lighting is predominantly fluorescent, with an increasing portion of metal halide, a small fraction of incandescent, and a growing use of LED lamps. High-efficiency fluorescent lamps, electronic ballasts, CFL lamps, and improved lighting controls are now the norm. Incandescent lamps still see use in retail for display lighting as well as in older buildings or for decorative or esthetic applications. Lighting—estimated by the EIA to represent 21% of commercial sector electricity use in 2011—shows a reduction over the last two decades, dropping from 27.7% in 1992. The EIA predicts lighting's share of commercial building electricity use will continue to drop, reaching an estimated 15% by 2040 (EIA 2013a).

Refrigeration is an important use of energy in supermarkets and several other types of commercial facilities. As in residential applications, commercial refrigeration's share of electricity use has decreased in the past few decades due to efficiency gains. For example, in 2011, refrigeration accounted for 8% of commercial electricity use, down from 10% in 1992; EIA predictions estimate its share will drop to 7% over the next decade (EIA 2013a).

Commercial electricity use by office equipment has changed substantially over the last 20 years; its share grew from 7% in 1992 to 18% in 1999 and has now decreased to 10% in 2011. Much of the increase at the turn of the millennium was due to a greater use of computers. Computers have now greatly penetrated the commercial sector, and efficiency is constantly improving. As a result, EIA estimates the absolute quantity of energy used by computers will stay relatively constant over the next decade.

Water heating is another energy use in commercial buildings, but here circulating systems (using a heater, storage tank, and pump) are more common. Many possibilities exist for using heat recovery as a source of hot water. The share of electricity use for water heating in commercial buildings has grown from about 1% in 1999 to 2% in 2011. The EIA predicts the absolute quantity of electricity use for water heating will stay relatively constant over the next couple of decades (EIA 2013a).

In commercial buildings, the balance of the electricity use is for elevators, escalators, and miscellaneous items.

---

## **22.2 Setting Up an Energy Management Program**

The general procedure for establishing an energy management program in buildings involves five steps:

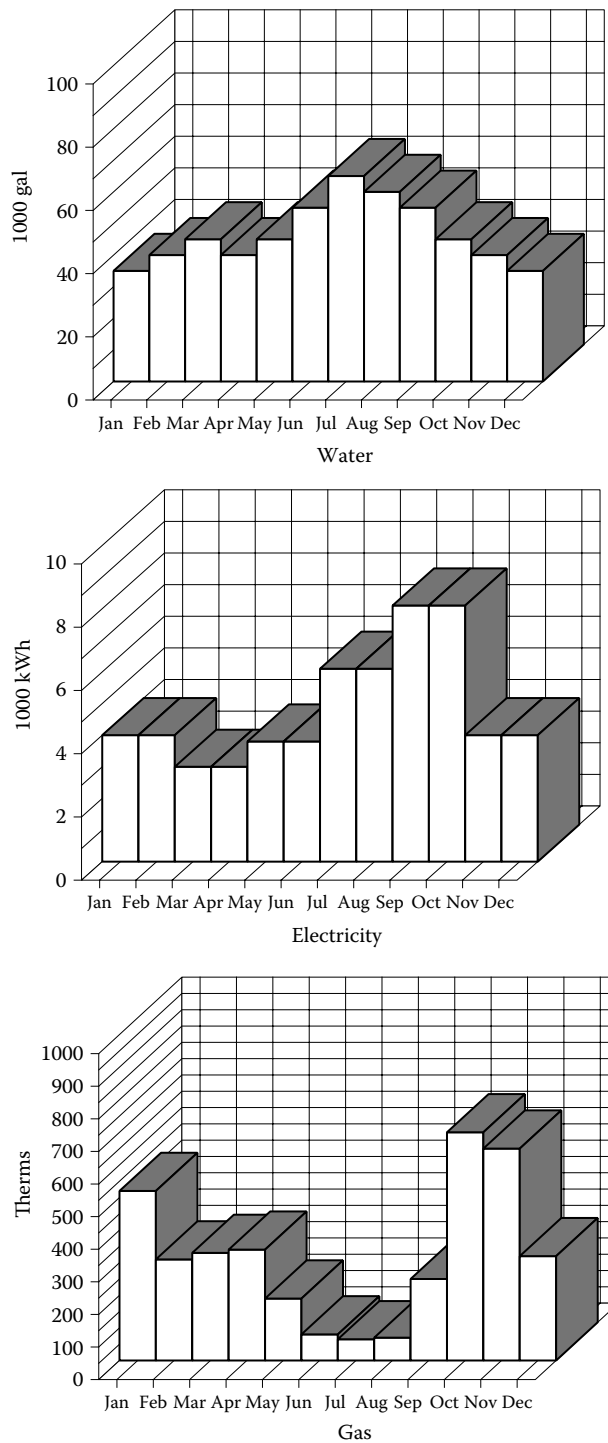

- Review historical energy use.
- Perform energy audits.
- Identify energy management opportunities (EMOs).
- Implement changes to save energy.
- Monitor the energy management program, set goals, and review progress.

Each step will be described briefly. These steps have been designed for homeowners, apartment owners, and commercial building owners or operators to carry out. Many electric utilities also provide technical and financial assistance for various types of energy efficiency studies and improvements, so building owners and operators are encouraged to seek support from their local utility.

### **22.2.1 Review of Historical Energy Use**

Utility records can be compiled to establish electricity use for a recent 12-month period. These should be graphed (see [Figure 22.3](#)) so that annual variations and trends can be evaluated. By placing several years (e.g., last year, this year, and next year projected) on the graph, past trends can be reviewed and future electricity use can be compared with goals. Alternatively, several energy graphs can be compared, or energy use versus production determined (meals served, for a restaurant, kilograms of laundry washed, for a laundry, etc.).

Previously, the norm was to review monthly data to look for energy use trends; however, daily, hourly, 15 min, and even 1 min energy data is now much more available due to the increasing deployment of interval meters. Studying trends in interval data allows building owners to have a greater understanding of exactly when electricity is used in addition to how much is used in a given billing cycle. This additional knowledge can

**FIGURE 22.3**  
Sample graph: Historical energy use in an office building.

**FIGURE 22.4**

Example of single family home daily electric load profile, summer.

help building owners or operators manage loads during peak demand periods. Figure 22.4 illustrates a daily load profile generated with hourly interval data for a single family home in California. The graph has two daily peaks: the midday peak is when the home's pool pump is on and the evening peak is when the family turns on lights, cooks dinner, uses the spa, and watches television.

### 22.2.2 Perform Energy Audits

Figures 22.5 and 22.6 are data sheets used in performing an energy audit of a building. The Building Energy Survey Form (Figure 22.5) provides a gross indication of how energy is used in the building in meeting the particular purpose for which it was designed. This form would not be applicable to single family residences, but it could be used with apartments. It is primarily intended for commercial buildings.

Figure 22.6 is a form used to gather information concerning energy used by each piece of equipment in the building. When totaled, the audit results can be compared with the historical energy use records plotted on Figures 22.3 and 22.4. The energy audit results show a detailed breakdown and permit identification of major energy using equipment items.

Another way to perform energy audits is to use a laptop and a commercially available database or spreadsheet program to record the data and make the calculations. If the workload is extensive, the program can include *look-up* tables of frequently used electrical loads, utility rates, and other essential information to automate the process. We have used teams of engineers with laptops to rapidly survey and collect the energy data from large commercial facilities. See Figure 22.7 for example results from a lighting audit conducted several years ago.

In some cases, monitoring of key equipment may be warranted to improve the accuracy of the audit results. Monitoring provides insight into the actual time-based loads of equipment. It can also be used to simply indicate when loads are turned on or off. It is particularly valuable for highly variable or weather-dependent loads, including HVAC equipment. Monitoring can be accomplished with temporary data loggers that are placed on equipment for a representative period of time (e.g., 2–4 weeks). Permanent monitoring devices integrated with building management system can also be used to characterize

<b>Building Description</b>

<sup>a</sup> Source EUI represents the quantity of raw fuel used to operate a building; it captures energy losses associated with the generation, transmission, and distribution of electricity.

<sup>b</sup> Site EUI represents the quantity of energy used directly on site.

#### 22.2.4 Implement Changes

Once certain actions to save energy have been identified, an economic analysis will be necessary to establish the economic benefits and to determine if the cost of the action is justified. (Refer to Chapter 12 for guidance.) Those changes that satisfy the economic criteria of the building owner (or occupant) will then be implemented. Economic criteria might include a minimum return on investment (e.g., 25%), a minimum payback period (e.g., 2 years), or a minimum benefit–cost ratio (e.g., 2.0).

#### 22.2.5 Monitor the Program, Establish Goals

This is the final—and perhaps most important—step in the program. A continuing monitoring program is necessary to ensure that energy savings do not gradually disappear as personnel return to their old ways of operation, equipment gets out of calibration, needed maintenance is neglected, etc. Also, setting goals (they should be realistic) provides energy management personnel with targets against which they can gauge their performance and the success of their programs.

#### 22.2.6 Summary of Energy Management Programs

The foregoing has been outlined in two tables to provide a step-by-step procedure for electrical energy management in buildings. Table 22.3 is directed at the homeowner or apartment manager, while Table 22.4 has been prepared for the commercial building owner or operator. Industrial facilities are treated separately; refer to Chapter 29. As mentioned previously, prior to undertaking an independent energy management program, ask your electric utility if you qualify for technical support or financial assistance.

One problem in performing the energy audit is determining the energy used by each item of equipment. In many cases, published data are available—as in Table 22.5 for residential appliances. In other cases, engineering judgments must be made, the manufacturer consulted, or instrumentation provided to actually measure energy use.

**TABLE 22.3****Energy Management Plan for the Homeowner or Apartment Manager****Review Historical Data**

1. Collect utility bills for a recent 12-month period.
2. Add up the bills and calculate total kWh, total \$, average kWh (divide total by 12), average \$, and note the months with the lowest and highest kWh. If you have access to interval data, investigate daily load profiles and note the hours of peak usage.
3. Calculate a seasonal variation factor (svf) by dividing the kWh for the greatest month by the kWh for the lowest month.

**Perform Energy Audits**

4. Identify all electrical loads greater than 1 kW (1000 W). Refer to [Table 22.5](#) for assistance. Most electrical appliances have labels indicating the wattage. If not, use the relation  $W = V \times A$ .
5. Estimate the number of hours per month each appliance is used.
6. Estimate the percentage of full load (pfl) by each device under normal use. For a lamp, it is 100%; for water heaters and refrigerators, which cycle on and off, about 30%, for an electric range, about 25% (only rarely are *all* burners *and* the oven used), etc.
7. For each device, calculate kWh by multiplying:  $\text{kW} \times \text{hours/month} \times \text{pfl} = \text{kWh/month}$ .
8. Add up all kWh calculated by this method. The total should be smaller than the average monthly kWh calculated in Step 2.
9. Note: if the svf is greater than 1.5, the load shows strong seasonal variation, for example, summer air conditioning, winter heating, etc. If this is the case, make two sets of calculation, one for the lowest month (when the fewest loads are operating) and one for the highest month.
10. Make a table listing the wattage of each lamp and the estimated numbers of hours of use per month for each lamp. Multiply Watts times hours for each, sum, and divide by 1000. This gives kWh for the lighting loads. Add this to the total shown.
11. Add the refrigerator, television, and all other appliances or tools that use 5 kWh/month or more.
12. By this process, you should now have identified 80%–90% of electricity using loads. Other small appliances that are used infrequently can be ignored. The test is to now compare with the average month (high or low month if svf is greater than 1.5). If your total is too high, you have overestimated the pfl or the hours of use.
13. Now rank each appliance in descending order of kWh used per month. Your list should read approximately like this:
  - First: Air conditioning (hot climates)
  - Second: Lighting
  - Third: Water heating
  - Fourth: Refrigeration
  - Fifth: Televisions and related equipment
  - Sixth: Space heating (electric)
  - Seventh to last: All others

**Identify Opportunities and Apply Energy Management Principles**

14. Attack the highest priority loads first. There are three general things that can be done to save energy and/or lower energy bills: (1) reduce kW (more efficient lamps and appliances); (2) reduce hours of use (turn lights off, etc.); (3) shift operation of loads to off-peak periods (if your electricity rates are higher during peak hours). Refer to the text for detailed suggestions.
15. *Educate* and get support from family members or other occupants of the space.

**Monitor Program, Calculate Savings**

16. After the energy management program has been initiated, examine subsequent utility bills to determine if you are succeeding.
17. Calculate energy and cost savings by comparing utility data.
18. Continue to set goals and try to meet them.

**TABLE 22.4****Energy Management Plan for Commercial Building Operator****Review Historical Data**

1. Collect utility bills for a recent 12-month period.
2. Add up the bills and calculate total kWh, total \$, average kWh (divide total by 12), average \$, and note the months with the lowest and highest kWh. If you have access to interval data, investigate daily load profiles and note hours of peak usage.
3. Calculate an svf by dividing the kWh for the greatest month by the kWh for the lowest month.
4. Prepare a graph of historical energy use (see [Figures 22.3](#) and [22.4](#)).

**Perform Energy Audits**

5. Evaluate major loads. In commercial buildings, loads can be divided into four categories:
  - a. HVAC (fans, pumps, chillers, heaters, cooling towers)
  - b. Lighting
  - c. Office equipment and appliances (elevators, computers, cash registers, copy machines, hot water heaters, etc.)
  - d. Process equipment (as in laundries, restaurants, bakeries, shops, etc.)

Items a–c are common to all commercial operations and will be discussed here. Item d overlaps with industry and the reader should also refer to Chapter 29. Generally items a, b, and d account for the greatest use of electricity and should be examined in that order.
6. In carrying out the energy audit, focus on major loads. Items that together comprise less than 1% of the total connected load in kW can often be ignored with little sacrifice in accuracy.
7. Use the methodology described earlier and in Chapter 31 for conducting the audit.
8. Compare audit results with historical energy use. If 80%–90% of the total (according to the historical records) has been identified, this is generally adequate.

**Formulate the Energy Management Plan**

9. Secure management commitment. The need for this varies with the size and complexity of the operation. However, any formal program will cost something, in terms of salary for the energy coordinator as well as (possibly) an investment in building modifications and new equipment. At this stage, it is very important to project current energy usage and costs ahead for the next 3–5 years, make a preliminary estimate of potential savings (typically 10%–50% per year), and establish the potential payback or return on investment in the program.
10. Develop a list of EMOs and estimate the cost of each EMO and its payback. Methods for economic analysis are given in Chapter 12. For ideas and approaches useful for identifying EMOs, refer to the text.
11. Communicate the plan to employees, department heads, equipment operators, etc. Spell out who will do what, why there is a need, what are the potential benefits and savings. Make the point (if appropriate) that *the energy you save may save your job*. If employees are informed, understand the purpose, and realize that the plan applies to everyone, including the president, cooperation is increased.
12. Set goals for department managers, building engineers, equipment operators, etc., and provide monthly reports so that they can measure their performance.
13. Enlist the assistance of all personnel in (1) better *housekeeping and operations* (e.g., turning off lights, keeping doors closed) and (2) locating obvious wastes of electricity (e.g., equipment operating needlessly, better methods of doing jobs).

**Implement Plan**

14. Implementation should be done in two parts. First, carry out operational and housekeeping improvements with a goal of, say, 10% reduction in electricity use at essentially no cost and no reduction in quality of service or quantity of production. Second, carry out those modifications (retrofitting of buildings, new equipment, process changes) that have been shown to be economically attractive.
15. As changes are made, it is important to continue to monitor electricity usage to determine if goals are being realized. Additional energy audits may be justified.

**Evaluate Progress, Management Report**

16. Compare actual performance to the goals established in Item 12. Make corrections for weather variations, increases or decreases in production or number of employees, addition of new buildings, etc.
17. Provide a summary report of energy quantities and dollars saved.
18. Prepare new plans for the future.

**TABLE 22.5**

Typical Residential Energy Usage for Common Appliances

Electric Appliances	Power (W)
<i>Home entertainment</i>	
Radio	10–20
Stereo	50–400

Filter pump (1–1/2 hp)	1,120
Filter pump (2 hp)	1,500
Spa electric heater	1,500–5,500

## 22.3 Electricity-Saving Techniques by Category of End Use

This section discusses strategies for saving energy in the major end uses found in residential and commercial buildings. Projects that can be implemented in a short time at zero or low capital cost are presented along with retrofit and new design strategies. The ordering of topics corresponds approximately to their importance in terms of building energy use. Smaller end uses and processes specific to select building types are excluded.

### 22.3.1 Residential HVAC

Residential HVAC units using electricity are generally air conditioning systems, electric resistance heaters, heat pumps, and ventilation fans. Cooling systems range from window

air conditioning units to central air conditioning systems. Evaporative coolers are also used in some climates. Heater types range from electric furnaces, small radiant heaters, duct heaters, and strip or baseboard heaters, to embedded floor or ceiling heating systems. Heat pump systems can be used for both heating and cooling and are a highly efficient alternative.

Principal operational and maintenance strategies for existing equipment include the following:

- System maintenance and cleanup
- Thermostat calibration and set-back
- Night cool down
- Improved controls and operating procedures
- Heated or cooled volume reduction
- Reduction of infiltration and exfiltration losses

System maintenance is an obvious but often neglected energy-saving tool. Dirty heat transfer surfaces decrease in efficiency. Clogged filters increase pressure drops and pumping power. Inoperable or malfunctioning dampers can waste energy and prevent proper operation of the system.

In residential systems, heating and cooling are generally controlled by a central or local thermostat. Thermostats should be set to about 26°C (78°F) or higher for cooling and 20°C (68°F) or lower for heating when occupants are home and awake. During periods when occupants are away or asleep, the temperature set points should be adjusted to reduce heating and cooling energy use. As a first step, check the calibration of the thermostat, since these low cost devices can be inaccurate by as much as  $\pm 5^\circ\text{C}$ . Programmable thermostats are now widely available. These can be programmed by the user to set-back or set-forward temperature automatically depending on the time of day and day of week. By eliminating the need for manual control, they ensure that the settings will indeed be changed, whereas manual resetting of thermostats depends on occupant diligence. Some utilities have set up demand response programs in which they can communicate with smart thermostats, also referred to as programmable communicating thermostats (PCTs). Participating customers can program their PCTs to control the temperature in response to pricing signals or other demand response event notifications from the utility, thereby reducing peak demand and lowering energy costs. In some programs, the utility uses the PCT to control the customer's equipment directly during high peak periods. A general rule of thumb is that for every 1°C of thermostat set-back (heating) or set-forward (cooling) during an 8 h period, there is a 1% savings in annual heating or cooling energy costs. (The energy savings are generally lower in more severe climates.)

Sometimes simple changes in controls or operating procedures will save energy. In cooling, use night air for summer cool-down. When the outside air temperature is cool, turn off the air conditioner and circulate straight outside air or simply open windows. If fan units have more than one speed, use the lowest speed that provides satisfactory operation. Also, check the balance of the system and the operation of dampers and vents to insure that heating and cooling is provided in the correct quantities where needed.

Reducing the volume of the heated or cooled space can yield energy savings. This can be accomplished by closing vents, doors, or other appropriate means. Usually, it is not necessary to heat or cool an entire residence; the spare bedroom is rarely used, halls can be closed off, etc.

A major cause of energy wastage is air entering or leaving a home. Unintentional air transfer toward the inside is referred to as *infiltration*, and unintentional air transfer toward the outside is referred to as *exfiltration*. However, *infiltration* is often used to imply air leakage both into and out of a home, and this is the terminology used in this chapter. In a poorly *sealed* residence, infiltration of cold or hot air will increase heating or cooling energy use. A typical home loses 25%–40% of its HVAC energy through infiltration. Infiltration also affects concentrations of indoor pollutants and can cause uncomfortable drafts. Air can infiltrate through numerous cracks and spaces created during building construction, such as those associated with electrical outlets, pipes, ducts, windows, doors, and gaps between ceilings, walls, floors, and so on. Infiltration results from temperature and pressure differences between the inside and outside of a home caused by wind, natural convection, and other forces. Major sources of air leakage are attic bypasses (paths within walls that connect conditioned spaces with the attic), fireplaces without dampers, leaky ductwork, window and door frames, and holes drilled in framing members for plumbing, electrical, and HVAC equipment. According to the U.S. Department of Energy, the most significant source for infiltration is the combination of walls, ceilings, and floors, which comprises 31% of the total infiltration in a typical home. Ducts (15%), fireplaces (14%), plumbing penetrations (13%), doors (11%), and windows (10%) are also substantial contributors to infiltration. Of lesser consequence are fans and vents (4%) and electrical outlets (2%).

To combat infiltration, builders of energy-efficient homes use house wraps, caulking, foam insulation, tapes, and other seals. Sealing ducts in the home is also important to prevent the escape of heated or cooled air. Homeowners should also check for open doors and windows, open fireplace dampers, inadequate weather stripping around windows and doors, and any other openings that can be sealed. Caution must be exercised to provide adequate ventilation, however. Standards vary, depending on the type of occupancy. Ventilation rates specified in the builder guidelines for the American Lung Association's Health House program state that for healthy homes "continuous general ventilation should be at least 1.0 cfm (cubic feet per minute) per 100 ft<sup>2</sup> of floor area plus at least 15 cfm for the first bedroom and 7.5 cfm for each additional bedroom." In addition, intermittent ventilation for the kitchen should be at least 100 cfm. For the bathrooms, rates should be 50 cfm intermittent or 20 cfm continuous. The Health House ventilation rates comply with ASHRAE standard 62.2.

In retrofit or new design projects, the following techniques will save energy:

- Site selection and building orientation
- Building envelope design
- Selection of efficient heating/cooling equipment

Site selection and building orientation are not always under the control of the owner/occupant. Where possible, though, select a site sheltered from temperature extremes and wind. Orient the building (in cold climates) with a maximum southerly exposure to take advantage of direct solar heating in winter. Use earth berms to reduce heat losses on northerly exposed parts of the building. Deciduous trees provide summer shading but permit winter solar heating.

Building envelope design can improve heat absorption and retention in winter and summer coolness. The first requirement is to design a well-insulated, thermally tight structure. Insulation reduces heating and cooling loads by resisting the transfer of heat through ceilings, walls, floors, and ducts. Reductions are usually proportionately higher for heating

than for cooling because of generally larger indoor-to-outdoor temperature differences in winter than in summer. Insulation is available in a variety of forms including batts, rolls, boards, blocks, loose-fill, or sprayed foam. The appropriate insulation material is selected on the basis of climate, building type, and recommended R-value. Higher R-values indicate better insulating properties. It is typically cost-effective to use greater than recommended R-values to improve energy efficiency above and beyond standard building practice.

Windows are an important source of heat gain and loss. The heat loss for single pane glazing is around  $5\text{--}7\text{ W/m}^2\text{C}$ . For double glazing, the comparable value is in the range of  $3\text{--}4\text{ W/m}^2\text{C}$ . Window technology is constantly improving. Newer windows often have low emissivity (low-E) or spectrally selective coatings to prevent heat gain and/or loss. Low-E windows with an argon gas fill have a heat loss rate of about  $2\text{ W/m}^2\text{C}$ . They have a higher visible transmittance, and are available with a low solar heat gain coefficient to reduce cooling loads in the summer. Low-E windows are available with an internal plastic film, which essentially makes them triple glazed. The heat loss rate for these windows is on the order of  $1\text{ W/m}^2\text{C}$ .

Windows equipped with vinyl, wood, or fiberglass frames, or aluminum frames with a thermal barrier, provide the best insulation. It is also important to seal windows to prevent infiltration, as well as to use window coverings to minimize heat loss by radiation to the exterior during the evening. The appropriate placement of windows can also save energy by providing daylighting.

In general, the most efficient electric heating and cooling system is the heat pump. Common types are air-to-air heat pumps, either a single package unit (similar to a window air conditioner) or a split system where the air handling equipment is inside the building and the compressor and related equipment are outdoors. Commercially available equipment demonstrates a wide range of efficiency. Heating performance is measured in terms of a heating seasonal performance factor (HSPF), in BTUs of heat added per Watt-hour of electricity input. Typical values are  $6.8\text{--}10.0$  for the most efficient heat pumps. Cooling performance of residential heat pumps, air conditioners, and packaged systems is measured in terms of a seasonal energy efficiency ratio (SEER), which describes the ratio of cooling capacity to electrical power input. Typical values are  $10.0\text{--}14.5$  and even higher for the most efficient systems. The Federal standards set in 2006 for air conditioners, heat pumps, and residential packaged units require a minimum SEER of 13 and a minimum HSPF of 7.7. Many existing older units have SEERs of  $6\text{--}7$ , or roughly half the new minimum requirement. Therefore, substantial efficiency improvements are possible by replacing older equipment. In purchasing new equipment, consider selecting systems with the highest HSPF and SEER. The operating savings almost always justify the higher initial cost of these units. In addition, many utilities offer rebates for installing the more efficient units.

Sizing of equipment is important, since the most efficient operation generally occurs at or near full load. Selection of oversized equipment is thus initially more expensive, and will also lead to greater operating costs.

The efficiency of heat pumps declines as the temperature difference between the heat source and heat sink decreases. Since outside air is generally the heat source, heat is most difficult to get when it is most needed. For this reason, heat pumps often have electrical backup heaters for extremely cold weather.

An alternate approach is to design the system using a heat source other than outside air. Examples include heated air (such as is exhausted from a building), a deep well (providing water at a constant year-round temperature), the ground, or a solar heat source. There are a great many variations on solar heating and heat pump combinations.

### 22.3.2 Nonresidential HVAC

HVAC systems in commercial buildings and other nonresidential installations may involve package rooftop or ground mounted units, or a central plant. Although the basic principles are similar to those discussed earlier in connection with residential systems, the equipment is larger and control more complex.

Efficiency of many existing HVAC systems can be improved. Modifications can reduce energy use by 10%–15%, often with building occupants unaware that changes have been made. Instituting an energy management program that includes evaluating and fine-tuning the operation of HVAC systems to ensure they are operating as originally designed (referred to as retrocommissioning in existing buildings) can uncover many inefficiencies and often yields significant energy savings and improved comfort.

The basic function of HVAC systems is to heat, cool, dehumidify, humidify, and provide air mixing and ventilating. The energy required to carry out these functions depends on the building design, its duty cycle (e.g., 24 h/day use as in a hospital vs. 10 h/day in an office), the type of occupancy, the occupants' use patterns and training in using the HVAC system, the type of HVAC equipment installed, and finally, daily and seasonal temperature and weather conditions to which the building is exposed.

A complete discussion of psychometrics, HVAC system design, and commercially available equipment types is beyond the scope of this chapter.

Energy management strategies will be described in three parts:

- Equipment modifications (control, retrofit, and new designs)
  - Fans
  - Pumps
  - Packaged air conditioning units
  - Chillers
  - Ducts and dampers
  - Systems
- Economizer systems and enthalpy controllers
- Heat recovery techniques

#### 22.3.2.1 Equipment Modifications (Control, Retrofit, and New Designs)

##### 22.3.2.1.1 Fans

All HVAC systems involve some movement of air. The energy needed for this motion can make up a large portion of the total system energy used. This is especially true in moderate weather when the heating or cooling load drops off, but the distribution systems often operate at the same level.

**22.3.2.1.1.1 Control** Simple control changes can save electrical energy in the operation of fans. Examples include turning off large fan systems when relatively few people are in the building or stopping ventilation a half hour before the building closes. The types of changes that can be made will depend upon the specific facility. Some changes involve more sophisticated controls, which may already be available in the HVAC system.

**22.3.2.1.1.2 Retrofit** The capacity of the building ventilation system is usually determined by the maximum cooling or heating load in the building. This load may change over time

due to reduced outside air requirements, more efficient lighting, and fluctuations in building occupancy. As a result, it may be feasible to decrease air flow in existing commercial buildings as long as adequate indoor air quality is maintained.

The volume rate of air flow through the fan,  $Q$ , varies directly with the speed of the impeller's rotation. This is expressed as follows for a fan whose speed is changed from  $N_1$  to  $N_2$ .

$$Q_2 = \left( \frac{N_2}{N_1} \right) \times Q_1 \quad (22.1)$$

The pressure developed by the fan,  $P$ , (either static or total) varies as the square of the impeller speed.

$$P_2 = \left( \frac{N_2}{N_1} \right)^2 \times P_1 \quad (22.2)$$

The power needed to drive the fan,  $H$ , varies as the cube of the impeller speed.

$$H_2 = \left( \frac{N_2}{N_1} \right)^3 \times H_1 \quad (22.3)$$

The result of these laws is that for a given air distribution system (specified ducts, dampers, etc.), if the air flow is to be doubled, eight ( $2^3$ ) times the power is needed. Conversely, if the air flow is to be cut in half, one-eighth ( $\frac{1}{2^3}$ ) of the power is required. This is useful in HVAC systems, because even a small reduction in air flow (say 10%) can result in significant energy savings (27%).

The manner in which the air flow is reduced is critical in realizing these savings. Sizing the motor exactly to the requirements helps to yield maximum savings. Simply changing pulleys to provide the desired speed will also result in energy reductions according to the cubic law. Note the efficiency of existing fan motors tends to drop off below the half load range.

If variable volume air delivery is required, it may be achieved through inlet vane control, outlet dampers, variable speed drives (VSDs), controlled pitch fans, or cycling. Energy efficiency in a retrofit design is best obtainable with VSDs on motors. This can be seen by calculating the power reduction that would accompany reduced flow using different methods of control, as noted in [Table 22.6](#). Numbers in the table are the percent of full-flow input power:

**22.3.2.1.1.3 New Design** The parameters for new design are similar to those for fan retrofit. It is desirable, when possible, to use a varying ventilation rate that will decrease as the load decreases. A system such as variable air volume incorporates this in the interior zones of a building. In some cases, there will be a trade-off between power saved by running the fan slower and the additional power needed to generate colder air. The choices should be determined on a case-by-case basis.

#### 22.3.2.1.2 Pumps

Pumps are found in a variety of HVAC applications such as chilled water, heating hot water, and condenser water loops. They are another piece of peripheral equipment that can use a large portion of HVAC energy, especially at low system loads.

TABLE 22.6

Comparison of Flow Control Alternatives for Fans and Pumps

Flow (%)	Percent of Full-Flow Input Power				
	Fans			Pumps	
	Inlet Vanes	Dampers	VSDs	Throttle Valve	VSDs
100	102	103	102	101	103
90	86	98	76	96	77
80	73	94	58	89	58
70	64	88	43	83	41
60	56	81	31	77	30
50	50	74	22	71	19
40	46	67	15	65	13
30	41	59	9	59	8

**22.3.2.1.2.1 Control** The control of pumps is often neglected in medium and large HVAC systems where it could significantly reduce the demand. A typical system would be a three chiller installation where only one chiller is needed much of the year. Two chilled water pumps in parallel are designed to handle the maximum load through all three chillers. Even when only one chiller is on, both pumps are used. When not needed to meet demand, two chillers could be bypassed and one pump turned off. All systems should be reviewed in this manner to ensure that only the necessary pumps operate under normal load conditions.

**22.3.2.1.2.2 Retrofit** Pumps follow laws similar to fan laws, the key being the cubic relationship of power to the volume pumped through a given system. Small decreases in flow rate can save significant portions of energy.

In systems in which cooling or heating requirements have been permanently decreased, flow rates may be reduced also. A simple way to do this is by trimming the pump impeller. The pump curve must be checked first, however, because pump efficiency is a function of the impeller diameter, flow rate, and pressure rise. After trimming, one should ensure that the pump will still be operating in an efficient region. This is roughly the equivalent of changing fan pulleys in that the savings follow the cubic law of power reduction.

Another method for decreasing flow rates is to use a *throttle* (pressure reducing) valve. The result is equivalent to that of the discharge damper in the air-side systems. The valve creates an artificial use of energy, which can be responsible for much of the work performed by the pumps. VSDs are more efficient for varying flow, as shown in Table 22.6.

**22.3.2.1.2.3 New Design** In a variable load situation, common to most HVAC systems, more efficient systems with new designs are available, rather than the standard constant volume pump. (These may also apply to some retrofit situations.)

One option is the use of several pumps of different capacity so that a smaller pump can be used when it can handle the load and a larger pump used the rest of the time. This can be a retrofit modification as well when a backup pump provides redundancy. Its impeller would be trimmed to provide the lower flow rate.

Another option is to use VSD pumps. While their initial cost is greater, they offer a significant improvement in efficiency over the standard pumps. The economic desirability of this or any similar change can be determined by estimating the number of hours the system will operate under various loads. Many utilities also offer rebates for installing variable speed pumps.

### 22.3.2.1.3 Package Air Conditioning Units

The most common space conditioning systems for commercial buildings are unitary equipment, either single package systems or split systems. These are used for cooling approximately two-thirds of the air-conditioned commercial buildings in the United States. For very large buildings or building complexes, absorption chillers or central chiller plants are used. (The following section describes Chillers.)

Air conditioner efficiency is typically rated by one or more of three parameters: the energy efficiency ratio (EER), the SEER as described previously, and the integrated energy efficiency ratio (IEER) that replaces a former metric used called the integrated part-load value (IPLV). The EER is easy to understand; it is the ratio of cooling capacity, expressed in BTU/hour (kilojoules/hour) to the power input required in Watts. The SEER is a calculated ratio of the total annual cooling produced per annual electrical energy input in Watt-hours for units rated at less than 65,000 BTU/h. The IEER is a new part-load metric introduced in ASHRAE Standard 90.1-2010 to replace the IPLV for rating commercial unitary loads of more than 65,000 BTU/h.

Great improvements in packaged air conditioner efficiency have been made in the last few decades, and new standards continue to increase efficiency even further. This is illustrated by the 30% increase in minimum SEER requirement that took effect in June 2008 for commercial three-phase central air conditioners and heat pumps under 65,000 BTU/h as the result of the EISA (2007). The current standard is a minimum SEER of 13.0. These commercial units are similar to the residential central air conditioners and heat pumps discussed earlier in the chapter in the residential HVAC section. Standards for larger units (>65,000 BTU/h) also continue to increase. All current standards are published in ASHRAE Standard 90.1-2010. Manufacturers sell systems with a broad range of efficiencies. Units with high EERs are typically more expensive, as the greater efficiency is achieved with larger heat exchange surface, more efficient motors, and so on.

To evaluate the economic benefit of the more efficient units, it is necessary to determine an annual operating profile, which depends in part on the nature of the load and on the weather and temperature conditions at the site where the equipment will be installed. Or, an approximate method can be used. ASHRAE publishes tables that show typical *equivalent full-load operating hours* for different climate zones. These can be used to estimate the savings in electrical energy use over a year and thereby determine if the added cost of a more efficient unit is justified. (It almost always is.)

Since the more efficient unit is almost always more cost-effective (except in light or intermittent load conditions), one might wonder why the less efficient units are sold. The reason is that many commercial buildings are constructed and sold by developers whose principal concern is keeping the initial cost of the building as low as practicable. They do not have to bear the annual operating expense of the building once it is sold, and therefore have less incentive to minimize operating expenses. However, the demand for energy-efficient and LEED-certified buildings is growing, causing many developers to rethink design approaches.\*

### 22.3.2.1.4 Chillers

Chillers are often the largest single energy user in the HVAC system. The chiller cools the water used to extract heat from the building and outside air. Optimizing chiller operation improves the performance of the whole system.

---

\* LEED stands for Leadership in Energy & Environmental Design, <http://www.usgbc.org/leed>.

Two basic types of chillers are found in commercial and industrial applications: absorption and mechanical chillers. Absorption units boil water, the refrigerant, at a low pressure through absorption into a high concentration lithium bromide solution. Mechanical chillers cool through evaporation of a refrigerant at a low pressure after it has been compressed, cooled, and passed through an expansion valve. Hydrochlorofluorocarbon (HCFC) products such as R22 are among the most common refrigerants used; however, they are currently being phased out, because they contribute to ozone depletion. The Environmental Protection Agency (EPA) lists acceptable refrigerant substitutes for various types of chillers on their website. Ammonia is a type of refrigerant that has been increasing in favor due to its efficiency advantages and the fact that it will continue to be available.

There are three common types of mechanical chillers. They have similar thermodynamic properties, but use different types of compressors. Reciprocating and screw-type compressors are both positive displacement units. The centrifugal chiller uses a rapidly rotating impeller to pressurize the refrigerant.

All of these chillers must reject heat to a heat sink outside the building. Some use air-cooled condensers, but most large units operate with evaporative cooling towers. Cooling towers have the advantage of rejecting heat to a lower-temperature heat sink, because the water approaches the ambient wet-bulb temperature, while air-cooled units are limited to the dry-bulb temperature. As a result, air-cooled chillers have a higher condensing temperature, which lowers the efficiency of the chiller. In full-load applications, air-cooled chillers require about 1–1.3 kW or more per ton of cooling, while water-cooled chillers usually require between 0.4 and 0.9 kW/ton. Air-cooled condensers are sometimes used, because they require much less maintenance than cooling towers and have lower installation costs. They can also be desirable in areas of the country where water is scarce and/or water and water treatment costs are high, since they do not depend on water for cooling.

Mechanical cooling can also be performed by direct expansion (DX) units. These are very similar to chillers except that they cool the air directly instead of using the refrigerant as a heat transfer medium. They eliminate the need for chilled water pumps and also reduce efficiency losses associated with the transfer of the heat to and from the water. DX units must be located close (~30 m) to the ducts they are cooling, so they are typically limited in size to the cooling required for a single air handler. A single large chiller can serve a number of distributed air handlers. Where the air handlers are located close together, it can be more efficient to use a DX unit.

**22.3.2.1.4.1 Controls** Mechanical chillers operate on a principle similar to the heat pump. The objective is to remove heat from a low-temperature building and deposit it in a higher temperature atmosphere. The lower the temperature rise that the chiller has to face, the more efficiently it will operate. It is useful, therefore, to maintain as warm a chilled water loop and as cold a condenser water loop as possible.

Using lower-temperature water from the cooling tower to reject the heat can save energy. However, as the condenser temperature drops, the pressure differential across the expansion valve drops, starving the evaporator of refrigerant. Many units with expansion valves, therefore, operate at a constant condensing temperature, usually 41°C (105°F), even when more cooling is available from the cooling tower. Field experience has shown that in many systems, if the chiller is not fully loaded, it can be operated with a lower cooling tower temperature.

**22.3.2.1.4.2 Retrofit** Where a heat load exists and the wet-bulb temperature is low, cooling can be done directly with the cooling tower. If proper filtering is available, the cooling tower water can be piped directly into the chilled water loop. Often a direct heat exchanger

between the two loops is preferred to protect the coils from fouling. Another technique is to turn off the chiller but use its refrigerant to transfer heat between the two loops. This *thermocycle* uses the same principles as a heat pipe, and only works on chillers with the proper configuration.

A low wet-bulb temperature during the night can also be utilized. It requires a chiller that handles low condensing temperatures and a cold storage tank. This thermal energy storage (TES) technique is particularly desirable for consumers with access to time-based electricity rates that reward peak-shaving or load-shifting.

**22.3.2.1.4.3 New Design** In the purchase of a new chiller, an important consideration should be the load control feature. Since the chiller will be operating at partial load most of the time, it is important that it can do so efficiently. Variable speed chillers are an efficient alternative. In addition to control of single units, it is sometimes desirable to use multiple compressor reciprocating chillers. This allows some units to be shut down at partial load. The remaining compressors operate near full load, usually more efficiently. Good opportunities to install a high-efficiency chiller are when an old unit needs to be replaced, or when it is necessary to retire equipment that uses environmentally unacceptable refrigerants.

#### 22.3.2.1.5 Ducting-Dampers

**22.3.2.1.5.1 Controls** In HVAC systems using dual ducts, static pressure dampers are often placed near the start of the hot or cold plenum run. They control the pressure throughout the entire distribution system and can be indicators of system operation. In an overdesigned system, the static pressure dampers may never open more than 25%. Reducing the fan speed and opening the dampers fully can eliminate the previous pressure drop. The same volume of air is delivered with a significant drop in fan power.

**22.3.2.1.5.2 Retrofit** Other HVAC systems use constant volume mixing boxes for balancing that create their own pressure drops as the static pressure increases. An entire system of these boxes could be overpressurized by several inches of water without affecting the air flow, but the required fan power would increase. (One inch of water pressure is about 250 N/m<sup>2</sup> or 250 Pa.) These systems should be monitored to ensure that static pressure is controlled at the lowest required value. It may also be desirable to replace the constant volume mixing boxes with boxes without volume control to eliminate their minimum pressure drop of approximately 1 in. of water. In this case, static pressure dampers will be necessary in the ducting.

Leakage in any dampers can cause a loss of hot or cold air. Adding or replacing seals on the blades can slow leakage considerably. If a damper leaks more than 10%, it can be less costly to replace the entire damper assembly with effective positive-closing damper blades rather than to tolerate the loss of energy.

**22.3.2.1.5.3 New Design** In the past, small ducts were installed because of their low initial cost despite the fact that the additional fan power required offset the initial cost on a life cycle basis. ASHRAE 90.1 guidelines now set a maximum limit on the fan power that can be used for a given cooling capacity. As a result, the air system pressure drop must be low enough to permit the desired air flow. In small buildings, this pressure drop is often largest across filters, coils, and registers. In large buildings, the duct runs may be responsible for a significant fraction of the total static pressure drop, particularly in high velocity systems. New designs should incorporate ducting that optimizes energy efficiency.

### 22.3.2.1.6 Systems

The use of efficient equipment is only the first step in the optimum operation of a building. Equal emphasis should be placed upon the combination of elements in a system and the control of those elements. This section discusses some opportunities for equipment modifications. Chapter 23 describes HVAC control systems in greater detail.

**22.3.2.1.6.1 Control** Some systems use a combination of hot and cold to achieve moderate temperatures. Included are dual duct, multizone, and terminal reheat systems, and some induction, variable air volume, and fan coil units. Whenever combined heating and cooling occurs, the temperatures of the hot and cold ducts or water loops should be brought as close together as possible, while still maintaining building comfort.

This can be accomplished in a number of ways. Hot and cold duct temperatures are often reset on the basis of the temperature of the outside air or the return air. Another approach is to monitor the demand for heating and cooling in each zone. For example, in a multizone building, the demand of each zone is communicated back to the supply unit. At the supply end, hot air and cold air are mixed in proportion to this demand. The cold air temperature should be just low enough to cool the zone calling for the most cooling. If the cold air were any colder, it would be mixed with hot air to achieve the right temperature. This creates an overlap in heating and cooling not only for the zone but for all the zones, because they would all be mixing in the colder air.

If no zone calls for total cooling, then the cold air temperature can be increased gradually until the first zone requires cooling. At this point, the minimum cooling necessary for that multizone configuration is performed. The same operation can be performed with the hot air temperature until the first zone is calling for heating only.

Note that simultaneous heating and cooling is still occurring in the rest of the zones. This is not an ideal system, but it is a first step in improving operating efficiency for these types of systems.

The technique for resetting hot and cold duct temperatures can be extended to the systems that have been mentioned. Ideally, it would be performed automatically with a control system, but it could also be done manually. In some buildings, it will require the installation of more monitoring equipment (usually only in the zones of greatest demand), but the expense should be relatively small and the payback period short.

Nighttime temperature set-back is another control option that can save energy without significantly affecting the comfort level. Energy is saved by shutting off or cycling fans. Building heat loss may also be reduced, because the building is cooler and no longer pressurized.

In moderate climates, complete night shutdown can be used with a morning warm-up period. In colder areas where the overall night temperature is below 4°C (40°F), it is usually necessary to provide some heat during the night. Building set-back temperature is partially dictated by the capacity of the heating system to warm the building in the morning. In some cases, it may be the mean radiant temperature of the building rather than air temperature that determines occupant comfort.

Some warm-up designs use *free heating* from people and lights to help attain the last few degrees of heat. This also provides a transition period for the occupants to adjust from the colder outdoor temperatures.

In some locations during the summer, it is desirable to use night air for a cool-down period. This *free cooling* can decrease the temperature of the building mass that has accumulated heat during the day. In certain types of massive buildings (such as libraries or buildings with thick walls), a long period of night cooling may decrease the building mass

temperature by a degree or two. This represents a large amount of cooling that the chiller will not have to perform the following day.

**22.3.2.1.6.2 Retrofit** Retrofitting HVAC systems may be an easy or difficult task depending upon the possibility of using existing equipment in a more efficient manner. Often retrofitting involves control or ducting changes that appear relatively minor but will greatly increase the efficiency of the system. Some of these common changes, such as decreasing air flow, are discussed elsewhere in this chapter. This section will describe a few changes appropriate to particular systems.

Both dual duct and multizone systems mix hot and cold air to achieve the proper degree of heating or cooling. In most large buildings, the need for heating interior areas is essentially nonexistent, due to internal heat generation. A modification that adjusts for this is simply shutting off air to the hot duct. The mixing box then acts as a variable air volume box, modulating cold air according to room demand as relayed by the existing thermostat. (It should be confirmed that the low volume from a particular box meets minimum air requirements.)

Savings from this modification come mostly from the elimination of simultaneous heating and cooling, depending on fan control strategies. That is, if fans in these systems are controlled by static pressure dampers in the duct after the fan, they do not unload very efficiently and would represent only a small portion of the savings.

### **22.3.2.2 Economizer Systems and Enthalpy Controllers**

The economizer cycle is a technique for introducing varying amounts of outside air to the mixed air duct. Basically, it permits mixing warm return air at 24°C (75°F) with cold outside air to maintain a preset temperature in the mixed air plenum (typically 10°C–15°C, 50°F–60°F). When the outside temperature is slightly above this set point, 100% outside air is used to provide as much of the cooling as possible. During very hot outside weather, minimum outside air will be added to the system.

A major downfall of economizer systems is poor maintenance. The failure of the motor or dampers may not cause a noticeable comfort change in the building, because the system is often capable of handling the additional load. Since the problem is not readily apparent, corrective maintenance may be put off indefinitely. In the meantime, the HVAC system will be working harder than necessary for any economizer installation.

Typically, economizers are controlled by the dry-bulb temperature of the outside air rather than its enthalpy (actual heat content). This is adequate most of the time, but can lead to unnecessary cooling of air. When enthalpy controls are used to measure wet-bulb temperatures, this cooling can be reduced. However, enthalpy controllers are more expensive and less reliable.

The rules that govern the more complex enthalpy controls for cooling-only applications are as follows:

- When outside air enthalpy is greater than that of the return air or when outside air dry-bulb temperature is greater than that of the return air, use minimum outside air.
- When the outside air enthalpy is below the return air enthalpy and the outside dry-bulb temperature is below the return air dry-bulb temperature but above the cooling coil control point, use 100% outside air.

- When outside air enthalpy is below the return air enthalpy and the outside air dry-bulb temperature is below the return air dry-bulb temperature and below the cooling coil controller setting, the return and outside air are mixed by modulating dampers according to the cooling set point.

These points are valid for the majority of cases. When mixed air is to be used for heating and cooling, a more intricate optimization plan will be necessary, based on the value of the fuels used for heating and cooling.

### 22.3.2.3 Heat Recovery

Heat recovery is often practiced in industrial processes that involve high temperatures. It can also be employed in HVAC systems.

Systems are available that operate with direct heat transfer from the exhaust air to the inlet air. These are most reasonable when there is a large volume of exhaust air, for example, in once-through systems, and when weather conditions are not moderate.

Common heat recovery systems are broken down into two types: regenerative and recuperative. Regenerative units use alternating air flow from the hot and cold stream over the same heat storage/transfer medium. This flow may be reversed by dampers or the whole heat exchanger may rotate between streams. Recuperative units involve continuous flow; the emphasis is upon heat transfer through a medium with little storage.

The rotary regenerative unit, or heat wheel, is one common heat recovery device. It contains a corrugated or woven heat storage material that gains heat in the hot stream. This material is then rotated into the cold stream where the heat is given off again. The wheels can be impregnated with a desiccant to transfer latent as well as sensible heat. Purge sections for HVAC applications can reduce carryover from the exhaust stream to acceptable limits for most installations.

The heat transfer efficiency of heat wheels generally ranges from 60% to 85% depending upon the installation, type of media, and air velocity. For easiest installation, the intake and exhaust ducts should be located near each other.

Another system that can be employed with convenient duct location is a plate type air-to-air heat exchanger. This system is usually lighter though more voluminous than heat wheels. Heat transfer efficiency is typically in the 60%–75% range. Individual units range from 1,000 to 11,000 SCFM and can be grouped together for greater capacity. Almost all designs employ counterflow heat transfer for maximum efficiency.

Another option to consider for nearly contiguous ducts is the heat pipe. This is a unit that uses a boiling refrigerant within a closed pipe to transfer heat. Since the heat of vaporization is utilized, a great deal of heat transfer can take place in a small space.

Heat pipes are often used in double wide coils, which look very much like two steam coils fastened together. The amount of heat transferred can be varied by tilting the tubes to increase or decrease the flow of liquid through capillary action. Heat pipes cannot be *turned off*, so bypass ducting is often desirable. The efficiency of heat transfer ranges from 55% to 75%, depending upon the number of pipes, fins per inch, air face velocity, etc.

Runaround systems are also used for HVAC applications, particularly when the supply and exhaust plenums are not physically close. Runaround systems involve two coils (air-to-water heat exchangers) connected by a piping loop of water or glycol solution and a small pump. The glycol solution is necessary if the air temperatures in the inlet coils are below freezing. Standard air conditioning coils can be used for the runaround system. Precaution

should be used when the exhaust air temperature drops below 0°C (32°F), which would cause freezing of the condensed water on its fins. A three-way bypass valve will maintain the temperature of the solution entering the coil at just above 0°C (32°F). The heat transfer efficiency of this system ranges from 60% to 75% depending upon the installation.

Another system similar to the runaround in layout is the desiccant spray system. Instead of using coils in the air plenums, it uses spray towers. The heat transfer fluid is a desiccant (lithium chloride) that transfers both latent and sensible heat—desirable in many applications. Tower capacities range from 7,700 to 92,000 SCFM; multiple units can be used in large installations. The enthalpy recovery efficiency is in the range of 60%–65%.

#### **22.3.2.4 Thermal Energy Storage**

TES systems are used to reduce the on-peak electricity demand caused by large cooling loads. TES systems utilize several different storage media, with chilled water, ice, or eutectic salts being most common. Chilled water requires the most space, with the water typically being stored in underground tanks. Ice storage systems can be aboveground insulated tanks with heat exchanger coils that cause the water to freeze, or can be one of several types of ice-making machines.

In a typical system, a chiller operates during off-peak hours to make ice (usually at night). Since the chiller can operate for a longer period of time than during the daily peak, it can have a smaller capacity. Efficiency is greater at night, when the condensing temperature is lower than it is during the day. During daytime operation, chilled water pumps circulate water through the ice storage system and extract heat. Systems can be designed to meet the entire load, or to meet a partial load, with an auxiliary chiller as a backup.

This system reduces peak demand and can also reduce energy use. With ice storage, it is possible to deliver water at a lower temperature than is normally done. This means that the chilled water piping can be smaller and the pumping power reduced. A low-temperature air distribution system will allow smaller ducts and lower capacity fans to deliver a given amount of cooling. Careful attention must be paid to the system design to ensure occupant comfort in conditioned spaces. Some government agencies and electric utilities offer incentives to customers installing TES systems. The utility incentives could be in the form of a set rebate per ton of capacity or per kW of deferred peak demand, or a time-of-use pricing structure that favors TES.

### **22.3.3 Water Heating**

#### **22.3.3.1 Residential Systems**

Residential storage water heaters typically range in size from 76 L (20 gal) to 303 L (80 gal). Electric units generally have one or two immersion heaters, each rated at 2–6 kW depending on tank size. Energy input for water heating is a function of the temperature at which water is delivered, the supply water temperature, and standby losses from the water heater, storage tanks, and piping.

Tankless water heaters are an energy-efficient alternative that has achieved greater market penetration over the last few years. These systems can be electric or gas-fired and provide hot water on demand, eliminating energy losses associated with a storage tank.

The efficiency of water heaters is referred to as the energy factor (EF). Higher EF values equate to more efficient water heaters. Typical EF values range from about 0.9–0.95 for electric resistance heaters, 0.6–0.86 for natural gas units, 0.5–0.85 for oil units, and 1.5–2.2

for heat pump water heaters. The higher efficiency values for each fuel type represent the more advanced systems available, while the lower efficiency values are for the more conventional systems.

In single tank residential systems, major savings can be obtained by

- Thermostat temperature set back to 60°C (140°F)
- Automated control
- Supplementary tank insulation
- Hot water piping insulation

The major source of heat loss from electric water heaters is standby losses through the tank walls and from piping, since there are no flame or stack losses in electric units. The heat loss is proportional to the temperature difference between the tank and its surroundings. Thus, lowering the temperature to 60°C will result in two savings: (1) a reduction in the energy needed to heat water and (2) a reduction in the amount of heat lost. Residential hot water uses do not require temperatures in excess of 60°C; for any special use which does, it would be advantageous to provide a booster heater to meet this requirement when needed, rather than maintain 100–200 L of water continuously at this temperature with associated losses. The temperature should be set back even lower when occupants are away during long periods of times.

When the tank is charged with cold water, both heating elements operate until the temperature reaches a set point. After this initial rise, one heating element thermostatically cycles on and off to maintain the temperature, replacing heat that is removed by withdrawing hot water or that is lost by conduction and convection during standby operation.

Experiments indicate that the heating elements may be energized only 10%–20% of the time, depending on the ambient temperature, demand for hot water, water supply temperature, etc. By carefully scheduling hot water usage, this time can be greatly reduced. In one case, a residential water heater was operated for 1 h in the morning and 1 h in the evening. The morning cycle provided sufficient hot water for clothes washing, dishes, and other needs. Throughout the day, the water in the tank, although gradually cooling, still was sufficiently hot for incidental needs. The evening heating cycle provided sufficient water for cooking, washing dishes, and bathing. Standby losses were eliminated during the night and much of the day. Electricity use was cut to a fraction of the normal amount. This method requires the installation of a time clock or other type of control to regulate the water heater. A manual override can be provided to meet special needs.

Supplementary tank insulation can be installed at a low cost to reduce standby losses. The economic benefit depends on the price of electricity and the type of insulation installed. However, paybacks of a few months up to a year are typical on older water heaters. Newer units have better insulation and reduced losses. Hot water piping should also be insulated, particularly when hot water tanks are located outside or when there are long piping runs. If copper pipe is used, it is particularly important to insulate the pipe for the first 3–5 m where it joins the tank, since it can provide an efficient heat conduction path.

Since the energy input depends on the water flow rate and the temperature difference between the supply water temperature and the hot water discharge temperature, reducing either of these two quantities reduces energy use. Hot water demand can be reduced by cold water clothes washing, and by providing hot water at or near the

use temperature, to avoid the need for dilution with cold water. Supply water should be provided at the warmest temperature possible. Since reservoirs and underground piping systems are generally warmer than the air temperature on a winter day in a cold climate, supply piping should be buried, insulated, or otherwise kept above the ambient temperature.

Solar systems are available today for heating hot water. Simple inexpensive systems can preheat the water, reducing the amount of electricity needed to reach the final temperature. Alternatively, solar heaters (some with electric backup heaters) are also available, although initial costs may be prohibitively high, depending on the particular installation.

Heat pump water heaters may save as much as 25%–30% of the electricity used by a conventional electric water heater. Some utilities have offered rebates of several thousand dollars to encourage customers to install heat pump water heaters.

The microwave water heater is an interesting technology that is just beginning to emerge in both residential and commercial applications. Microwave water heaters are tankless systems that produce hot water only when needed, thereby avoiding the energy losses incurred by conventional water heaters during the storage of hot water. These heaters consist of a closed stainless steel chamber with a silica-based flexible coil and a magnetron. When there is a demand for hot water, either because a user has opened a tap or because of a heater timing device, water flows into the coil and the magnetron bombards it with microwave energy at a frequency of 2450 MHz. The microwave energy excites the water molecules, heating the water to the required temperature.

Heat recovery is another technique for preheating or heating water, although opportunities in residences are limited. This is discussed in more detail under commercial water heating.

Apartments and larger buildings use a combined water heater/storage tank, a circulation loop, and a circulating pump. Cold water is supplied to the tank, which thermostatically maintains a preset temperature, typically 71°C (160°F). The circulating pump maintains a flow of water through the circulating loop, so hot water is always available instantaneously upon demand to any user. This method is also used in hotels, office buildings, etc.

Adequate piping and tank insulation is even more important here, since the systems are larger and operate at higher temperature. The circulating hot water line should be insulated, since it will dissipate heat continuously otherwise.

#### **22.3.3.2 Heat Recovery in Nonresidential Systems**

Commercial/industrial hot water systems offer many opportunities for employing heat recovery. Examples of possible sources of heat include air compressors, chillers, heat pumps, refrigeration systems, and water-cooled equipment. Heat recovery permits a double energy savings in many cases. First, recovery of heat for hot water or space heating reduces the direct energy input needed for heating. The secondary benefit comes from reducing the energy used to dissipate waste heat to a heat sink (usually the atmosphere). This includes pumping energy and energy expended to operate cooling towers and heat exchangers. Solar hot water systems are also finding increasing use. Interestingly enough, the prerequisites for solar hot water systems also permit heat recovery. Once the hot water storage capacity and backup heating capability has been provided for the solar hot water system, it is economical to tie in other sources of waste heat, for example, water jackets on air compressors.

### 22.3.4 Lighting

There are seven basic techniques for improving the efficiency of lighting systems:

- Delamping
- Relamping
- Improved controls
- More efficient lamps and devices
- Task-oriented lighting
- Increased use of daylight
- Room color changes, lamp maintenance

The first two techniques and possibly the third are low cost and may be considered operational changes. The last four items generally involve retrofit or new designs. (Chapter 25 contains further details on energy-efficient lighting technologies.)

The first step in reviewing lighting electricity use is to perform a lighting survey. An inexpensive handheld light meter can be used as a first approximation; however, distinction must be made between raw intensities (lux or foot-candles) recorded in this way and illumination quality.

Many variables can affect the *correct* lighting values for a particular task: task complexity, age of employee, glare, etc. For reliable results, consult a lighting specialist or refer to the literature and publications of the Illuminating Engineering Society.

The lighting survey indicates those areas of the building where lighting is potentially inadequate or excessive. Deviations from illumination levels that are adequate can occur for several reasons: over design; building changes; change of occupancy; modified layout of equipment or personnel, more efficient lamps, improper use of equipment, dirt buildup, etc.

Once the building manager has identified areas with potentially excessive illumination levels, he or she can apply one or more of the seven techniques listed previously. Each of these will be described briefly.

Delamping refers to the removal of lamps to reduce illumination to acceptable levels. With incandescent lamps, remove unnecessary bulbs. With fluorescent or high intensity discharge (HID) lamps, remove lamps and disconnect ballasts, since ballasts account for 10%–20% of total energy use. Note that delamping is not recommended if it adversely affects the distribution of the lighting; instead, consider relamping.

Relamping refers to the replacement of existing lamps by lamps of lower wattage and lower lumen output in areas with excessive light levels. More efficient lower wattage fluorescent tubes are available that require 15%–20% less wattage while producing 10%–15% less light. In some types of HID systems, it is possible to substitute a more efficient lamp with lower lumen output directly. However, in most cases, ballasts must also be changed.

Improved controls permit lamps to be used only when and where needed. For example, certain office buildings have all lights for one floor or large area on a single contactor. These lamps will be switched on at 6 a.m. before work begins, and are not turned off until 10 p.m. when maintenance personnel finish their cleanup duties. In such cases, energy usage can be cut by as much as 50% by better control and operation strategies: installing individual switches for each office or work area; installing timers, occupancy sensors, daylighting controls, and/or dimmers; and instructing custodial crews to turn lights on as needed and turn them off when work is complete.

Sophisticated building-wide lighting control systems are also available, and today are being implemented at an increasing rate, particularly in commercial buildings.

There is a great variation in the efficacy (a measure of light output per electricity input) of various lamps. Incandescent lamps have the lowest efficacy, typically 5–20 lm/W. Wherever possible, substitute incandescent lamps with fluorescent lamps, or with other efficient alternatives. This not only saves energy, but offers substantial economic savings as well, since fluorescent lamps last 10–50 times longer. Conventional fluorescent lamps have efficacies in the range of 30–70 lm/W; high-efficiency fluorescent systems yield about 85–100 lm/W.

CFLs and LED lamps are also good substitutes for a wide range of incandescent lamps. They are available in a variety of wattages and will replace incandescent lamps with a fraction of the energy consumption. Typical efficacies are 55–70 lm/W for CFLs and 60–100 lm/W for LEDs. In addition to the energy savings, they have longer rated life-times and thus do not need to be replaced as often as incandescent lamps. As mentioned previously, EISA (2007) put standards in place to phase out common incandescent lamps (40–100 W) with more efficient CFL and LED options. Replacement lighting must use at least 27% less energy. The first phase began in January 2012 and affects 100 W bulbs; the second phase took effect in January 2013, affecting 75 W bulbs.

Still greater improvements are possible with HID lighting, particularly metal halide lamps. While they are generally not suited to residential use (high light output and high capital cost), they are increasingly being used in commercial and industrial buildings for their high efficiency and long life. It should be noted that HID lamps are not suited for any area that requires lamps to be switched on-and-off, as they still take several minutes to restart after being turned off.

Improving ballasts is another way of saving lighting energy. One example of a significant increase in efficacy in the commercial sector is illustrated in the transition from T12 (1.5 in. diameter) fluorescent lamps with magnetic ballasts to T8 (1 in. diameter) fluorescent lamps with electronic ballasts. This transition began to occur in the late 1970s and early 1980s. Now T8 electronic ballast systems are the standard for new construction and retrofits. The efficacy improvement, depending on the fixture, is roughly 20%–40% or even more. For example, a two-lamp F34T12 fixture (a fixture with two 1.5 in. diameter, 34 W lamps) with energy-saving magnetic ballast requires 76 W, whereas a two-lamp F32T8 fixture (a fixture with two 1 in. diameter, 32 W lamps) with electronic ballast requires only 59 W, which is an electricity savings of 22%. The savings is attributable to the lower wattage lamps as well as the considerably more efficient ballast.

In recent years, T5 (5/8 in. diameter) fluorescent lamps have been gaining a foothold in the fluorescent market. They are smaller and have a higher optimum operating temperature than T8s, which makes them advantageous in certain applications. One common use is for high bay lighting, where they are displacing HID alternatives because of their better coloring rendering, longer life, shorter warm-up time, and greater lumen maintenance properties.

Task-oriented lighting is another important lighting concept. In this approach, lighting is provided for work areas in proportion to the needs of the task. Hallways, storage areas, and other nonwork areas receive less illumination.

Task lighting can replace the so-called uniform illumination method sometimes used in offices and other types of commercial buildings. The rationale for uniform illumination was based on the fact that the designer could never know the exact layout of desks and equipment in advance, so designs provided for uniform illumination and the flexibility it offers. With today's higher electricity costs, a more customized task lighting approach is often a cost-effective alternative.

Daylighting was an important element of building design for centuries before the discovery of electricity. In certain types of buildings and operations today, daylighting can be utilized to at least reduce (if not replace) electric lighting. Techniques include windows, an atrium, skylights, etc. There are obvious limitations such as those imposed by the need for privacy, 24 h operation, and building core locations with no access to natural light.

The final step is to review building and room color schemes and decor. The use of light colors can substantially enhance illumination without modifying existing lamps.

An effective lamp maintenance program also has important benefits. Light output gradually decreases over lamp lifetime. This should be considered in the initial design and when deciding on lamp replacement. Dirt can substantially reduce light output; simply cleaning lamps and luminaries more frequently can gain up to 5%–10% greater illumination, permitting some lamps to be turned off.

In addition to the lighting energy savings, efficient lighting also reduces energy requirements for cooling since efficient systems produce less heat. This is a yearlong benefit in many commercial buildings, since space conditioning equipment often operates year-round. However, it is an energy penalty when buildings operate heating systems, since the heating systems have to work a little harder.

### **22.3.5 Refrigeration**

The refrigerator, at roughly 40–140 kWh/month depending on the size and age of the model, is among the top four residential users of electricity. In the last 60 years, the design of refrigerator/freezers has changed considerably, with sizes increasing from 5–10 ft<sup>3</sup> to 20–25 ft<sup>3</sup> today. At the same time, the energy input per unit increased up until the oil embargo, after which efforts were made that led to a steady decline in energy use per unit between the mid-1970s through today, despite increases in average refrigerator size. As noted earlier, current refrigerators use about one-quarter the energy (average of ~450 kWh/year in 2011) smaller units did 40 years ago (average of ~1800 kWh/year in 1972).

Energy losses in refrigerators arise from a variety of sources. The largest losses are due to heat gains through the walls and frequent door openings. Since much of the energy used by a refrigerator depends on its design, care should be used in selection. Choose a refrigerator that is the correct size for the application and look for ENERGY STAR models to maximize efficiency. Refrigerators with freezers on the top or bottom are more efficient than side-by-side models. In addition, refrigerators without in-door ice and water dispensers use less energy, as do models with automatic moisture control and manual defrost.

Purchase of a new, more efficient unit is not a viable option for many individuals who have a serviceable unit and do not wish to replace it. In this case, the energy management challenge is to obtain the most effective operation of the existing equipment. Techniques include the following:

- Reducing operation of automatic defrost and antisweat heaters
- Providing a cool location for the refrigerator
- Reducing the number of door openings
- Maintaining temperature settings recommended levels for food safety (not lower)
- Precooling foods before refrigerating

Commercial refrigeration systems are found in supermarkets, liquor stores, restaurants, hospitals, hotels, schools, and other institutions—about one-fifth of all commercial

facilities. Systems include walk-in dairy cases, open refrigerated cases, and freezer cases. In a typical supermarket, lighting, HVAC, and miscellaneous uses account for half the electricity use, while refrigerated display cases, compressors, and condenser fans account for the other half. Thus, commercial refrigeration can be an important element of electric energy efficiency.

It is a common practice in some types of units to have the compressor and heat exchange equipment located remotely from the refrigerator compartment. In such systems, try to locate the compressor in a cool location rather than placing it next to other equipment that gives off heat. Modern commercial refrigerators often come equipped with heat recovery systems, which recover compressor heat for space conditioning or water heating.

Walk-in freezers and refrigerators lose energy through door openings; refrigerated display cases have direct transfer of heat. Covers, strip curtains, air curtains, glass doors, or other thermal barriers can help mitigate these problems. In addition, it is important to use the most efficient light sources in large refrigerators and freezers; elimination of 1 W of electricity to produce light also eliminates two additional Watts required to extract the heat. Other potential energy saving improvements include high-efficiency motors, VSDs, more efficient compressors, and improved refrigeration cycles and controls, such as the use of floating head pressure controls.

### 22.3.6 Cooking

Consumer behavior toward cooking has changed dramatically since the first edition of this handbook. Consumers today are cooking less in the home and dining out or picking up prepared food more often. Consumers are also purchasing more foods that are easier to prepare—convenience is key to the modern family. In response, the food processing industry offers a wide variety of pre-prepared, ready-to-eat products. Recent end use electricity data illustrate this change in behavior. Cooking accounted for about 7% of residential electricity use in 2001; in 2011, it accounted for only 2%.

Though habits are changing and more cooking is occurring outside the home (in restaurants and food processing facilities), reductions in energy use are still important. In general, improvements in energy use efficiency for cooking can be divided into three categories:

- More efficient use of existing appliances
- Use of most efficient existing appliances
- More efficient new appliances

The most efficient use of existing appliances can lead to substantial reductions in energy use. While slanted toward electric ranges and appliances, the following observations also apply to cooking devices using other sources of heat.

First, select the right size equipment for the job. Do not heat excessive masses or large surface areas that will needlessly radiate heat. Second, optimize heat transfer by ensuring that pots and pans provide good thermal coupling to the heat sources. Flat-bottomed pans should be used on electric ranges. Third, be sure that pans are covered to prevent heat loss and to shorten cooking times. Fourth, when using the oven, plan meals so that several dishes are cooked at once. Use small appliances (electric fry pans, *slow* cookers, toaster ovens, etc.) whenever they can be substituted efficiently for the larger appliances such as the oven.

Different appliances perform similar cooking tasks with widely varying efficiencies. For example, the electricity used and cooking time required for common foods items can

vary as much as ten to one in energy use and five to one in cooking times, depending on the method. As an example, four baked potatoes require 2.3 kWh and 60 min in an oven (5.2 kW) of an electric range, 0.5 kWh and 75 min in a toaster oven (1.0 kW), and 0.3 kWh and 16 min in a microwave oven (1.3 kW). Small appliances are generally more efficient when used as intended. Measurements in a home indicated that a pop-up toaster cooks two slices of bread using only 0.025 kWh. The toaster would be more efficient than using the broiler in the electric range oven, unless a large number of slices of bread (more than 17 in this case) were to be toasted at once.

If new appliances are being purchased, select the most efficient ones available. Heat losses from some ovens approach 1 kW, with insulation accounting for about 50%; losses around the oven door edge and through the window are next in importance. These losses are reduced in certain models. Self-cleaning ovens are normally manufactured with more insulation. Careful design of heating elements can also contribute to better heat transfer. Typically, household electric ranges require around 2300–3200 W for oven use, 3600 W for broiler use, and 4000 W for use of the self-cleaning feature.

Microwave cooking is highly efficient for many types of foods, since the microwave energy is deposited directly in the food. Energy input is minimized, because there is no need to heat the cooking utensil. Although many common foods can be prepared effectively using a microwave oven, different methods must be used as certain foods are not suitable for microwave cooking. A typical microwave oven requires 750–1100 W. Convection ovens and induction cook tops are two additional electric alternatives that can reduce cooking energy use.

Commercial cooking operations range from small restaurants and cafes where methods similar to those described previously for residences are practiced, to large institutional kitchens in hotels and hospitals. Many of the same techniques apply. Careful scheduling of equipment use, and provision of several small units rather than a single large one, will save energy. For example, in restaurants, grills, soup kettles, bread warmers, etc., often operate continuously. Generally, it is unnecessary to have full capacity during off-peak hours; one small grill might handle midmorning and midafternoon needs, permitting the second and third units to be shut down. The same strategy can be applied to coffee warming stations, hot plates, etc.

### **22.3.7 Residential Appliances**

A complete discussion of EMOs associated with all the appliances found in homes is beyond the scope of this chapter. However, the following subsections discuss several of the major ones and general suggestions applicable to the others are provided.

#### **22.3.7.1 Clothes Drying**

Clothes dryers typically use about 2.5 kWh or more per load, depending on the unit and size of the load. A parameter called the EF, which is a measure of the lbs of clothing dried per kWh of electricity consumed, can be used to quantify the efficiency of clothes drying. The current minimum EF for a standard capacity electric dryer is 3.01. New standards based on a new metric that incorporates standby energy use (combined energy factor [CEF]) are scheduled to take effect in January 2014. ENERGY STAR certified models are not yet available. In the United States, new dryers are not required to display energy use information, so it is difficult to compare models. In fact, most electric dryers in the market are pretty comparable in their construction and the basic heating technology. However, the actual energy consumption of the dryer varies with the types of controls it has, and

how the operator uses those controls. Models with moisture-sensing capability can result in the most energy savings—savings on the order of 15% compared to conventional operation are common.

In addition, electric clothes dryers operate most efficiently when fully loaded. Operating with one-third to one-half load costs roughly 10%–15% in energy efficiency.

Locating clothes dryers in heated spaces could save 10%–20% of the energy used by reducing energy needed for heating up. Another approach is to save up loads and do several loads sequentially, so that the dryer does not cool down between loads.

The heavier the clothes, the greater the amount of water they hold. Mechanical water removal (pressing, spinning, and wringing) generally requires less energy than electric heat. Therefore, be certain the washing machine goes through a complete spin cycle (0.1 kWh) before putting clothes in the dryer.

Solar drying, which requires a clothesline (rope) and two poles or trees, has been practiced for millennia and is very sparing of electricity. The chief limitation is, of course, inclement weather. New technologies such as microwave or heat pump clothes dryers may help reduce clothes drying energy consumption in the future.

#### **22.3.7.2 Clothes Washing**

The modified energy factor (MEF) can be used to compare different models of clothes washers. It is a measure of the machine energy required during washing, the water heating energy, and the dryer energy needed to remove the remaining moisture. A higher MEF value indicates a more efficient clothes washer. According to Federal standards, all new clothes washers manufactured or imported after January 2007 are required to have an MEF of at least 1.26. In addition, as of February 2013, to be qualified as an ENERGY STAR unit, residential clothes washers must have an MEF of at least 2.0.

Electric clothes washers are designed for typical loads of 3–7 kg. Surprisingly, most of the energy used in clothes washing is for hot water; the washer itself only requires a few percent of the total energy input. Therefore, the major opportunity for energy management in clothes washing is the use of cold or warm water for washing. Under normal household conditions, it is not necessary to use hot water. Clothes are just as clean (in terms of bacteria count) after a 20°C wash as after a 50°C wash. If there is concern for sanitation (e.g., a sick person in the house), authorities recommend use of chlorine bleach. If special cleaning is required, such as removing oil or grease stains, hot water (50°C) and detergent will emulsify oil and fat. There is no benefit in a hot rinse.

A secondary savings can come from using full loads. Surveys indicate that machines are frequently operated with partial loads, even though a full load of hot water is used.

#### **22.3.7.3 Dishwashers**

The two major energy uses in electric dishwashers are the hot water and the dry cycle. Depending on the efficiency of the model and operation, dishwashers use between about 2 and 5 kWh/load.

The water heating often accounts for 80% of the total energy requirement of a dishwasher. The volume of hot water used ranges from about 5 gal for the more efficient units to more than double that for less efficient models. The water volume can be varied on some machines depending on the load.

Since 1990, new models have been required to allow for a no-heat drying option. If you are using a very old unit in which that option is not available, stop the cycle prior to the

drying step and let the dishes air-dry. Operating the dishwasher with a full load and using a cold water prerinse are additional ways to minimize energy use.

New standards that took effect in mid-2013 require standard-size residential dishwashers to use a maximum of 307 kWh/year and 5.0 gal/cycle and compact dishwashers to use a maximum of 222 kWh/year and 3.5 gal/cycle. ENERGY STAR models are also available.

#### **22.3.7.4 General Suggestions for Residential Appliances and Electrical Equipment**

Many electrical appliances (pool pumps, televisions, stereos, DVD and CD players, electronic gaming systems, aquariums, blenders, floor polishers, hand tools, mixers, etc.) perform unique functions that are difficult to duplicate. This is their chief value.

Attention should be focused on those appliances that use more than a few percent of annual electricity use. General techniques for energy management include

- Reduce use of equipment where feasible (e.g., turn off entertainment systems when not in use).
- Perform maintenance to improve efficiency (e.g., clean pool filters to reduce pumping power).
- Schedule use for off-peak hours (evenings).

The last point requires further comment and applies to large electric appliances such as washers, dryers, and dishwashers as well. Some utilities now offer time-based pricing that includes a premium charge for usage occurring on-peak (when the greatest demand for electricity takes place) and lower energy costs for off-peak electricity use. By scheduling energy-intensive activities for off-peak hours (e.g., clothes washing and drying in the evening), the user helps the utility reduce its peaking power requirement, thereby reducing generating costs. The utility then returns the favor by providing lower rates for off-peak use.

---

## **22.4 Closing Remarks**

This chapter has discussed the management of electrical energy in buildings. Beginning with a discussion of energy use in buildings, we next outlined the major energy using systems and equipment, along with a brief description of their features that influence energy use and efficiency. A systematic methodology for implementing an energy management program was then described. The procedure has been implemented in a wide variety of situations including individual homes, commercial buildings, institutions, multinational conglomerates, and cities, and has worked well in each case. Following the discussion of how to set up an energy management program, a series of techniques for saving electricity in each major end use were presented. The emphasis has been on currently available, cost-effective technology. There are other techniques available, some of which are provided in other chapters of this handbook, but we have concentrated on those of we know will work in today's economy, for the typical energy consumer.

The first edition of this book was published in 1980. Much of the data in the first edition dated from the 1975 to 1980 time frame, when the initial response to the oil embargo of 1973 was gathering momentum and maturing. It is remarkable to return to those data

and look at the progress that has been made. In 1975, total U.S. energy use was 72 quads (1 quad =  $10^{15}$  BTU = 1.055 EJ). Most projections at that time predicted U.S. energy use in excess of 100 quads by 1992; instead, we saw that it only reached 85 quads by 1992. In fact, by 2004, total U.S. energy use had just reached the 100 quad mark. Estimates for 2012 show that usage has actually declined to a value of 95 quads (EIA 2013c). In addition, between 1975 and 2012, energy consumption per real dollar of the U.S. gross domestic product (GDP) decreased by half, from 14.76 to 7.00 thousand BTU per chained 2005 dollar (EIA 2013c). Some of this is due to a decrease in domestic energy-intensive industry and the recent economic recession, but much of it represents a remarkable improvement in overall energy efficiency.

As noted earlier in this chapter (Table 22.1), a significant growth in total energy consumption in the residential and commercial sectors has occurred in the intervening decades, but efficiency improvements have helped to moderate this growth rate considerably. The improvement in energy efficiency in lighting, refrigerators, air conditioning, and other devices has been truly remarkable. Today the local hardware or home improvement store has supplies of energy-efficient devices that were beyond imagination in 1973.

This is a remarkable accomplishment, technically and politically, given the diversity of the residential/commercial market. Besides the huge economic savings this has meant to millions of homeowners, apartment dwellers, and businesses, think of the environmental benefits associated with avoiding the massive additional amounts of fuel, mining, and combustion, which otherwise would have been necessary.

### 23.1 Introduction: The Need for Control

This chapter describes the essentials of control systems for heating, ventilating, and air conditioning (HVAC) of buildings designed for energy conserving operation. Of course, there are other renewable and energy conserving systems that require control. The principles described herein for buildings also apply with appropriate and obvious modification to these other systems. For further reference, the reader is referred to several standard references in the list at the end of this chapter.

HVAC system controls are the information link between varying energy demands on a building's primary and secondary systems and the (usually) approximately uniform demands for indoor environmental conditions. Without a properly functioning control system, the most expensive, most thoroughly designed HVAC system will be a failure. It simply will not control indoor conditions to provide comfort.

The HVAC control system must

- Sustain a comfortable building interior environment
- Maintain acceptable indoor air quality
- Be as simple and inexpensive as possible and yet meet HVAC system operation criteria reliably for the system lifetime
- Result in efficient HVAC system operation under all conditions
- Be commissioned, including the building, equipment, and control systems
- Be fully documented, so that the building staff successfully operates and maintains the HVAC system

A considerable challenge is presented to the HVAC system designer to design a control system that is energy efficient and reliable. Inadequate control system design, inadequate commissioning, and inadequate documentation and training for the building staff often create problems and poor operational control of HVAC systems. This chapter develops the basics of HVAC control and follows through with the operational needs for successfully maintained operation. The reader is encouraged to review the following references on the subject: ASHRAE (2002, 2003, 2004, 2005), Haines (1987), Honeywell (1988), Levine (1996), Sauer et al. (2001), Stein and Reynolds (2000), and Tao and Janis (2005).

To achieve proper control based on the control system design, the HVAC system must be designed correctly and then constructed, calibrated, and commissioned according to the mechanical and electrical systems drawings. These must include properly sized primary and secondary systems. In addition, air stratification must be avoided, proper provision for control sensors is required, freeze protection is necessary in cold climates, and proper attention must be paid to minimizing energy consumption subject to reliable operation and occupant comfort.

The principal and final controlled variable in buildings is zone temperature (and to a lesser extent humidity and/or air quality in some buildings). This chapter will therefore focus on methods to control temperature. Supporting the zone temperature control, numerous other control loops exist in buildings within the primary and secondary HVAC systems, including boiler and chiller control, pump and fan control, liquid and airflow control, humidity control, and auxiliary system control (e.g., thermal energy storage control). This chapter discusses only *automatic* control of these subsystems. Honeywell (1988)

**FIGURE 23.1**

Simple water level controller. The set point is the full water level; the error is the difference between the full level and the actual level.

defines an automatic control system as “a system that reacts to a change or imbalance in the variable it controls by adjusting other variables to restore the system to the desired balance.”

Figure 23.1 defines a familiar control problem with feedback. The water level in the tank must be maintained under varying outflow conditions. The float operates a valve that admits water to the tank as the tank is drained. This simple system includes all the elements of a control system:

Sensor—float; reads the controlled variable, the water level.

Controller—linkage connecting float to valve stem; senses difference between full tank level and operating level and determines needed position of valve stem.

Actuator (controlled device)—internal valve mechanism; sets valve (the final control element) flow in response to level difference sensed by controller.

Controlled system characteristic—water level; this is often termed the *controlled variable*.

This system is called a *closed-loop* or *feedback* system because the sensor (float) is directly affected by the action of the controlled device (valve). In an open-loop system, the sensor operating the controller does not directly sense the action of the controller or actuator. An example would be a method of controlling the valve based on an external parameter such as the time of day, which may have an indirect relation to water consumption from the tank.

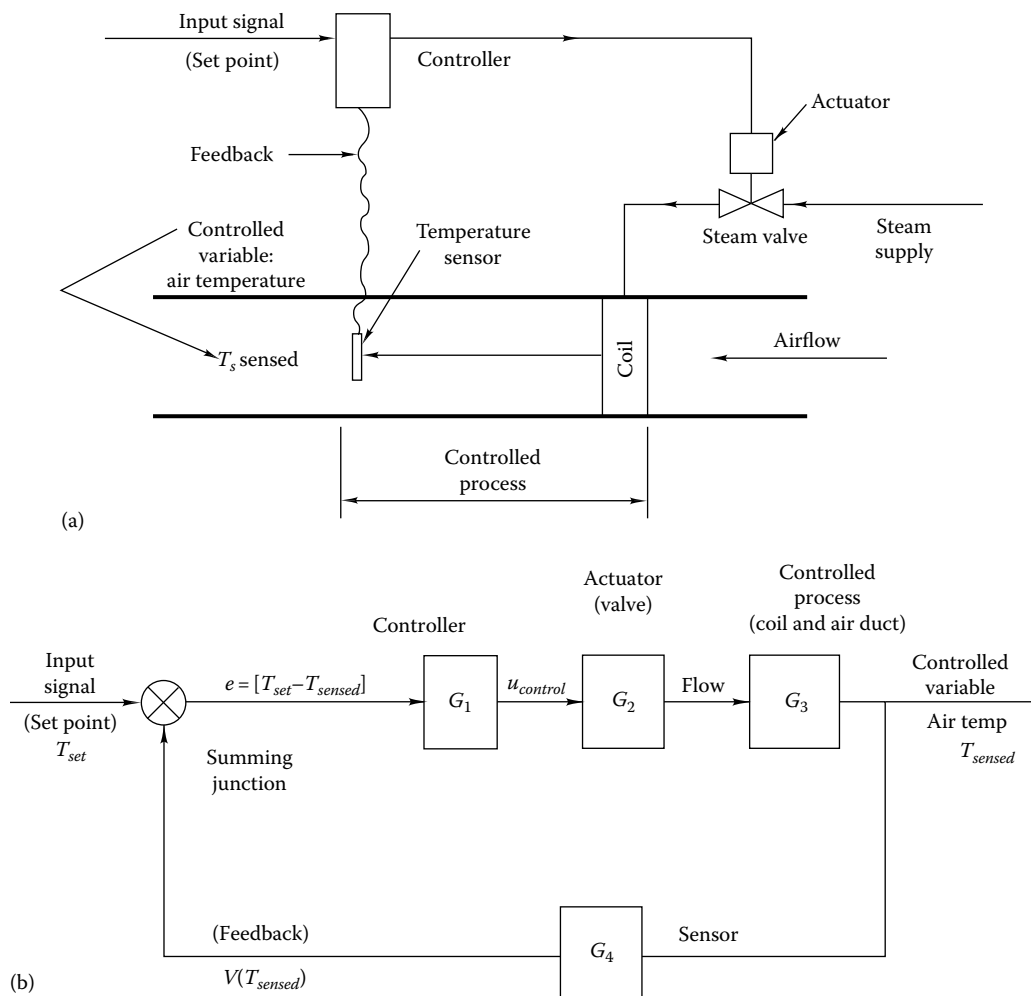

There are four common methods of control of which Figure 23.1 shows, but one. In the next section, we will describe each with relation to an HVAC system example.

## 23.2 Modes of Feedback Control

Feedback control systems adjust an output control signal based on feedback. The feedback is used to generate an error signal, which then drives a control element. Figure 23.1 illustrates a basic control system with feedback. Both off-on (i.e., two-position) control and analog (i.e., variable) control can be used. Numerous methodologies have been developed

to implement analog control. These include proportional, proportional–integral (PI), proportional–integral–differential (PID), state feedback control, adaptive control, and predictive control. Proportional and PI controls are currently used for most applications in HVAC control, although more advanced strategies offer the potential for significantly improved performance.

Figure 23.2a shows a steam coil used to heat air in a duct. The simple control system shown includes an air temperature sensor, a controller that compares the sensed temperature to the set point, a steam valve controlled by the controller, and the coil itself. We will use this example system as the point of reference when discussing the various control system types. Figure 23.2b is the control diagram corresponding to the physical system shown in Figure 23.2a.

**FIGURE 23.2**

(a) Simple heating coil control system showing the process (coil and short duct length), controller, controlled device (valve and its actuator), and sensor. The set point entered externally is the desired coil outlet temperature. (b) Equivalent control diagram for heating coil. The  $G$ s represent functions relating the input to the output of each module.

**FIGURE 23.3**

Two-position (on-off) control characteristic.

*Two-position control* applies to an actuator that is either fully open or fully closed.

This is also known as *on-off*, *bang-bang*, or *hysteretic* control. In Figure 23.2a, the valve is a two-position valve if two-position control is used. The position of the steam valve is determined by the value of the coil outlet temperature. Figure 23.3 depicts two-position control of the valve. If the air temperature drops below 95°F, the valve opens and remains open until the air temperature reaches 100°F. The differential is usually adjustable, as is the temperature setting itself. Two-position control is the least expensive method of automatic control and is suitable for control of HVAC systems with large time constants and where an oscillatory response is acceptable. Examples include residential space and water heating systems. Systems that are fast reacting should not be controlled using this approach, since overshoot and undershoot may be excessive.

*Proportional control* adjusts the controlled variable in proportion to the difference between the controlled variable and the set point. For example, a proportional controller would increase the coil heat rate in Figure 23.2 by 10% if the coil outlet air temperature dropped by an amount equal to 10% of the temperature range specified for the heating to go from off to fully on. The following equation defines the behavior of a proportional control loop:

$$u = u_0 + K_p e \quad (23.1)$$

where

$u$  is the controller output

$u_0$  is the constant value of controller output when no error exists

$K_p$  is the proportional *control gain*; it determines the rate or proportion at which the control signal changes in response to the error

$e$  is the *error*; in the case of the steam coil, it is the difference between the air temperature set point and the sensed supply air temperature:

$$e = T_{\text{set}} - T_{\text{sensed}} \quad (23.2)$$

**FIGURE 23.4**

Proportional control characteristic showing various throttling ranges and the corresponding proportional gains  $K_p$ . This characteristic is typical of a heating coil temperature controller.

As coil air outlet temperature drops farther below the set temperature, error  $e$  increases leading to increased control action—an increased steam flow rate. Note that the temperatures in Equations 23.1 and 23.2 are often replaced by voltages or other variables, particularly in electronic controllers.

The *throttling range* is the total change in the controlled variable that is required to cause the actuator or controlled device to move between its limits. For example, if the nominal temperature of a zone is 72°F and the heating controller throttling range is 6°F, then the heating control undergoes its full travel between a zone temperature of 69°F and 75°F. This control, whose characteristic is shown in Figure 23.4, is *reverse acting*; that is, as the temperature (controlled variable) increases, the heating valve position decreases.

The throttling range is inversely proportional to the gain as shown in Figure 23.4. Beyond the throttling range, the system is out of control. In actual hardware, one can set the set point and either the gain or the throttling range (most common), but not both of the latter. Proportional control by itself is not capable of reducing the error to zero, since an error is needed to produce the capacity required for meeting a load as we will see in the following example. This unavoidable value of the error in proportional systems is called the *offset*. From Figure 23.4, it is easy to see that the offset is larger for systems with smaller gains. There is a limit to which one can increase the gain to reduce offset, because high gains can produce control instability.

### Example 23.1 Proportional Gain Calculation

If the steam heating coil in Figure 23.2a has a heat output that varies from 0 to 20 kW as the outlet air temperature varies from 35°C to 45°C in an industrial process, what is the coil gain and what is the throttling range? Find an equation relating the heat rate at any sensed air temperature to the maximum rate in terms of the gain and set point.

Given

$$\dot{Q}_{\max} = 20 \text{ kW}$$

$$\dot{Q}_{\min} = 0 \text{ kW}$$

$$T_{\max} = 45^{\circ}\text{C}$$

$$T_{\min} = 35^{\circ}\text{C}$$

Figure: See [Figure 23.2a](#).

Assumptions: Steady-state operation

Find:  $K_p$ ,  $\Delta T_{\max}$

*Solution:* The throttling range is the range of the controlled variable (air temperature) over which the controlled system (heating coil) exhibits its full capacity range. The temperature varies from 35°C to 45°C. Assuming that a temperature of 35°C corresponds to heating rate of 0 kW, then the throttling range is

$$\Delta T_{\max} = 45^{\circ}\text{C} - 35^{\circ}\text{C} = 10^{\circ}\text{C} \quad (23.3)$$

The proportional gain is the ratio of the controlled system (coil) output to the throttling range. For this example, the  $Q$  controller output is  $\dot{Q}$  and the gain is

$$K_p = \frac{\dot{Q}_{\max} - \dot{Q}_{\min}}{\Delta T_{\max}} = \frac{(20 - 0) \text{ kW}}{10 \text{ K}} = 2.0 \text{ kW/K} \quad (23.4)$$

The controller characteristic can be found by inspecting [Figure 23.4](#). It is assumed that the average air temperature (40°C) occurs at the average heat rate (10 kW). The equation of the straight line shown is

$$\dot{Q} = K_p (T_{\text{set}} - T_{\text{sensed}}) + \frac{\dot{Q}_{\max} - \dot{Q}_{\min}}{2} = K_p e + \frac{\dot{Q}_{\max} - \dot{Q}_{\min}}{2} \quad (23.5)$$

Note that the quantity  $(T_{\text{set}} - T_{\text{sensed}})$  is the **error**  $e$  and a nonzero value indicates that the set temperature is not met. However, the proportional control system used here requires the presence of an error signal to fully open or fully close the valve.

Inserting the numerical values, we have

$$\dot{Q} = 2.0 \text{ kW/K}(40 - T_{\text{sensed}}) + 10 \text{ kW} \quad (23.6)$$

*Comments:* In an actual steam coil control system, it is the steam valve that is controlled directly to indirectly control the heat rate of the coil. This is typical of many HVAC system controls in that the desired control action is achieved indirectly by controlling another variable that in turn accomplishes the desired result. That is why the controller and actuator are often shown separately as in [Figure 23.2b](#).

This example illustrates with a simple system how proportional control uses an error signal to generate an offset and how the offset controls an output quantity. Using a bias value, the error can be set to be zero at one value in the control range. Proportional control generally results in a nonzero error over the remainder of the control range, as shown later.

A common approach for modeling dynamic HVAC systems where only one input–output is considered is a process control model (Equation 23.7). The basic form of this model includes a gain,  $k_0$ , a first-order dynamic characterized by the time constant,  $\tau$ , and a pure time delay,  $T_d$ . This basic model is easily augmented with additional time constants as needed:

$$G(s) = \frac{k_0 e^{-T_d s}}{\tau s + 1} \quad (23.7)$$

Assuming the basic feedback control loop (Figure 23.2b) where the controller is selected to be a proportional control and the system model is given as in Equation 23.7, then the relationship between the desired reference signal and the system error is given as follows:

$$\frac{E(s)}{R(s)} = \frac{1}{1 + C(s)G(s)} = \frac{1}{\tau s + 1 + K_p k_0 e^{-T_d s}} \quad (23.8)$$

Assuming a unit step change in the reference signal, then the steady-state value of the system output is given by

$$e_{ss} = \lim_{s \rightarrow 0} \left[ s \left( \frac{E(s)}{R(s)} \right) R(s) \right] = \frac{1}{1 + C(0)G(0)} = \frac{1}{1 + K_p k_0} \quad (23.9)$$

Thus, using proportional control, the system error (i.e., the difference between the reference signal and system output) becomes smaller as the proportional gain is increased, but the error will never be zero. For more details regarding this type of analysis, see Franklin et al. (2006) for a detailed discussion of transfer functions, final value theorem, and steady-state error analysis.

Real systems also have a dynamic response. This means that proportional control is best suited to slow-response systems, where the throttling range can be set so that the system achieves stability. Typically, slow-responding mechanical systems include pneumatic thermostats for zone control and air handler unit damper control.

*Integral* control is often added to proportional control to eliminate the offset inherent in proportional-only control. The result, proportional plus integral control, is identified by the acronym PI. Initially, the corrective action produced by a PI controller is the same as for a proportional-only controller. After the initial period, a further adjustment due to the integral term reduces the offset to zero. The rate at which this occurs depends on the timescale of the integration. In equation form, the PI controller is modeled by

$$V = V_0 + K_p e + K_i \int e dt \quad (23.10)$$

in which  $K_i$  is the integral gain constant. It has units of reciprocal time and is the number of times that the integral term is calculated per unit time. This is also known as the reset rate; reset control is an older term used by some to identify integral control.

Today, most PI control implementations use electronic sensors, analog-to-digital converters (A/Ds), and digital logic to implement the PI control. Integral windup must be taken into account when using PI control, which occurs when actuators reach hardware or software limitations, and the tracking error is nonzero. The integral term will continue to grow, or *wind up*, and creates a large offset. This can prevent the control loop from performing as desired for long periods until the integral term recovers. Various methods exist to minimize or eliminate the windup problem.

The integral term in Equation 23.10 has the effect of adding a correction to the output signal  $V$  as long as the error term exists. The continuous offset produced by the proportional-only controller can thereby be reduced to zero because of the integral term. For HVAC systems, the timescale ( $K_p/K_i$ ) of the integral term is often in the range of 10+ s to 10+ min. Using large integral gains will allow the control system to converge quickly to the desired set point value. However, large gains also tend to increase the oscillations in the response, and thus a balance must be found.

PI control is used for fast-acting systems for which accurate control is needed. Examples include mixed-air controls, duct static pressure controls, and coil controls. Because the offset is eventually eliminated with PI control, the throttling range can be set rather wide to ensure stability under a wider range of conditions than good control would permit with proportional-only control. Hence, PI control is also used on almost all electronic thermostats.

*Derivative* control is used to speed up the action of PI control. When derivative control is added to PI control, the result is called PID control. The derivative term added to Equation 23.10 generates a correction signal proportional to the time rate of change of error. This term has little effect on a steady proportional system with uniform offset (time derivative is zero) but initially, after a system disturbance, produces a larger correction more rapidly. The derivative control action is anticipatory in nature and can be effective in dampening oscillations caused by an aggressive PI controller. Equation 23.11 includes the derivative term in the mathematical model of the PID controller

$$V = V_0 + K_p e + K_i \int e dt + K_d \frac{de}{dt} \quad (23.11)$$

in which  $K_d$  is the derivative gain constant. The timescale ( $K_d/K_p$ ) of the derivative term is typically in the range of 0.2–15 min. Since HVAC systems do not often require rapid control response, the use of PID control is less common than use of PI control. Since a derivative is involved, any noise in the error (i.e., sensor) signal must be avoided, or this noise will be amplified in the control action, creating undesirable fluctuations. One application in buildings where PID control has been effective is in duct static pressure control, a fast-acting subsystem that has a tendency to be unstable otherwise.

Derivative control has limited application in HVAC systems because it requires correct tuning for each of the three gain constants ( $K_s$ ) over the performance range that the control loop will need to operate. Another serious limitation centers on the fact that most facility operators lack training and skills in tuning PID control loops.

**FIGURE 23.5**

Performance comparison of P, PI, and PID controllers when subjected to a uniform, input step change.

As a result, many PID controllers are *detuned* and use artificially low control gains. This has the effect of sacrificing good performance, so as to ensure a stable, albeit slow, response.

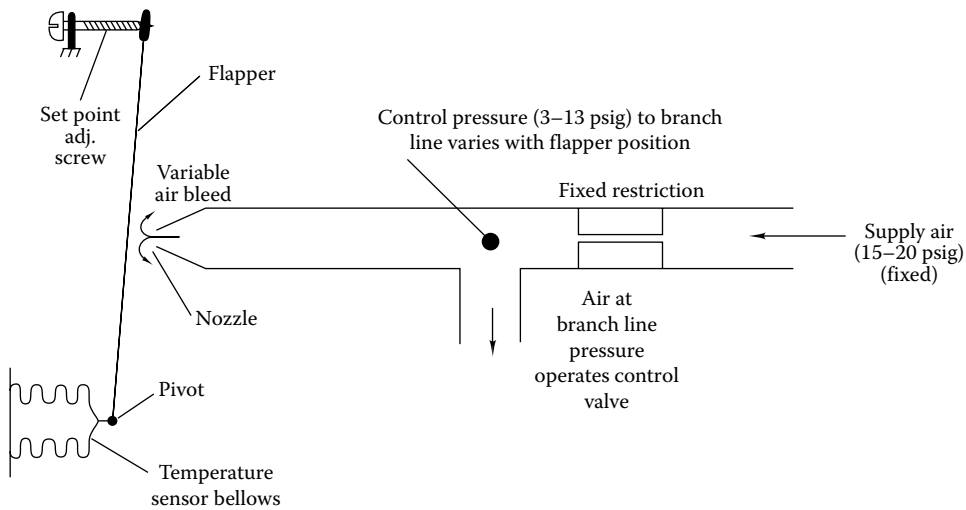

Figure 23.5 illustrates the loop response for three correctly configured systems when a step function change, or disturbance, occurs. Note that the PI loop achieves the same final control as the PID, and only the PI error signal is larger. An improperly configured PID loop can oscillate from the high value to the low value in a continuous oscillatory manner.

## 23.3 Basic Control Hardware

In this section, the various physical components needed to achieve the actions required by the control strategies of the previous section are described. Since there are two fundamentally different control approaches—pneumatic and electronic—the following material is so divided. Sensors, controllers, and actuators for principal HVAC applications are described.

### 23.3.1 Pneumatic Systems

The first widely adopted automatic control systems used compressed air as the signal transmission medium. Compressed air had the advantage that it could be *metered* through various sensors and could power large actuators. The fact that the response of a normal pneumatic loop could take several minutes often worked as an advantage. Pneumatic controls use compressed air (approximately 20 psig in the United States) for the operation of sensors

**FIGURE 23.6**

Drawing of pneumatic thermostat showing adjustment screw used to change temperature setting.

and actuators. Though most new buildings use electronic controls, many existing buildings use pneumatic controls. This section provides an overview of how these devices operate.

Temperature control and damper control comprise the bulk of pneumatic loop controls. Figure 23.6 shows a method of sensing temperature and producing a control signal. Main supply air, supplied by a compressor, enters a branch line through a restriction. The zone thermostat bleeds a variable amount of air out, depending on the position of the flapper, controlled by the temperature sensor bellows. As more air bleeds out, the branch line pressure (control pressure) drops. This reduction in the total pressure to the control element changes the output of the control element. This control can be forward acting or reverse acting. The restrictions typically have hole diameters on the order of a few thousandths of an inch and consume very little air. Typical pressures in the branch lines range between 3 and 13 psig (20–90 kPa). In simple systems, this pressure from a thermostat could operate an actuator such as a control valve for a room heating unit. In this case, the thermostat is both the sensor and the controller—a rather common configuration.

Many other temperature sensor approaches can be used. For example, the bellows shown in Figure 23.6 can be eliminated and the flapper can be made of a bimetallic strip. As temperature changes, the bimetal strip changes curvature, opening or closing the flapper/nozzle gap. Another approach uses a remote bulb filled with either liquid or vapor that pushes a rod (or a bellows) against the flapper to control the pressure signal. This device is useful if the sensing element must be located where direct measurement of temperature by a metal strip or bellows is not possible, such as in a water stream or high-velocity ductwork. The bulb and connecting capillary size may vary considerably by application.

Pressure sensors may use either bellows or diaphragms to control branch line pressure. For example, the motion of a diaphragm may replace that of the flapper in Figure 23.6 to control the bleed rate. A bellows similar to that shown in the same figure may be internally pressurized to produce a displacement that can control air bleed rate. A bellows produces significantly greater displacements than a single diaphragm.

**FIGURE 23.7**

Pneumatic control valve showing counterforce spring and valve body. Increasing pressure closes the valve.

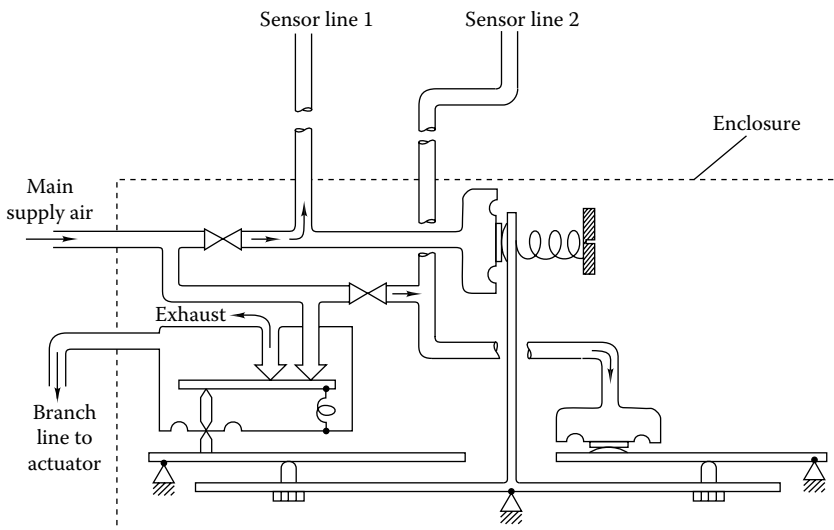

Humidity sensors in pneumatic systems are made from materials that change size with moisture content. Nylon or other synthetic hygroscopic fibers that change size significantly (i.e., 1%–2%) with humidity are commonly used. Since the dimensional change is relatively small on an absolute basis, mechanical amplification of the displacement is used. The materials that exhibit the desired property include nylon, hair, and cotton fibers. Human hair exhibits a much more linear response with humidity than nylon; however, because the properties of hair vary with age, nylon has much wider use (Letherman, 1981). Humidity sensors for electronic systems are quite different and are discussed in the next section.

An *actuator* converts pneumatic energy to motion—either linear or rotary. It creates a change in the controlled variable by operating control devices such as dampers or valves. Figure 23.7 shows a pneumatically operated control valve. The valve opening is controlled by the pressure in the diaphragm acting against the spring. The spring is essentially a linear device. Therefore, the motion of the valve stem is essentially linear with air pressure. However, this does not necessarily produce a linear effect on flow as discussed later. Figure 23.8 shows a pneumatic damper actuator. Linear actuator motion is converted into rotary damper motion by the simple mechanism shown.

Pneumatic *controllers* produce a branch line (see Figure 23.6) pressure that is appropriate to produce the needed control action for reaching the set point. Such controls are manufactured by a number of control firms for specific purposes. Classifications of controllers include the sign of the output (direct or reverse acting) produced by an error, by the control action (proportional, PI, or two-position), or by number of inputs or outputs. Figure 23.9 shows the essential elements of a dual-input, single-output controller. The two inputs could be the heating system supply temperature and the outdoor temperature sensors, used to control the output water temperature setting of a boiler in a building heating system. This is essentially a boiler *temperature reset* system that reduces heating water temperature with increasing ambient temperature for better system control and reduced energy use.

**FIGURE 23.8**

Pneumatic damper actuator. Increasing pressure closes the parallel-blade damper.

**FIGURE 23.9**

Example pneumatic controller with two inputs and one control signal output.

The air supply for pneumatic systems must produce very clean, oil-free, dry air. A compressor producing 80–100 psig is typical. Compressed air is stored in a tank for use as needed, avoiding continuous operation of the compressor. The air system should be oversized by 50%–100% of estimated, nominal consumption. The air is then dried to avoid moisture freezing in cold control lines in air-handling units (AHUs) and elsewhere. Dried air should have a dew point of  $-30^{\circ}\text{F}$  or less in severe heating climates. In deep cooling climates, the lowest temperature to which the compressed air lines are exposed may be the building cold air supply. Next, the air is filtered to remove water droplets,

oil (from the compressor), and any dirt. Finally, the air pressure is reduced in a pressure regulator to the control system operating pressure of approximately 20 psig. Control air piping uses either copper or nylon (in accessible locations).

### 23.3.2 Electronic Control Systems

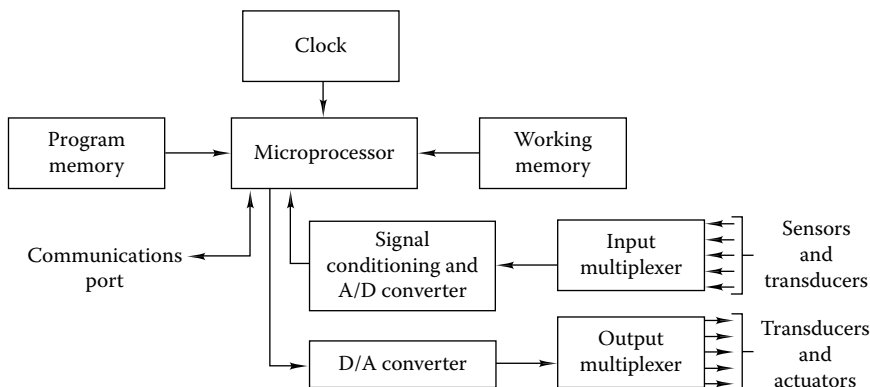

Electronic controls comprise the bulk of the controllers for HVAC systems. Direct digital control (DDC) systems began to make inroads in the early 1990s and now make up over 80% of all controller sales. Low-end microprocessors now cost under \$0.50 each and are thus very economical to apply. Along with the decreased cost, increased functionality can be obtained with DDC. BACnet has emerged as the standard communication protocol (ASHRAE, 2001) and most control vendors offer a version of the BACnet protocol. In this section, we survey the sensors, actuators, and controllers used in modern electronic control systems for buildings.

DDC enhances the previous analog-only electronic system with digital features. Modern DDC systems use analog sensors (converted to digital signals within a computer) along with digital computer programs to control HVAC systems. The output of this microprocessor-based system can be used to control either electronic, electrical, or pneumatic actuators or a combination. DDC systems have the advantage of reliability and flexibility that others do not. For example, accurately setting control constants in computer software is easier than making adjustments at a controller panel with a screwdriver. DDC systems offer the option of operating energy management systems (EMSs) and HVAC diagnostic, knowledge-based systems since the sensor data used for control are very similar to that used in EMSs. Pneumatic systems do not offer this ability. Figure 23.10 shows a schematic diagram of a DDC controller. The entire control system must include sensors and actuators not shown in this controller-only drawing.

Temperature measurements for DDC applications are made by three principal methods:

1. Thermocouples
2. Resistance temperature detectors (RTDs)
3. Thermistors

Each has its advantages for particular applications. Thermocouples consist of two dissimilar metals chosen to produce a measurable voltage at the temperature of interest

**FIGURE 23.10**

Block diagram of a DDC controller.

(i.e., Seebeck effect). The voltage output is low (millivolts) but is a well-established function of the junction temperature. By themselves, thermocouples generally produce voltages too small to be useful in most HVAC applications (e.g., a type J thermocouple produces only 5.3 mV at 100°C). However, modern signal conditioning equipment can easily amplify these signals, as well as provide calibration (also known as cold junction compensation).

RTDs use small, responsive sensing sections constructed from metals whose resistance–temperature characteristic is well established and reproducible. To first order,

$$R = R_0(1 + kT) \quad (23.12)$$

where

$R$  is the resistance, ohms

$R_0$  is the resistance at the reference temperature (0°C), ohms

$k$  is the temperature coefficient of resistance, °C<sup>-1</sup>

$T$  is the RTD temperature, °C

This equation is easy to invert to find the temperature as a function of resistance. Although complex higher order expressions exist, their use is not needed for HVAC applications.

Two common materials for RTDs are platinum and Balco (a 40% nickel, 60% iron alloy). The nominal values of  $k$ , respectively, are  $3.85 \times 10^{-3} \text{°C}^{-1}$  and  $4.1 \times 10^{-3} \text{°C}^{-1}$ .

Modern electronics measure current and voltage and then determine the resistance using Ohm's law. The measurement causes power dissipation in the RTD element, raising the temperature and creating an error in the measurement. This Joule self-heating can be minimized by minimizing the power dissipated in the RTD. Raising the resistance of the RTD helps, but the most effective approach requires pulsing the current and making the measurement in a few milliseconds. Since one measurement per second will generally satisfy the most demanding HVAC control loop, the power dissipation can be reduced by a factor of 100 or more. Modern digital controls can easily handle the calculations necessary to implement piecewise linearization and other curve-fitting methods to improve the accuracy of the RTD measurements. In addition, lead wire resistance can cause lack of accuracy for the class of platinum RTDs whose nominal resistance is only 100 ohms because the lead resistance of 1–2 ohms is not negligible by comparison to that of the sensor itself.

*Thermistors* are semiconductors that exhibit a standard exponential dependence for resistance versus temperature given by

$$R = Ae^{(B/T)} \quad (23.13)$$

$A$  is related to the nominal value of resistance at the reference temperature (77°F) and is of the order of several thousands of ohms. The exponential coefficient  $B$  (a weak function of temperature) is of the order of 5400–7200 R (3000–4000 K). The nonlinearity inherent in thermistors can be reduced by connecting a properly selected fixed resistor in parallel with it. The resulting linearity is desirable from a control system design viewpoint. Thermistors can have a problem with long-term drift and aging; the designer and control manufacturer should consult on the most stable thermistor design for HVAC applications. Some manufacturers provide linearized thermistors that combine both positive and negative resistive dependence on temperature to yield a more linear response function.

*Humidity* measurements are needed for control of enthalpy economizers or may also be needed to control special environments such as clean rooms, hospitals, and areas

housing computers. Relative humidity, dew point, and humidity ratio are all indicators of the moisture content of air. An electrical, capacitance-based approach using a polymer with interdigitated electrodes has become the most common sensor type. The polymer material absorbs moisture and changes the dielectric constant of the material, changing the capacitance of the sensor. The capacitance of the sensor forms part of a resonant circuit so when the capacitance changes, the resonant frequency changes. This frequency then can be correlated to the relative humidity and provide reproducible readings if not saturated by excessive exposure to high humidity levels (Huang, 1991). The response times of tens of seconds easily satisfy most HVAC application requirements. These humidity sensors need frequent calibration, generally yearly. If a sensor becomes saturated or has condensation on the surface, they become uncalibrated and exhibit an offset from their calibration curve. Older technologies used ionic salts on gold grids. These expensive sensors frequently failed.

Pressure measurements are made by electronic devices that depend on a change of resistance or capacitance with imposed pressure. Figure 23.11 shows a cross-sectional drawing

**FIGURE 23.11**

(a) Resistance- and (b) capacitance-type pressure sensors.

of each. In the resistance type, stretching of the membrane lengthens the resistive element thereby increasing resistance. This resistor is an element in a Wheatstone bridge; the resulting bridge voltage imbalance is linearly related to the imposed pressure. The capacitive-type unit has a capacitance between a fixed and a flexible metal that decreases with pressure. The capacitance change is amplified by a local amplifier that produces an output signal proportional to pressure. Pressure sensors can burst from overpressure or a water hammer effect. Installation needs to carefully follow the manufacturer's requirements.

DDC systems require *flow* measurements to determine the energy flow for air and water delivery systems. Pitot tubes (or arrays of tubes) and other flow measurement devices can be used to measure either air or liquid flow in HVAC systems. Airflow measurements allow for proper flow in variable air volume (VAV) system control, building pressurization control, and outside air control. Water flow measurements enable chiller and boiler control and monitoring and various water loops used in the HVAC system. Some controls only require the knowledge of flow being present. Open-closed sensors fill this need and typically have a paddle that makes a switch connection under the presence of flow. These types of switches can also be used to detect *end of range*, that is, fully open or closed for dampers and other mechanical control elements.

Temperature, humidity, and pressure *transmitters* are often used in HVAC systems. They amplify signals produced by the basic devices described in the preceding paragraphs and produce an electrical signal over a standard range thereby permitting standardization of this aspect of DDC systems. The standard ranges are

*Current:* 4–20 mA (dc)

*Voltage:* 0–10 V or 0–5 V (dc)

Although the majority of transmitters produce such signals, the noted values are not universally used.

Figure 23.10 shows the elements of a DDC controller. The heart of the controller is the microprocessor that can be programmed in either a standard or system-specific language. Control algorithms (linear or not), sensor calibrations, output signal shaping, and historical data archiving can all be programmed as the user requires. A number of firms have constructed controllers on standard personal computer platforms. Describing the details of programming HVAC controllers is beyond the scope of this chapter, since each manufacturer uses a different approach. The essence of any DDC system, however, is the same as shown in the figure. Honeywell (1988) discusses DDC systems and their programming in more detail.

*Actuators* for electronic control systems include

Motors—operate valves, dampers

Variable speed controls—pump, fan, chiller drives

Relays and motor starters—operate other mechanical or electrical equipment (pumps, fans, chillers, compressors), electrical heating equipment

Additional components provide necessary functionality, such as transducers that convert signal types (e.g., electrical to pneumatic) and visual displays that inform system operators of control and HVAC system functions.

Pneumatic and DDC systems have their own advantages and disadvantages. Pneumatics possess increasing disadvantages of cost, hard-to-find replacements, requiring an air

compressor with clean oil-free air, sensor drift, imprecise control, and a lack of automated monitoring. The retained advantages include explosion-proof operation and a fail-soft degradation of performance. DDC systems have emerged and have taken the lead for HVAC systems over pneumatics because of the ability to integrate the control system into a large energy management and control system (EMCS), the accuracy of the control, and the ability to diagnose problems remotely. Systems based on either technology require maintenance and skilled operators.

### 23.4 Basic Control System Design Considerations

This section discusses selected topics in control system design including control system zoning, valve and damper selection, and control logic diagrams. The following section shows several HVAC system control design concepts. Bauman (1998) may be consulted for additional information.

The ultimate purpose of an HVAC control system is to control zone temperature (and secondarily air motion and humidity) to conditions that assure maximum comfort and productivity of the occupants. From a controls viewpoint, the HVAC system is assumed to be able to provide comfort conditions if controlled properly. Basically, a zone is a portion of a building that has loads that differ in magnitude and timing sufficiently from other areas so that separate portions of the secondary HVAC system and control system are needed to maintain comfort.

Having specified the zones, the designer must select the thermostat (and other sensors, if used) location. Thermostat signals are either passed to the central controller or used locally to control the amount and temperature of conditioned air or coil water introduced into a zone. The air is conditioned either locally (e.g., by a unit ventilator or baseboard heater) or centrally (e.g., by the heating and cooling coils in the central air handler). In either case, a flow control actuator is controlled by the thermostat signal. In addition, airflow itself may be controlled in response to zone information in VAV systems. Except for variable speed drives used in variable-volume air or liquid systems, flow is controlled by valves or dampers. The design selection of valves and dampers is discussed next.

#### 23.4.1 Steam and Liquid Flow Control

The flow through valves such as that shown in [Figure 23.7](#) is controlled by valve stem position, which determines the flow area. The variable flow resistance offered by valves depends on their design. The flow characteristic may be linear with position or not. [Figure 23.12](#) shows flow characteristics of the three most common types. Note that the plotted characteristics apply only for *constant valve pressure drop*. The characteristics shown are idealizations of actual valves. Commercially available valves will resemble but not necessarily exactly match the curves shown.

The *linear* valve has a proportional relation between volumetric flow  $V$  and valve stem position  $z$ :

$$\dot{V} = kz \quad (23.14)$$

The flow in *equal percentage* valves increases by the same fractional amount for each increment of opening. In other words, if the valve is opened from 20% to 30% of full travel, the

**FIGURE 23.12**

Quick-opening, linear, and equal percentage valve characteristics.

flow will increase by the same percentage as if the travel had increased from 80% to 90% of its full travel. However, the absolute volumetric flow increase for the latter case is much greater than for the former. The equal percentage valve flow characteristic is given by

$$\dot{V} = Ke^{(kz)} \quad (23.15)$$

where  $k$  and  $K$  are proportionality constants for a specific valve. Quick-opening valves do not provide good flow control but are used when rapid action is required with little stem movement for on/off control.

### Example 23.2: Equal Percentage Valve

A valve at 30% of travel has a flow of 4 gal/min. If the valve opens another 10% and the flow increases by 50% to 6 gal/min, what are the constants in Equation 23.15? What will be the flow at 50% of full travel?

Figure: See [Figure 23.15](#).

Assumptions: Pressure drop across the valve remains constant.

Find:  $k$ ,  $K$ ,  $\dot{V}_{50}$

*Solution:* Equation 23.15 can be evaluated at the two flow conditions. If the results are divided by each other, we have

$$\frac{\dot{V}_2}{\dot{V}_1} = \frac{6}{4} = e^{k(z_2 - z_1)} = e^{k(0.4 - 0.3)} \quad (23.16)$$

In this expression, the travel  $z$  is expressed as a fraction of the total travel and is dimensionless. Solving this equation for  $k$  gives the result

$$k = 4.05 \text{ (no units)}$$

From the known flow at 30% travel, we can find the second constant  $K$ :

$$K = \frac{4 \text{ gal/min}}{e^{4.05 \times 0.3}} = 1.19 \text{ gal/min} \quad (23.17)$$

Finally, the flow is given by

$$\dot{V} = 1.19e^{4.05z} \quad (23.18)$$

At 50% travel, the flow can be found from the following expression:

$$\dot{V}_{50} = 1.19e^{4.05 \times 0.5} = 9.0 \text{ gal/min} \quad (23.19)$$

*Comments:* This result can be checked, since the valve is an equal percentage valve. At 50% travel, the valve has moved 10% beyond its 40% setting at which the flow was 6 gal/min. Another 10% stem movement will result in another 50% flow increase from 6 to 9 gal/min, confirming the solution.

The plotted characteristics of all three valve types assume constant pressure drop across the valve. In an actual system, the pressure drop across a valve will not remain constant, but if the valve is to maintain its control characteristics, the pressure drop across it must be the majority of the entire loop pressure drop. If the valve is designed to have a full-open pressure drop equal to that of the balance of the loop, good flow control will exist. This introduces the concept of valve *authority* defined as the valve pressure drop as a fraction of total system pressure drop:

$$A \equiv \frac{\Delta p_{v,open}}{(\Delta p_{v,open} + \Delta p_{system})} \quad (23.20)$$

For proper control, the full-open valve authority should be at least 0.50. If the authority is 0.5 or more, control valves will have installed characteristics not much different from those shown in [Figure 23.12](#). If not, the valve characteristic will be distorted upward, since the majority of the system pressure drop will be dissipated across the system at high flows.

Valves are further classified by the number of connections or ports. [Figure 23.13](#) shows sections of typical *two-way* and *three-way* valves. Two-port valves control flow through coils or other HVAC equipment by varying valve flow resistance as a result of flow area changes. As shown, the flow must oppose the closing of the valve. If not, near closure, the valve would slam shut or oscillate, both of which cause excessive wear and noise. The three-way valve shown in the figure is configured in the *diverting* mode. That is, one stream is split into two depending on the valve opening.

**FIGURE 23.13**

Cross-sectional drawings of direct-acting, single-seated two-way valve and dual-seated, three-way, diverting valve.

The three-way valve shown is double seated (single-seated three-way valves are also available); it is therefore easier to close than a single-seated valve, but tight shutoff is not possible.

Three-way valves can also be used as *mixing* valves. In this application, two streams enter the valve and one leaves. Mixing and diverting valves *cannot be used interchangeably*, since their internal design is different to ensure that they can each seat properly. Particular attention is needed by the installer to be sure that connections are made properly; arrows cast in the valve body show the proper flow direction. Figure 23.14 shows an example of three-way valves for both mixing and diverting applications.

Valve flow capacity is denoted in the industry by the dimensional flow coefficient  $C_v$  defined by

$$\dot{V} \text{ (gal/min)} = C_v [\Delta p \text{ (psi)}]^{0.5} \quad (23.21)$$

$\Delta p$  is the pressure drop across the fully open valve, so  $C_v$  is specified as the flow rate of 60°F water that will pass through the fully open valve if a pressure difference of 1.0 psi is imposed across the valve. If SI units ( $\text{m}^3/\text{s}$  and Pa) are used, the numerical value of  $C_v$  is 17% larger than in USCS units. Once the designer has determined a value of  $C_v$ , manufacturer's tables can be consulted to select a valve for the known pipe size. If a fluid other than water is to be controlled, the  $C_v$  found from Equation 23.21, should be multiplied by the square root of the fluid's specific gravity.

**FIGURE 23.14**

Three-way mixing and diverting valves. Note the significant difference in internal construction. Mixing valves are more commonly used.

Steam valves are sized using a similar dimensional expression:

$$\dot{m} \text{ (lb/h)} = 63.5C_v \left[ \frac{\Delta p \text{ (psi)}}{v \text{ (ft}^3/\text{lb)}} \right]^{0.5} \quad (23.22)$$

in which  $v$  is the steam-specific volume. If the steam is highly superheated, multiply  $C_v$  found from Equation 23.22 by 1.07 for every 100°F of superheat. For wet steam, multiply  $C_v$  by the square root of the steam quality. Honeywell (1988) recommends that the pressure drop across the valve to be used in the equation be 80% of the difference between steam supply and return pressures (subject to the sonic flow limitation discussed later). Table 23.1 can be used for preliminary selection of control valves for either steam or water.

The type of valve (linear or not) for a specific application must be selected so the controlled system is as nearly linear as possible. Control valves are very commonly used to control the heat transfer rate in coils. For a linear system, the combined characteristic of the actuator, valve, and coil should be linear. This will require quite different valves for hot water and steam control, for example, as we shall see.

Figure 23.15 shows the part load performance of a hot water coil used for air heating; at 10% of full flow, the heat rate is 50% of its peak value. The heat rate in a cross-flow heat exchanger increases roughly in exponential fashion with flow rate, a highly nonlinear characteristic. This heating coil nonlinearity follows from the longer water residence time in a coil at reduced flow and the relatively large temperature difference between air being heated and the water heating it.

However, if one were to control the flow through this heating coil by an equal percentage valve (positive exponential increase in flow with valve position), the combined valve plus the coil characteristic would be roughly linear. Referring to Figure 23.15, we see that 50% of stem travel corresponds to 10% flow. The third graph in the figure is the combined characteristic. This approximately linear subsystem is much easier to control than if a linear valve were used with the highly nonlinear coil. Hence the general rule: use equal percentage valves for heating coil control.

<sup>a</sup> Assuming a 4–8 in. vacuum.

<sup>b</sup> Pressure drop across fully open valve taking 80% of the pressure difference between supply and return main pressures.

**FIGURE 23.15**

Heating coil, equal percentage valve, and combined coil-plus-valve linear characteristic.

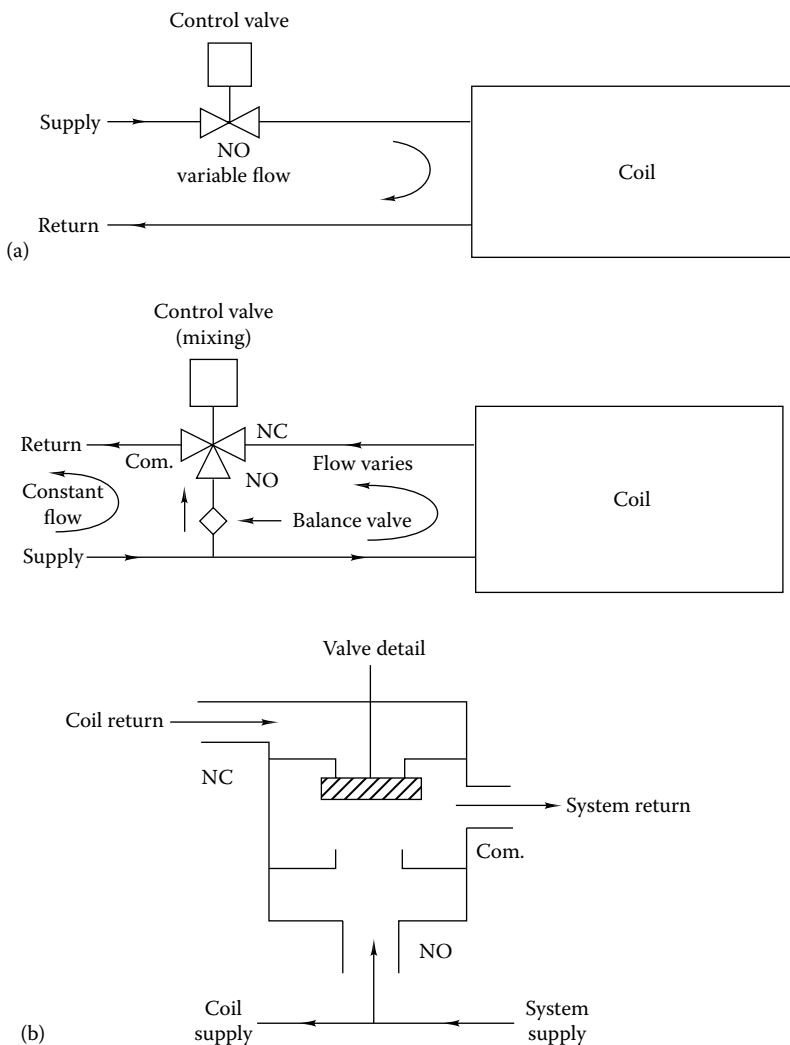

Linear, two-port valves are to be used for steam flow control to coils, since the transfer of heat by steam condensation is a linear, constant temperature process—the more steam supplied, the greater the heat rate in exact proportion. Note that this is a completely different coil flow characteristic than for hot water coils. However, steam is a compressible fluid, and the sonic velocity sets the flow limit for a given valve opening when the pressure drop across the valve is more than 60% of the steam supply line absolute pressure. As a result, the pressure drop to be used in Equation 23.22 is the *smaller* of (1) 50% of the absolute stream pressure upstream of the valve and (2) 80% of the difference between the steam supply and return line pressures. The 80% rule gives good valve modulation in the subsonic flow regime (Honeywell, 1988).

Chilled water control valves should also be linear, since the performance of chilled water coils (smaller air–water temperature difference than in hot water coils) is more similar to steam coils than to hot water coils.

Either two- or three-way valves can be used to control flow at part load through heating and cooling coils as shown in [Figure 23.16](#). The control valve can either be controlled from

coil outlet water or air temperature. Two- or three-way valves achieve the same local result at the coil when used for part load control. However, the designer must consider the effects on the balance of the secondary system when selecting the valve type.

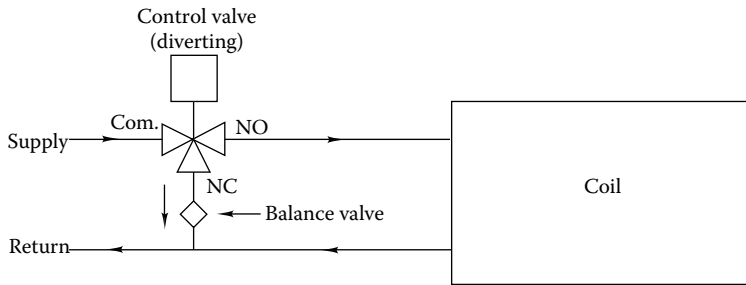

In essence, the two-way valve flow control method results in variable flow (tracking variable loads) with constant coil water temperature change, whereas the three-way valve approach results in roughly constant secondary loop flow rate but smaller coil water temperature change (beyond the local coil loop itself). In large systems, a primary/secondary design with two-way valves is preferred, unless the primary equipment can handle the range of flow variation that will result without a secondary loop. Since chillers and boilers require that flow remain within a restricted range, the energy and cost savings that could accrue due to the two-way valve, variable-volume system are difficult to achieve in small

**FIGURE 23.16**

Various control valve piping arrangements: (a) two-way valve, (b) three-way mixing valve.

(Continued)

**FIGURE 23.16 (Continued)**

Various control valve piping arrangements: (c) three-way diverting valve, and (d) pumped coil with three-way mixing valve.

systems unless a two-pump, primary/secondary loop approach is employed. If this dual-loop approach is not used, the three-way valve method is required to maintain required boiler or chiller flow.

The location of the three-way valve at a coil must also be considered by the designer. [Figure 23.16b](#) shows the valve used downstream of the coil in a mixing, bypass mode. If a balancing valve is installed in the bypass line and set to have the same pressure drop as the coil, the local coil loop will have the same pressure drop for both full and zero coil flows. However, at the valve mid-flow position, overall flow resistance is less, since two parallel paths are involved, and the total loop flow increases to 25% more than that at either extreme.

Alternatively, the three-way valve can also be used in a diverting mode as shown in [Figure 23.16c](#). In this arrangement, essentially the same considerations apply as for the mixing arrangement discussed earlier.\* However, if a circulator (small pump) is inserted as shown in [Figure 23.16d](#), the direction of flow in the branch line changes and a mixing valve is used. The reason that pumped coils are used is that control is improved. With constant coil flow, the highly nonlinear coil characteristic shown in [Figure 23.15](#) is reduced, since the residence time of hot water in the coil is constant independent of load. However, this arrangement appears to the external secondary loop the same as a two-way valve. As load is decreased, flow into the local coil loop also decreases. Therefore, the uniform secondary loop flow normally associated with three-way valves is not present unless the optional bypass is used.

For HVAC systems requiring precise control, high-quality control valves are required. The best controllers and valves are of *industrial quality*; the additional cost for these valves compared to conventional building hardware results in more accurate control and longer lifetime.

### 23.4.2 Airflow Control

Dampers are used to control airflow in secondary HVAC air systems in buildings. In this section, we discuss the characteristics of dampers used for flow control in systems where constant-speed fans are involved. [Figure 23.17](#) shows cross sections of the two common types of dampers used in commercial buildings. Parallel-blade dampers use blades that rotate in the same direction. They are most often applied to two position locations—open or closed. Use for flow control is not recommended. The blade rotation changes airflow direction, a characteristic that can be useful when airstreams at different temperatures are to be effectively blended.

Opposed-blade dampers have adjacent counterrotating blades. Airflow direction is not changed with this design, but pressure drops are higher than for parallel blading. Opposed-blade dampers are preferred for flow control. [Figure 23.18](#) shows the flow characteristics of these dampers to be closer to the desired linear behavior. The parameter  $\alpha$  on the curves is the ratio of system pressure drop to fully open damper pressure drop.

---

\* A little-known disadvantage of three-way valve control has to do with the *conduction* of heat from a closed valve to a coil. For example, the constant flow of hot water through two ports of a *closed* three-way heating coil control valve keeps the valve body hot. Conduction from the closed, hot valve mounted close to a coil can cause sufficient air heating to actually decrease the expected cooling rate of a downstream cooling coil during the cooling season. Three-way valves have a second practical problem; installers often connect three-way valves incorrectly given the choice of three pipe connections and three pipes to be connected. Both of these problems are avoided by using two-way valves.

**FIGURE 23.17**  
Diagram of parallel and opposed-blade dampers.

**FIGURE 23.18**  
Flow characteristics of opposed-blade dampers. The parameter  $\alpha$  is the ratio of system resistance (not including the damper) to damper resistance. An approximately linear damper characteristic is achieved if this ratio is about 10 for opposed-blade dampers.

**FIGURE 23.19**

Face and bypass dampers used for preheating coil control.

A common application of dampers controlling the flow of outside air uses two sets in a *face and bypass* configuration as shown in Figure 23.19. For full heating, all air is passed through the coil and the bypass dampers are closed. If no heating is needed in mild weather, the coil is bypassed (for minimum flow resistance and fan power cost, flow through fully open face and bypass dampers can be used if the preheat coil water flow is shut off). Between these extremes, flow is split between the two paths. The face and bypass dampers are sized so that the pressure drop in full bypass mode (damper pressure drop only) and full heating mode (coil plus damper pressure drop) is the same.

### 23.5 Example HVAC System Control Systems

Several widely used control configurations for specific tasks are described in this section. These have been selected from the hundreds of control system configurations that have been used for buildings. The goal of this section is to illustrate how control components described previously are assembled into systems and what design considerations are involved. For a complete overview of HVAC control system configurations, see ASHRAE (2002, 2003, 2004), Grimm and Rosaler (1990), Tao and Janis (2005), Sauer et al. (2001), and Honeywell (1988). The illustrative systems in this section are drawn in part from the latter reference.

In this section, we will discuss seven control systems in common use. Each system will be described using a schematic diagram, and its operation and key features will be discussed in the accompanying text.

S—switch

SP—static pressure sensor used in VAV systems

T—temperature sensor; must be located to read the average temperature representative of the air volume being controlled

This system is able to provide the minimum outside air during occupied periods, to use outdoor air for cooling when appropriate by means of a temperature-based economizer cycle, and to operate fans and dampers under all conditions. The numbering system used in the figure indicates the sequence of events as the air-handling system begins operation after an off period:

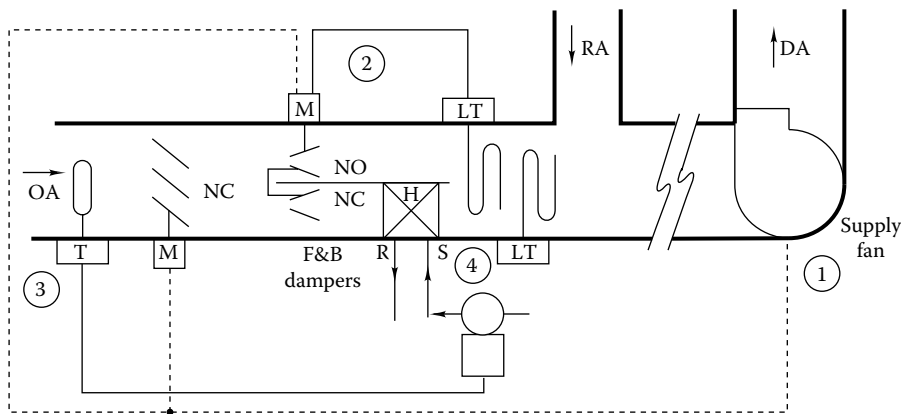

1. The fan control system turns on when the fan is turned on. This may be by a clock signal or a low- or high-temperature space condition.
2. The space temperature signal determines if the space is above or below the set point. If above, the economizer feature will be activated if the OA temperature is below the upper limit for economizer operation and control the outdoor and mixed-air dampers. If below, the outside air damper is set to its minimum position.
3. The discharge air PI controller controls both sets of dampers (OA/RA and EA) to provide the desired mixed-air temperature.
4. When the outdoor temperature rises above the upper limit for economizer operation, the outdoor air damper is returned to its minimum setting.
5. Switch S is used to set the minimum setting on outside and exhaust air dampers manually. This is ordinarily done only once during building commissioning and flow testing.
6. When the supply fan is off, the outdoor air damper returns to its NC position and the return air damper returns to its NO position.
7. When the supply fan is off, the exhaust damper also returns to its NC position.
8. Low temperature sensed in the duct will initiate a freeze-protect cycle. This may be as simple as turning on the supply fan to circulate warmer room air. Of course, the OA and EA dampers remain tightly closed during this operation.

### 23.5.2 Heating Control

If the minimum air setting is large in the preceding system, the amount of outdoor air admitted in cold climates may require preheating. [Figure 23.21](#) shows a preheating system using face and bypass dampers. (A similar arrangement is used for DX cooling coils.) The equipment shown is installed upstream of the fan in [Figure 23.20](#). This system operates as follows:

1. The preheat subsystem control is activated when the supply fan is turned on.
2. The preheat PI controller senses temperature leaving the preheat section. It operates the face and bypass dampers to control the exit air temperature between 45°F and 50°F.
3. The outdoor air sensor and associated controller controls the water valve at the preheat coil. The valve may be either a modulating valve (better control) or an on-off valve (less costly).
4. The low-temperature sensors (LTs) activate coil freeze protection measures including closing dampers and turning off the supply fan.

**FIGURE 23.21**

Preheat control system. Counterflow of air and hot water in the preheat coil results in the highest heat transfer rate.

Note that the preheat coil (as well as all coils in this section) is connected so that the hot water (or steam) flows counter to the direction of airflow. Counterflow provides a higher heating rate for a given coil than does parallel flow. Mixing of heated and cold bypass air must occur upstream of the control sensors. Stratification can be reduced by using sheet metal *air blenders* or by propeller fans in the ducting. The preheat coil should be located in the bottom of the duct. Steam preheat coils must have adequately sized traps and vacuum breakers to avoid condensate buildup that could lead to coil freezing at light loads.

The face and bypass damper approach enables air to be heated to the required system supply temperature without endangering the heating coil. (If a coil were to be as large as the duct—no bypass area—it could freeze when the hot water control valve cycles are opened and closed to maintain the discharge temperature.) The designer should consider pumping the preheat coil as shown in [Figure 23.19d](#) to maintain water velocity above the 3 ft/s needed to avoid freezing. If glycol is used in the system, the pump is not necessary but heat transfer will be reduced.

During winter, in heating climates, heat must be added to the mixed airstream to heat the outside air portion of mixed air to an acceptable discharge temperature. [Figure 23.22](#) shows a common heating subsystem controller used with central air handlers. (It is assumed that the mixed-air temperature is kept above freezing by the action of the preheat coil, if needed.) This system has the added feature that coil discharge temperature is adjusted for ambient temperature, since the amount of heat needed decreases with increasing outside temperature. This feature, called coil discharge reset, provides better control and can reduce energy consumption. The system operates as follows:

1. During operation, the discharge air sensor and PI controller control the hot water valve.
2. The outside air sensor and controller reset the *set point* of the discharge air PI controller up as ambient temperature drops.
3. Under sensed low-temperature conditions, freeze protection measures are initiated as discussed earlier.

**FIGURE 23.22**

Heating coil control subsystem using two-way valve and optional reset sensor.

Reheating at zones in VAV or other systems uses a system similar to that just discussed. However, boiler water temperature is reset and no freeze protection is normally included. The air temperature sensor is the zone thermostat for VAV reheat, not a duct temperature sensor.

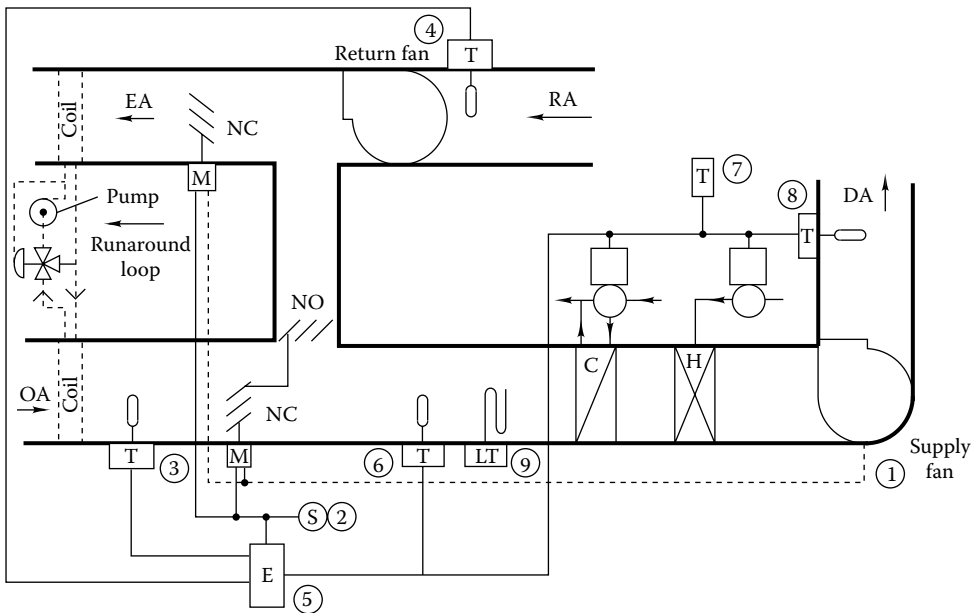

### 23.5.3 Cooling Control

Figure 23.23 shows the components in a cooling coil control system for a single-zone system. Control is similar to that for the heating coil discussed earlier except that the zone thermostat (not a duct temperature sensor) controls the coil. If the system were a central system serving several zones, a duct sensor would be used. Chilled water supplied to the coil

**FIGURE 23.23**

Cooling coil control subsystem using three-way diverting valve.

**FIGURE 23.25**

Control for a complete, constant-volume HVAC system. Optional runaround heat recovery system is shown to left by dashed lines.

remainder of this section, we will describe briefly two complete HVAC control systems widely used in commercial buildings. The first is a constant-volume system, whereas the second is a VAV system.

Figure 23.25 shows a constant-volume central system air-handling system equipped with supply and return fans, heating and cooling coils, and economizer for a single-zone application. If the system were to be used for multiple zones, the zone thermostat shown would be replaced by a discharge air temperature sensor. This constant-volume system operates as follows:

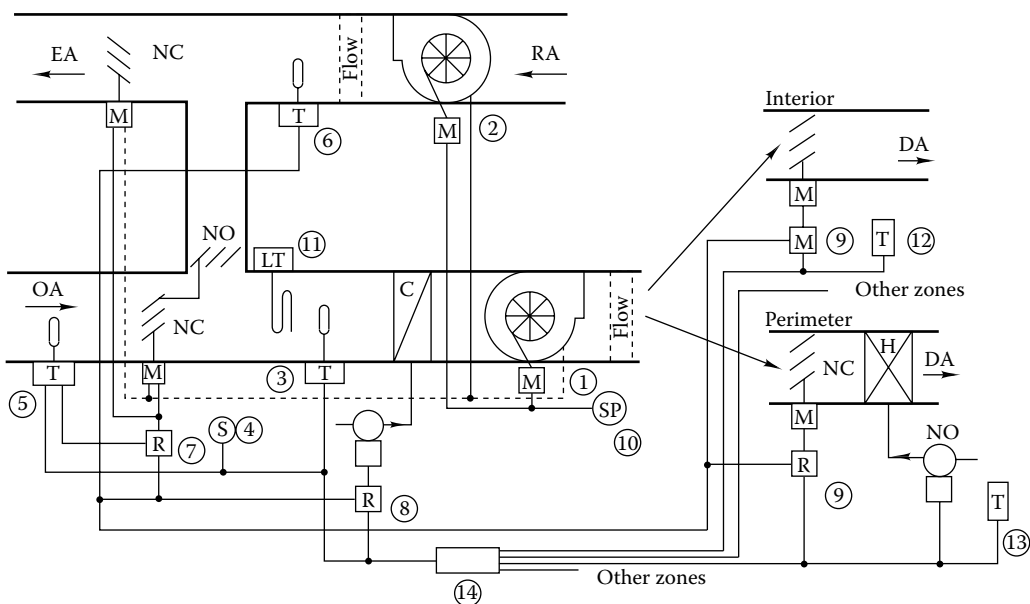

1. When the fan is energized, the control system is activated.
2. The minimum outside air setting is set (usually only once during commissioning as described earlier).
3. The OA temperature sensor supplies a signal to the damper controller.
4. The RA temperature sensor supplies a signal to the damper controller.
5. The damper controller positions the dampers to use outdoor or return air depending on which is cooler.
6. The mixed-air low-temperature controller controls the outside air dampers to avoid excessively low-temperature air from entering the coils. If a preheating system were included, this sensor would control it.
7. The space temperature sensor resets the coil discharge air PI controller.
8. The discharge air controller controls the
  - a. Heating coil valve
  - b. Outdoor air damper
  - c. Exhaust air damper

- d. Return air damper
- e. Cooling coil valve after the economizer cycle upper limit is reached
9. The low-temperature sensor initiates freeze protection measures as described previously.

A method for reclaiming either heating or cooling energy is shown by dashed lines on the left side of [Figure 23.25](#). This so-called *runaround* system extracts energy from exhaust air and uses it to precondition outside air. For example, the heating season exhaust air may be at 75°F while the outdoor air is at 10°F. The upper coil in the figure extracts heat from the 75°F exhaust and transfers it through the lower coil to the 10°F intake air. To avoid icing of the air intake coil, the three-way valve controls this coil's liquid inlet temperature to a temperature above freezing. In heating climates, the liquid loop should also be freeze protected with a glycol solution. Heat reclaiming systems of this type can also be effective in the cooling season, when the outdoor temperatures are well above the indoor temperature.

A VAV system has additional control features including a motor speed (or inlet vanes in some older systems) control and a duct static pressure control. [Figure 23.26](#) shows a VAV system serving both perimeter and interior zones. It is assumed that the core zones always require cooling during the occupied period. The system shown has a number of options and does not include every feature present in all VAV systems. However, it is representative of VAV design practice. The sequence of operation during the heating season is as follows:

1. When the fan is energized, the control system is activated. Prior to activation during unoccupied periods, the perimeter zone baseboard heating is under control of room thermostats.
2. Return and supply fan interlocks are used to prevent pressure imbalances in the supply air ductwork.

**FIGURE 23.26**

Control for complete, VAV system. Optional supply and return flow stations shown by dashed lines.

3. The mixed-air sensor controls the outdoor air dampers (and/or preheat coil not shown) to provide proper coil air inlet temperature. The dampers will typically be at their minimum position at about 40°F.
4. The damper minimum position controls the minimum outdoor airflow.
5. As the upper limit for economizer operation is reached, the OA dampers are returned to their minimum position.
6. The return air temperature is used to control the morning warm-up cycle after night setback (option present only if night setback is used).
7. The outdoor air damper is not permitted to open during morning warm-up by the action of the relay shown.
8. Likewise, the cooling coil valve is deenergized (NC) during morning warm-up.
9. All VAV box dampers are moved full open during morning warm-up by the action of the relay override. This minimizes the warm-up time. Perimeter zone coils and baseboard units are under control of the local thermostat.
10. During operating periods, the PI static pressure controller controls both the supply and return fan speeds (or inlet vane positions) to maintain approximately 1.0 in. WG of static pressure at the pressure sensor location (or optionally to maintain building pressure). An additional pressure sensor (not shown) at the supply fan outlet will shut down the fan if fire dampers or other dampers should close completely and block airflow. This sensor overrides the duct static pressure sensor shown.
11. The low-temperature sensor initiates freeze protection measures.
12. At each zone, room thermostats control VAV boxes (and fans if present); as zone temperature rises, the boxes open more.
13. At each perimeter zone room, thermostats close VAV dampers to their minimum settings and activate zone heat (coil and/or perimeter baseboard) as zone temperature falls.
14. The controller, using temperature information for all zones (or at least for enough zones to represent the characteristics of all zones), modulates outdoor air dampers (during economizer operation) and the cooling control valve (above the economizer cycle cutoff) to provide air sufficiently cooled to maintain acceptable zone humidity and meet the load of the warmest zone.

The duct static pressure controller is critical to the proper operation of VAV systems. The static pressure controller must be of PI design, since a proportional-only controller would permit duct pressure to drift upward as cooling loads drop due to the unavoidable offset in P-type controllers. In addition, the control system should position inlet vanes (if present) closed during fan shutdown to avoid overloading on restart.

Return fan control is best achieved in VAV systems by an actual flow measurement in supply and return ducts as shown by dashed lines in the figure. The return airflow rate is the supply rate less local exhausts (fume hoods, toilets, etc.) and exfiltration needed to pressurize the building.

VAV boxes are controlled locally, assuming that adequate duct static pressure exists in the supply duct and that supply air is at an adequate temperature to meet the load (this is the function of the controller described in item 14). [Figure 23.27](#) shows a *local* control system used with a series-type, fan-powered VAV box. This particular system delivers a

**FIGURE 23.27**

Series-type, fan-powered VAV box control subsystem and primary flow characteristic. The total box flow is constant at the level identified as *maximum* in the figure. The difference between primary and total airflow is secondary air recirculated through the return air grille. Optional reheat coil requires airflow shown by dashed line.

constant flow rate to the zone, to assure proper zone air distribution, by the action of the airflow controller. Primary air varies with cooling load as shown in the lower part of the figure. Optional reheating is provided by the coil shown.

### 23.5.5 Other Systems

This section has not covered the control of central plant equipment such as chillers and boilers. Most primary system equipment controls are furnished with the equipment and as such do not offer much flexibility to the designer. However, Braun et al. (1989) have shown that considerable energy savings can be made by properly sequencing cooling tower stages on chiller plants and by properly sequencing chillers themselves in multiple chiller plants.

Fire and smoke control are important for life safety in large buildings. The design of smoke control systems is controlled by national codes. The principal concept is to eliminate

smoke from the zones where it is present while keeping adjacent zones pressurized to avoid smoke infiltration. Some components of space conditioning systems (e.g., fans) can be used for smoke control, but HVAC systems are generally not smoke control systems by design.

Electrical systems are primarily the responsibility of the electrical engineer on a design team. However, HVAC engineers must make sure that the electrical design accommodates the HVAC control system. Interfaces between the two occur where the HVAC controls activate motors on fans or chiller compressors, pumps, electrical boilers, or other electrical equipment.

In addition to electrical specifications, the HVAC engineer often conveys electrical control logic using a *ladder diagram*. An example is shown in [Figure 23.28](#) for the control of the supply and return fans in a central system. The electrical control system is shown at the bottom and operates on low voltage (24 or 48 VAC) from the control transformer shown. The supply fan is manually started by closing the *start* switch. This activates the motor starter coil labeled 1M, thereby closing the three contacts labeled 1M in the supply fan circuit. The fourth 1M contact (in parallel with the start switch) holds the starter closed after the start button is released.

The hand-off-auto switch is typical and allows both automatic and manual operations of the return fan. When switched to the *hand* position, the fan starts. In the *auto* position, the fans will operate only when the adjacent contacts 3M are closed. Either of these actions activates the relay coil 2M, which in turn closes the three 2M contacts in the return fan motor starter. When either fan produces actual airflow, a flow switch is closed in the ducting, thereby completing the circuit to the pilot lamps L. The fan motors are protected by fuses and thermal overload heaters. If motor current draw is excessive, the heaters shown in the figure produce sufficient heat to open the normally closed thermal overload contacts.

This example ladder diagram is primarily illustrative and is not typical of an actual design. In a fully automatic system, both fans would be controlled by 3M contacts actuated by the HVAC control system. In a fully manual system, the return fan would be activated by a fifth 1M contact, not by the 3M automatic control system.

---

## 23.6 Commissioning and Operation of Control Systems

This chapter emphasizes the importance of making sound decisions in the design of HVAC control systems. Ensuring that the control system be commissioned and used properly is extremely important. The design process requires many assumptions about the building and its use. The designer must be sure that the systems will provide comfort under extreme conditions, and the sequence of design decisions and construction decisions often leads to systems that are substantially oversized. Operation at loads far below design conditions is generally much less efficient than at larger loads. Normal control practice can be a major contributor to this inefficiency. For example, it is quite common to see variable-volume air handler systems that operate at minimum flow as constant-volume systems almost all the time due to design flows that sometimes are twice as large as the maximum flow used in the building.

Hence it is very important that following construction, the control system and the rest of the HVAC system be *commissioned*. This process (ASHRAE, 2005) normally seeks to ensure that the control system operates according to design intent. This is really a minimum requirement to be sure that the system functions as designed. However, after construction, the control system setup can be modified to meet the loads actually present in

the building and fit the way the building is actually being used rather than basing these decisions on the design assumptions. If the VAV system is designed for more flow than is required, minimum flow settings of the terminal boxes can be reduced below the design value so that the system will operate in the VAV mode most of the time. Numerous other adjustments may be made as well. Such adjustments, as commonly made during the version of commissioning known as *Continuous Commissioning*<sup>®\*</sup> (CC<sup>®</sup>), can frequently reduce the overall building energy use by 10% or more (Liu et al., 2002). If the process is applied to an older building where control practices have drifted away from design intent and undetected component failures have further eroded system efficiency, energy savings often exceed 20% (Claridge et al., 2004).

### 23.6.1 Control Commissioning Case Study

A case study in which this process was applied to a major army hospital facility located in San Antonio, TX (Zhu et al., 2000a–c), is provided. The Brooke Army Medical Center (BAMC) was a relatively new facility when the CC process was begun. The facility was operated for the army by a third-party company, and it was operated in accordance with the original design intent (Figure 23.29).

BAMC is a large, multifunctional medical facility with a total floor area of 1,349,707 ft<sup>2</sup>. The complex includes all the usual in-patient facilities as well as out-patient and research areas. The complex is equipped with a central energy plant, which has four 1200-ton water-cooled electric chillers. Four primary pumps (75 hp each) are used to pump water through the chillers. Two secondary pumps (200 hp each), equipped with VFDs, supply chilled water from the plant to the building entrance. Fourteen chilled water risers equipped with 28 pumps totaling 557 hp are used to pump chilled water to all of the

**FIGURE 23.29**  
The BAMC in San Antonio, TX.

\* Continuous Commissioning and CC are registered trademarks of the Texas A&M Engineering Experiment Station.

AHUs and small fan coil units. All of the chilled water riser pumps are equipped with VFDs. There are four natural gas-fired steam boilers in this plant. The maximum output of each boiler is 20 MMBtu/h. Steam is supplied to each building at 125 psi (prior to CC) where heating water is generated.

There are 90 major AHUs serving the whole complex with a total fan power of 2570 hp. VFDs are installed on 65 AHUs, while the others are constant-volume systems. There are 2700 terminal boxes in the complex of which 27% are dual-duct variable-volume boxes, 71% are dual-duct constant-volume boxes, and 2% are single-duct variable-volume boxes.

The HVAC systems (chillers, boilers, AHUs, pumps, terminal boxes, and room conditions) are controlled by a DDC system. Individual controller-field panels are used for the AHUs and water loops located in the mechanical rooms. The control program and parameters can be changed either by the central computers or by the field panels.

#### **23.6.1.1 Design Conditions**

The design control program was being fully utilized by the EMCS. It included the following features:

1. Hot deck reset control for AHUs
2. Cold deck reset during unoccupied periods for some units
3. Static pressure reset between high and low limits for VAV units
4. Hot water supply temperature control with reset schedule
5. VFD control of chilled water pumps with  $\Delta P$  set point (no reset schedule)
6. Terminal box level control and monitoring

It was also determined that the facility was being well maintained by the facility operator in accordance with the original design intent. The building is considered energy efficient for a large hospital complex.

The commissioning activities were performed at the terminal box level, AHU level, loop level, and central plant level. Several different types of improved operation measures and energy solutions were implemented in different HVAC systems due to the actual function and usage of the areas and rooms. Each measure will be discussed briefly, starting with the AHUs.

#### **23.6.1.2 Optimization of AHU Operation**

EMCS trending complemented by site measurements and use of short-term data loggers found that many supply fans operated above 90% of full speed most of the time. Static pressures were much higher than needed. Wide room temperature swings due to AHU shutoff lead to hot and cold complaints in some areas. Through field measurements and analysis, the following opportunities to improve the operation of the two AHUs were identified:

1. Zone air balancing and determination of new static pressure set points for VFDs
2. Optimize the cold deck temperature set points with reset schedules
3. Optimize the hot deck temperature reset schedules
4. Control of outside air intake and relief dampers during unoccupied periods to reduce ventilation during these periods

5. Optimized time schedule for fans to improve room conditions
6. Improve the preheat temperature set point to avoid unnecessary preheating

Implementation of these measures improved comfort and reduced heating, cooling, and electric use.

#### **23.6.1.3 Optimization at the Terminal Box Level**

Field measurements showed that many VAV boxes had minimum flow settings that were higher than necessary, and some boxes were unable to supply adequate hot air due to specific control sequences. A new control logic was developed, which increased hot air capacity by 30% on average, in the full heating mode, and reduced simultaneous heating and cooling. During unoccupied periods, minimum flow settings on VAV boxes were reduced to zero and flow settings were reduced in constant-volume boxes.

During commissioning, it was found that some terminal boxes could not provide the required airflow either before or after the control program modification. Specific problems were identified in about 200 boxes, with most being high flow resistance due to kinked flex ducts.

#### **23.6.1.4 Water Loop Optimization**

There are 14 chilled water risers equipped with 28 pumps that provide chilled water to the entire complex. During the commissioning assessment phase, the following were observed:

1. All the riser pumps were equipped with VFDs and they were running from 70% to 100% of full speed.
2. All the manual balancing valves on the risers were only 30%–60% open.
3. The  $\Delta P$  sensor for each riser was located 10–20 ft from the far-end coil of the AHU on the top floor.
4. Differential pressure set points for each riser ranged from 13 to 26 psi.
5. There is no control valve on the return loop.
6. Although most of the cold deck temperatures were holding well, there were 13 AHUs whose cooling coils were 100% open but could not maintain cold deck temperature set points.

Since the risers are equipped with VFDs, traditional manual balancing techniques are not appropriate. All the risers were rebalanced by initially opening all of the manual balancing valves. The actual pressure requirements were measured for each riser, and it was determined that the  $\Delta P$  for each riser could be reduced significantly. Pumping power requirements were reduced by more than 40%.

#### **23.6.1.5 Central Plant Measures**

*Boiler system:* Steam pressure was reduced from 125 to 110 psi and one boiler was operated instead of two during summer and swing seasons.

*Chilled water loop:* Before the commissioning, the blending valve separating the primary and secondary loops at the plant was 100% open. The primary and secondary pumps were both running. The manual valves were partially open for the secondary loop although the

secondary loop pumps are equipped with VFDs. After the commissioning assessment and investigations, the following were implemented:

1. Open the manual valves for the secondary loop.
2. Close the blending stations.
3. Shut down the secondary loop pumps.

As a result, the primary loop pumps provide required chilled water flow and pressure to the building entrance for most of the year, and the secondary pumps stay offline for most of the time. The operator drops the online chiller numbers according to the load conditions and the minimum chilled water flow can be maintained to the chillers. At the same time, the chiller efficiency is also increased.

#### **23.6.1.6 Results**

For the 14-month period following initial CC implementation, measured savings were nearly \$410,000, or approximately \$30,000/month, for a reduction in both electricity and gas use of about 10%. The contracted cost to meter, monitor, commission, and provide a year's follow-up services was less than \$350,000. This cost does not include any time for the facilities operating staff who repaired kinked flex ducts, replaced failed sensors, implemented some of the controls and subroutines, and participated in the commissioning process.

#### **23.6.2 Commissioning Existing Buildings**

The savings achieved from commissioning HVAC systems in older buildings are even larger. In addition to the opportunities for improving efficiency similar to those in new buildings, opportunities come from the following:

1. Control changes that have been made to *solve* problems, often resulting in lower operating efficiency
2. Component failures that compromise efficiency without compromising comfort
3. Deferred maintenance that lowers efficiency

Mills et al. (2004, 2005) surveyed 150 existing buildings that had been commissioned and found median energy cost savings of 15%, with savings in one-fourth of the buildings exceeding 29%. Over 60% of the problems corrected were control changes, and another 20% were related to faulty components that prevented proper control.

This suggests that relatively few control systems are operated to achieve the efficiency they are capable of providing.

---

### **23.7 Advanced Control System Design Topics**

Modern control techniques can offer significant benefits compared to basic control algorithms such as PID. This section provides a short introduction to two approaches that are being used with increasing frequency to improve the stability and performance of HVAC control systems. These include nonlinear compensation and model predictive control (MPC).

### 23.7.1 Nonlinear Compensation

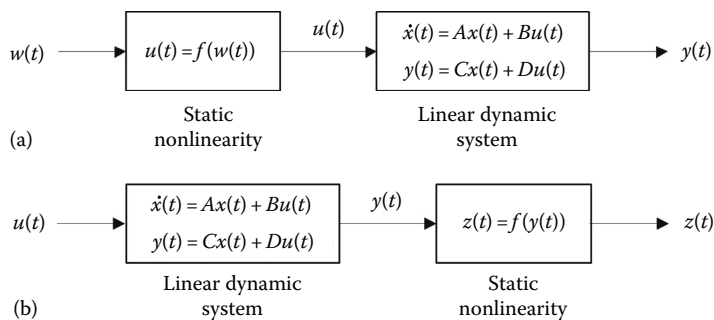

Most HVAC and refrigeration systems exhibit nonlinear dynamics. The physics of these systems are described by nonlinear thermo-fluid relationships that result in dynamic behavior that changes based on operating condition, external conditions, and controllable inputs. Despite the many factors that contribute to the system nonlinearity, the dominant source tends to be the system actuators that manipulate the flow of mass; compressors, valves, pumps, and fans all are intended to vary the flow of primary/secondary fluids. In contrast, the control objectives are generally posed in terms of regulating the flow or state of energy, such as regulating chiller outlet water temperature or specifying a desired amount of cooling. As mass flow devices, HVAC actuators are typically designed to provide a linear relationship between control input and flow rate. However, the remaining portion of the system generally exhibits a nonlinear relationship between flow rate and system outputs (temperatures, pressures, etc.).

There are many established methods or ways to account for these dynamic nonlinearities. Although these can be approximated with linear models, they are typically only valid for a small operating range. Common approaches to extend model validity include Hammerstein/Wiener models (i.e., identified linear models with a nonlinear input or output function, Figure 23.30) and linear parameter-varying models where parameter values are determined at multiple conditions and then scheduled based on a measured signal:

$$G(s, \theta) = \frac{k(\theta)}{\tau(\theta)s + 1} \quad (23.23)$$

Fixed controllers (such as PID) are typically tuned for a single operating condition and thus perform poorly at off-design conditions because the fundamental behavior of the system is different. Oscillations, hunting behavior, and sluggish responses are all symptomatic of this problem. Common nonlinear control techniques include the following:

- *Gain-scheduled control*: An approach where multiple linear controllers are designed to cover the range in operating conditions and then interpolated appropriately (Khalil, 1996). Examples of this approach applied to HVAC systems include Outtagarts et al. (1997) and Finn and Doyle (2000).

**FIGURE 23.30**

Nonlinear process models: (a) Hammerstein model and (b) Wiener model.

- *Adaptive control*: A technique for updating the dynamic model using real-time measurements and then using a model-based control strategy that is likewise updated (e.g., Astrom and Wittenmark, 1995).
- *Static nonlinearity compensation*: For systems whose dominant nonlinearity is a change in system gain, for example,  $k(\theta)$ . Various methods have been proposed, including inverse modeling (Franklin et al., 2006) and nonlinear mapping (Singhal and Salsbury, 2007). The interested reader can find a survey of linearization through feedback in Guardabassi and Savaresi (2001).
- *Cascaded feedback loops*: Using multiple feedback loops has immediate practical benefits in terms of inherent robustness (Skogestad and Postlethwaite, 1996) and can partially compensate for nonlinear system gains (Elliott and Rasmussen, 2010).

### 23.7.1.1 Case Study: Nonlinear Compensation for Air Conditioning Expansion Valves

In this section, we present an example of a particularly simple and effective technique for compensating for the static nonlinearities present in many HVAC systems. The system being considered is a vapor compression cycle, which is used extensively for air conditioning and refrigeration systems. During operation, an expansion valve modulates the refrigerant flow through the evaporator and regulates the temperature at the evaporator outlet (i.e., superheat). In these systems, superheat must not only be kept low to ensure efficient operation, but also remain high enough to prevent liquid refrigerant from entering the compressor.

As with many HVAC actuators, the relationship between valve input and system outputs is highly nonlinear, with the system gain,  $k(\theta)$ , varying several hundred percent between low-flow and high-flow conditions. This can lead to poor performance in practice. If fixed-gain controllers (e.g., PID) are designed for the high-flow conditions, then the system will oscillate at low- and medium-flow conditions (i.e., valve hunting). However, if the controller gains are selected based on the low-flow conditions, the performance will be extremely sluggish at medium- and high-flow conditions.

One simple method for compensating for the nonlinear system gain is to utilize cascaded control loops (Figure 23.31). An inner loop controller utilizes a high proportional

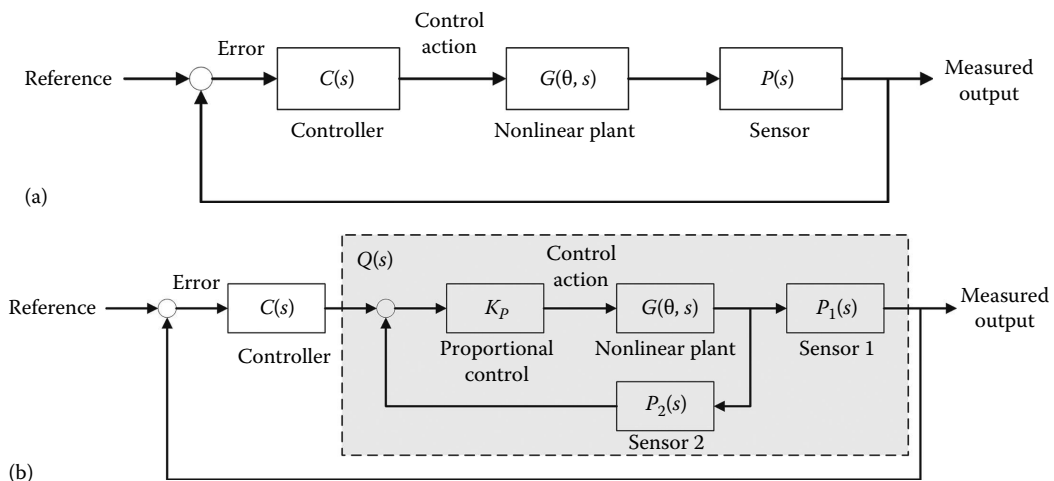

FIGURE 23.31

Feedback control architectures: (a) standard feedback control and (b) cascaded feedback control.

**FIGURE 23.32**

Superheat response to step change in valve position for high and low flows: (a) standard feedback control and (b) cascaded feedback control. Note the difference in speed of response, as well as the nonlinear compensation.

gain, which significantly lessens the sensitivity of the resulting closed-loop system,  $Q(s)$ , to changes in the system gain. A standard fixed controller, such as PID, is then designed and implemented in cascade. The resulting system generally exhibits improved performance over a wide range of operating conditions. This approach was advocated by Elliott et al. (2009) and Elliott and Rasmussen (2010) who analyzed the effects for nonlinear electronic expansion valve (EEV) controlled evaporator using temperature and pressure sensors. The resulting step responses under different operating conditions are shown in Figure 23.32 and clearly show that the use of cascaded control loops improves the response time, as well as virtually eliminates the dynamic differences due to system nonlinearities.

### 23.7.2 Model Predictive Control

MPC is an overarching term for a suite of control strategies first developed for the process industries during the 1970s and 1980s. With the increased computational capabilities of embedded controllers, MPC is increasingly being used in a wide range of control applications. MPCs use an explicit dynamic model to optimize a user-defined cost function. System constraints, such as actuator limitations, can be explicitly accounted for in the optimization, which permits better operation than mere saturation of actuator signals. Additionally, output constraints can be imposed upon the controller, which will keep the system operating in a safe range. Since for many industrial systems, the most efficient operating point is at or near a set of operating constraints, MPC has been successfully implemented as a cost and energy minimization technology (Garcia et al., 1989; Qin and Badgwell, 2003).

MPC is a discrete-time control approach. At each time step, the controller uses a system model to predict outputs over a finite-time prediction horizon (Figure 23.33a) and then determine the optimal choice of the control inputs for a defined control horizon (Figure 23.33b). The controller can also account for the effect of external disturbances, input constraints, and, to some extent, output constraints. The controller then implements the first

**FIGURE 23.33**

MPC: (a) prediction horizon and (b) control horizon.

control action in this optimal sequence. At the next time step, the process is repeated, accounting for any new information. The ability to anticipate future outcomes and optimize the response while conforming to constraints is unique to MPC and is not found in basic PID controllers, or even fixed optimal controllers such as the linear quadratic regulator.

The majority of MPC techniques assume a linear model of the system dynamics, usually a discrete-time model based on empirical data. A representative model is defined in Equation 23.24, where  $x$  are the dynamic states of the system,  $u$  are the control inputs,  $w$  and  $v$  are the external disturbances,  $y$  is the measured output,  $r$  is the desired reference,  $e$  is the tracking error, and  $k$  is the sampling index. The controller uses this model to determine the sequence of control actions that minimizes the

cost function  $J(x, u)$  (Equation 23.25), without violating the constraints (Equation 23.26). In this formulation,  $Q$  and  $R$  are matrices that define the relative penalty of tracking errors and actuator effort,  $p$  and  $n$  are the prediction and control horizons, and  $T$  and  $P$  are the matrices that define the hard actuator constraints and soft state constraints, respectively:

$$x(k+1) = Ax(k) + B_u u(k) + B_w w(k)$$

$$y(k) = Cx(k) + Dv(k)$$

$$e(k) = r(k) - y(k) \quad (23.24)$$

$$J(x, u) = \sum_0^p e(k)^T Q e(k) + \sum_0^n u(k)^T R u(k) \quad (23.25)$$

$$Tu \leq b$$

$$Px \leq c \quad (23.26)$$

MPC is attractive for many applications because of its capability to optimize performance while explicitly handling constraints. MPC is a mature technology with extensive research literature addressing issues of stability, constrained feasibility, robustness, and nonlinearities. Since optimal operating conditions often lie at the intersection of constraints, MPC offers a safe way to drive the system to the optimum while not violating performance or actuation limitations. The interested reader is referred to Garcia et al. (1989), Clarke (1994), Kothare et al. (1996), Scokaert and Rawlings (1999), Mayne et al. (2000), Qin and Badgwell (2003), Rossiter (2003), Camacho and Bordons (2004), Allgower (2005), and Rawlings and Mayne (2009), and the references therein for additional details on each of these topics.

Given these advantages, it is not surprising that MPC quickly found success beyond its origins in the chemical industries and is applied with increasing frequency to HVAC systems, including the following:

- Direct application of MPC to basic HVAC components, such as AHUs, VAVs, or heating systems (e.g., MacArthur and Woessner, 1993; He et al., 2005; Yuan and Perez, 2006; Xi et al., 2007; Freire et al., 2008; Huang et al., 2010; Xu et al., 2010; May-Ostendorp et al., 2011; Privara et al., 2011)
- Indirect application as a method of tuning standard HVAC control algorithms (e.g., Dexter and Haves, 1989; MacArthur and Woessner, 1993; Sousa et al., 1997; Xu et al., 2005)
- In the form of the generalized predictive control algorithm, which is perhaps most widely used in HVAC applications (Clarke, 1987)
- Vapor compression systems (e.g., Leducq et al., 2006; Elliott and Rasmussen, 2012, 2013)
- As a supervisory control for HVAC applications (Wang and Ma, 2008)

### 23.7.2.1 Case Study: MPC for Air Conditioning Expansion Valves

The ability to explicitly account for constraints when determining appropriate control actions is a unique capability of MPC. This capability has numerous potential applications for HVAC equipment. This section presents an experimental example of MPC's constraint handling.

Again we examine the case of expansion valve control for vapor compression systems. Although most valves are designed to regulate superheat to a fixed level, the exact superheat set point is not of particular importance for system efficiency; as long as superheat is kept in a reasonable band, the coefficient of performance (COP) does not vary significantly. By using an MPC-based controller, the superheat can be kept in a band around an optimal point without exerting a large amount of actuator effort, achieving efficient operation while minimizing actuator wear. The following experimental results demonstrate that an MPC controller can be used with an EEV to keep superheat in a band, exerting little effort until superheat begins to leave the defined range.

Figures 23.33 and 23.34 present the results of experiments conducted on a residential air conditioning system. For these tests, an MPC controller is used to keep the evaporator superheat between 5°C and 13°C, with a set point of 9°C. As long as the superheat does not leave the designated band, the controller will not react. While similar tracking results can be had with a very nonaggressive PID controller, the construction of the MPC controller allows the actuator to react very strongly to large disturbances while responding slowly to small disturbances, so long as the user-defined constraints are not violated. This capability is not

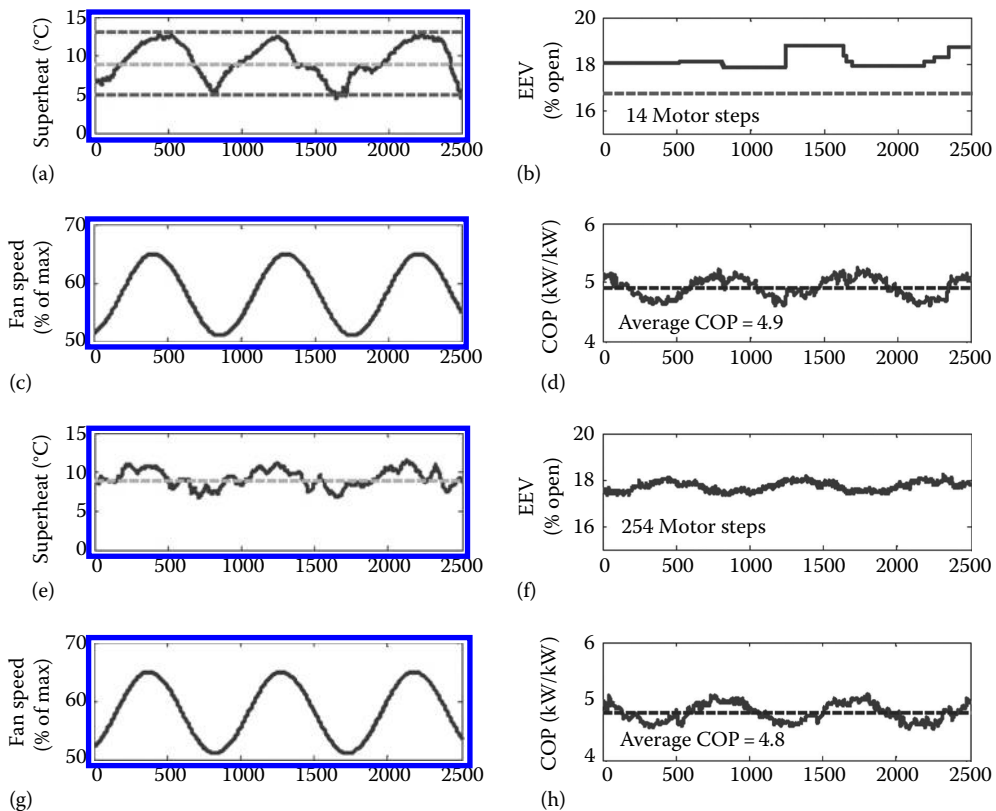

**FIGURE 23.34**

Superheat response using MPC of the EEV with compressor stage change: (a) superheat response and soft output constraints, (b) EEV actuation with hard input constraints.

available under a PID control paradigm. An illustration of this is provided in the test displayed in Figure 23.33a. At 100 s, the compressor changes from stage 1 (low cooling) to stage 2 (high cooling). As the superheat leaves the prescribed band, the EEV reacts strongly, opening up to the EEV maximum constraint, which is set to 23% open. As the superheat drops down toward its minimum constraint, the valve reacts again by closing, bringing superheat back within the desired band. As Figure 23.33b shows, very little actuator effort is expended, even for such a large disturbance as a compressor step change.

Figure 23.34 displays the system efficiency under two different control paradigms. The left-hand side shows the superheat, actuator effort, evaporator fan speed, and system COP under the same MPC controller as that used in Figure 23.33. The right-hand side shows the same data for a standard PID controller. The evaporator fan speed oscillated as shown, with a period of 20 min. In the MPC-controlled case, the superheat oscillates within the prescribed limits, with the valve only moving as necessary to respect the constraints. In the PID-controlled case, the superheat is kept within a much tighter band, as is expected. The bottom figures show that the mean COP that each control paradigm achieves is virtually the same (4.9 for MPC, 4.8 for PID). Additionally, the MPC controller requires much less motion from the EEV—a total of 14 steps as opposed to 254 steps over 2500 s of test time. Despite the relatively poor set point tracking of the MPC controller, neither system efficiency nor compressor safety is compromised, and the actuator is used much less heavily, implying a longer service life for the valve (Figure 23.35).

**FIGURE 23.35**

Comparison of superheat response for MPC- and PID-controlled EEV : (a–d) evaporator superheat, EEV actuation, fan speed, and COP using MPC control; (e–h) evaporator superheat, EEV actuation, fan speed, and COP using standard PID control

---

### 23.8 Summary

This chapter has introduced the important features of properly designed control systems for HVAC applications. Sensors, actuators, and control methods have been described. The method for determining control system characteristics either analytically or empirically has been discussed.

The following rules (ASHRAE, 2003) should be followed to ensure that the control system is as energy efficient as possible:

1. Operate HVAC equipment only when the building is occupied or when heat is needed to prevent freezing.
2. Consider the efficacy of night setback vis-à-vis building mass. Massive buildings may not benefit from night setback due to overcapacity needed for the morning pickup load.
3. Do not supply heating and cooling simultaneously. Do not supply humidification and dehumidification at the same time.
4. Reset heating and cooling air or water temperature to provide only the heating or cooling needed.
5. Use the most economical source of energy first, the most costly last.
6. Minimize the use of outdoor air during the deep heating and cooling seasons subject to ventilation requirements.
7. Consider the use of *dead-band* or *zero-energy* thermostats.
8. Establish control settings for stable operation to avoid system wear and to achieve proper comfort.

Finally, consider the use of nonlinear compensation and MPC techniques where appropriate.

24.2 Examples of Solar Stirling Power Systems .....	624
References .....	628

The efficiency of the ideal Sterling cycle is the same as that of a Carnot cycle operating between the same temperatures. The Sterling cycle was originally proposed by a Scottish minister, Reverend Robert Sterling, as an alternative to a steam engine. Sterling engines have recently received increased attention because they can utilize concentrated solar energy, which can be produced by parabolic concentrators. Since a Sterling engine is an external combustion engine, it can use any fuel or concentrated energy. Sterling engines can operate at high temperatures, typically between 600°C and 800°C, resulting in conversion efficiency of 30%–40%. Sterling engines have also recently been developed for cryogenic applications [1], and the advances in that field can be applied to solar-driven Sterling systems.

### 24.1 Thermodynamics of a Sterling Cycle

Figure 24.1 shows the thermodynamic diagram of an ideal Sterling cycle with a perfect gas as the working fluid. The gas is compressed isothermally (at constant temperature) from state 1 to 2 by means of heat rejection at the low temperature of the cycle,  $T_L$ . The gas is then heated at constant volume from state 2 to 3, followed by an isothermal expansion from state 3 to 4. During this expansion process, heat is added at the high temperature in the cycle,  $T_H$ . Finally, the gas is cooled at constant volume from  $T_H$  to  $T_L$  during the process from state 4 to 1. Figure 24.1 shows the thermodynamic diagrams of an ideal Sterling engine on pressure–volume and temperature–entropy diagrams. The cross-hatched areas in the temperature–entropy diagram during the constant-volume process between states 2 and 3 represent the heat addition to the working gas while raising its temperature from  $T_L$  to  $T_H$ . Similarly, the cross-hatched area between states 4 and 1 represents the heat rejection as the gas is cooled from  $T_H$  to  $T_L$ . Note that the heat addition from state 2 to 3 is equal

**FIGURE 24.1**

Thermodynamic diagrams of an ideal Stirling engine cycle. (a) Pressure–volume and (b) temperature–entropy. (From Goswami, Y. et al., *Principles of Solar Engineering*, 2nd edn., Taylor & Francis, Philadelphia, PA, 2000. With permission.)

to the heat rejection from state 4 to 1 and that the processes occur between the same temperature limits. In the ideal cycle, the heat rejected between 4 and 1 is stored and transferred by perfect regeneration to the gas in processes 2–3. Hence, the only external heat addition in the cycle occurs in the process between states 3 and 4, and is given by

$$Q_{3-4} = -W_{3-4} = \int_3^4 p dV = mRT_H \ln \frac{V_4}{V_3}. \quad (24.1)$$

The work input during compression from state 1 to 2 is

$$\begin{aligned} W_{1-2} &= -\int_1^2 p dV = mRT_L \ln \frac{V_1}{V_2} \\ &= -mRT_L \ln \frac{V_2}{V_1}. \end{aligned} \quad (24.2)$$

Noting that the ratio  $V_2/V_1 = V_3/V_4$ , and combining the earlier two equations, the net work output is

$$mR \ln \frac{V_3}{V_4} (T_H - T_L). \quad (24.3)$$

Therefore, the cycle efficiency

$$\eta = \frac{\text{Net work out}}{\text{Heat input}} = \frac{T_H - T_L}{T_L}. \quad (24.4)$$

This efficiency, which is equal to the Carnot cycle efficiency, is based on the assumption that regeneration is perfect, which is not possible in practice. Therefore, the cycle efficiency

would be lower than that indicated by the earlier equation. For a regeneration effectiveness  $e$  as defined later, the efficiency is given by

$$\eta = \frac{T_H - T_L}{T_H + [(1-e)/(k-1)][T_H - T_L/\ln(V_1/V_2)]}, \quad (24.5)$$

where

$e = (T_R - T_L)/(T_H - T_L)$  and  $T_R$  = regenerator temperature  
 $k = C_p/C_v$  for the gas

For perfect regeneration ( $e = 1$ ), this expression reduces to the Carnot efficiency. It is also seen from the earlier equation that regeneration is not necessary for the cycle to work because even for  $e = 0$ , the cycle efficiency is not zero.

### Example 24.1

A Stirling engine with air as the working fluid operates at a source temperature of 400°C and a sink temperature of 80°C. The compression ratio is 5.

Assuming perfect regeneration, determine the following:

1. Expansion work
2. Heat input
3. Compression work
4. Efficiency of the machine

If the regenerator temperature is 230°C, determine

5. The regenerator effectiveness
6. Efficiency of the machine
7. If the regeneration effectiveness is zero, what is the efficiency of the machine?

### Solution

1. Expansion work per unit mass of the working fluid  
 Assuming air as an ideal gas,

$$w_{34} = -\int_3^4 p dv = RT_H \ln \frac{v_4}{v_3} = (0.287)(400 - 273) \ln 5 = -310.9 \text{ kJ/kg.}$$

Minus sign shows work output.

2. Heat input per unit mass of the working fluid

$$q_{34} = w_{34} = 310.9 \text{ kJ/kg.}$$

3. Compression work per unit mass of the working fluid

$$w_{12} = -\int_1^2 p dv = RT_L \ln \frac{v_2}{v_1} = -(0.287)(80 + 273) \ln \left( \frac{1}{5} \right) = 163.1 \text{ kJ/kg.}$$

## 4. Efficiency of the machine

$$\eta = \frac{T_H - T_L}{T_H} = \frac{400 - 80}{(400 - 273)} = 0.475 = 47.5\%.$$

## 5. The regenerator effectiveness

$$e = \frac{T_R - T_L}{T_H - T_L} = \frac{230 - 80}{400 - 80} = 0.469.$$

## 6. Efficiency of the machine

$$\eta = \frac{T_H - T_L}{T_H + \frac{(1-e)(T_H - T_L)}{(k-1)\ln(v_1/v_2)}} = \frac{400 - 800}{(400 + 273) + \frac{(1-0)}{(1.4-1)} \frac{(400-80)}{\ln(5)}} = 0.341,$$

$$\eta = 34.1\%.$$

## 7. If the regeneration effectiveness is zero, the efficiency of the machine is

$$\eta = \frac{T_H - T_L}{T_H + \frac{(1-e)(T_H - T_L)}{(k-1)\ln(v_1/v_2)}} = \frac{400 - 80}{(400 + 273) + \frac{(1-0)}{(1.4-1)} \frac{(400-80)}{\ln(5)}} = 0.273,$$

$$\eta = 27.3\%.$$

## 24.2 Examples of Solar Stirling Power Systems

In order to understand how the Stirling cycle shown in [Figure 24.1](#) may operate, in practice, the simple arrangement and sequence of processes shown in [Figure 24.2](#) are helpful. In the proposed arrangement, two cylinders with pistons are connected via a porous media, which allows gas to pass through from one cylinder to the other. As the gas passes through the porous media, it exchanges heat with the media. The porous media, therefore, serves as the regenerator. In practice, this arrangement can be realized in three ways, as shown in [Figure 24.3](#), by alpha, beta, and gamma types.

The choice of a working fluid for Stirling engine depends mainly on the thermal conductivity of the gas in order to achieve high heat transfer rates. Air has traditionally been used as the working fluid. Helium has a higher ratio of specific heats ( $k$ ), which lessens the impact of imperfect regeneration.

In the alpha configuration, there are two cylinders and pistons on either side of a regenerator. Heat is supplied to one cylinder, and cooling is provided to the other. The pistons move at the same speed to provide constant-volume processes. When all the gas has moved to one cylinder, the piston of that cylinder moves with the other remaining fixed to provide expansion or compression. Compression is done in the cold cylinder and

**FIGURE 24.2**

Stirling cycle states and processes with reference to [Figure 24.1](#).

expansion in the hot cylinder. The Stirling Power Systems V-160 engine ([Figure 24.4](#)) is based on an alpha configuration.

The beta configuration has a power piston and a displacer piston, which divides the cylinder into hot and cold sections. The power piston is located on the cold side and compresses the gas when the gas is in the cold side and expands it when it is in the hot side. The original patent of Robert Stirling was based on beta configuration, as are free-piston engines.

The gamma configuration also uses a displacer and a power piston. In this case, the displacer is also the regenerator, which moves gas between the hot and cold ends. In this configuration, the power piston is in a separate cylinder.

In a piston/displacer drive, the power and displacer pistons are designed to move according to a simple harmonic motion to approximate the Stirling cycle. This is done by a crankshaft or a bouncing spring/mass second-order mechanical system [2].

**FIGURE 24.3**

Three basic types of Stirling engine arrangements. (a) Alpha type, (b) beta type, and (c) gamma type. R, regenerator; D, displacer; 1, expansion space; 2, compression space.

**FIGURE 24.4**

Stirling power systems/Solo Kleinmotoren V-160 alpha-configuration Stirling engine. (Adapted from Kistler, B.L., A user's manual for DELSOL3: A computer code for calculating the optical performance and optimal system design for solar thermal central receiver plants, Sandia National Labs, Albuquerque, NM, 1986, SAND86-80112.1.)

**FIGURE 24.5**

The McDonnell Douglas/United Stirling dish–Stirling 25 kW<sub>e</sub> module. (From Goswami, Y. et al., *Principles of Solar Engineering*, 2nd edn., Taylor & Francis, Philadelphia, PA, 2000. With permission.)

In a kinematic engine, the power piston is connected to the output shaft by a connecting rod crankshaft arrangement. Free-piston arrangement is an innovative way to realize the Stirling cycle. In this arrangement, the power piston is not connected physically to an output shaft. The piston bounces between the working gas space and a spring (usually a gas spring). The displacer is also usually free to bounce. This configuration is called the Beale free-piston Stirling engine after its inventor, William Beale [2]. Since a free-piston Stirling engine has only two moving parts, it offers the potential of simplicity, low cost, and reliability. Moreover, if the power piston is made magnetic, it can generate current in the stationary conducting coil around the engine as it moves. This is the principle of the free piston/linear alternator in which the output from the engine is electricity.

Stirling engines can provide very high efficiencies with high-concentration solar collectors. Since practical considerations limit the Stirling engines to relatively small sizes, a Stirling engine fixed at the focal point of a dual tracking parabolic dish provides an optimum match, as shown in Figure 24.5. Therefore, all of the commercial solar developments to date have been in parabolic dish–Stirling engine combination. The differences in the commercial systems have been in the construction of the dish and the type of Stirling engine. A thorough description of past and current dish–Stirling technologies is presented in Ref. [3].

## 25.1 Introduction

Electricity for lighting accounts for approximately 15% of global power consumption and 5% of worldwide greenhouse gas (GHG) emissions [1]. According to the United Nations Environment Programme's en.lighten initiative,\* replacing all inefficient grid-connected lighting globally would reduce global electricity consumption by approximately 5% and CO<sub>2</sub> emissions by 490 million tons per year [2]. Grid-connected *space* lighting accounts for 99% of total lighting energy use, with vehicle lighting (0.9%) and off-grid fuel-based lighting (0.1%) constituting the remainder [3]. Together, residential and commercial lighting constitute about three quarters of global grid-connected lighting (Figure 25.1).

Per-capita consumption of artificial light averages about 20 megalumen-hours per year globally but varies widely. North Americans consume about 100 megalumen-hours per year on average. By comparison, Chinese consume about 10, and Indians consume only 3, megalumen-hours per year [3]. Given global demographic trends, lighting efficiency improvements not only offer significant energy savings in developed countries, but more importantly, the opportunity to contain large growth in lighting energy use in less developed countries.

Figure 25.2 shows the historic efficacies of different light source technologies (solid lines). Incandescent lamps, including halogen incandescent lamps, are the lowest efficiency light source type. (Lighting efficiency, referred to as efficacy, is quantified in units of lm/W.)

**FIGURE 25.1**

Global grid-connected lighting consumption by sector in 2005. (From IEA, *Light's Labour's Lost*, International Energy Agency, Paris, France, 2006, <http://www.iea.org/publications/freepublications/publication/light2006.pdf>.)

\* The en.lighten initiative was created in 2009 as a partnership between the United Nations Environment Programme, OSRAM AG, Philips Lighting, and the National Lighting Test Centre of China, with the support of the Global Environment Facility.

**FIGURE 25.2**

Historic best-on-market lamp efficacy trends by light source and lamp type and projected trends for solid-state lighting. (From DOE, Solid-state lighting research and development: Multi-year Program Plan, U.S. Department of Energy, Energy Efficiency & Renewable Energy Building Technologies Program, Washington, DC, April 2012.)

Compact fluorescent lamps (CFLs) are the next highest with efficacies approximately four times those of incandescent lamps. Linear fluorescents have trended with an efficacy intermediate that of low and high wattage high-intensity discharge (HID) lamps. Light-emitting diodes (LEDs) are now starting to exceed the efficacy of fluorescent lamps, and expected to reach about 200 lm/W by 2020—approximately twice that of today's most efficacious conventional lighting technologies.

Up to the present, different lighting technologies have dominated different sectors. For example, in 2010 in the United States, an estimated 86% of outdoor lighting was provided by HID lamps, 72% of commercial lighting was provided by linear fluorescent lamps, and 79% of residential lighting was provided by incandescent lamps [5]. Given the large differences in efficiency of the different light sources (Figure 25.2), this has resulted in large sectoral differences in efficiency. Solid-state lighting is poised to change that equation with LED rapidly entering all sectors of the lighting market.

LEDs are expected to replace essentially all other lighting technologies in the coming decades. Navigant Research anticipates LED's global market share of replacement lamps to grow from 5% in 2013 to 63% by 2021 [6]. The U.S. Department of Energy expects LEDs to represent 70% of the U.S. residential and commercial lighting markets by 2030 (Figure 25.3). In combination with an expected doubling in LED lamp efficacy anticipated by 2020 (also shown in Figure 25.3), the total energy savings are expected to be very large. This is particularly true in the residential sector, where the dominant incumbent technology (incandescent lamps) has an efficacy of only about 15 lm/W. In addition to the trend toward LED lighting, increased use of lighting controls is expected to further reduce energy use.

Because LED lights are significantly longer lived than conventional residential and commercial lamps, global lamp sales are expected to peak and decline as a result of the LED takeover of global lighting markets. Table 25.1 compares the typical lifetimes of various lamp technologies currently on the market. Figure 25.4 shows projected revenues from technology-specific lamps sales through 2021. This implies that, not only will consumers

save money as a result of efficiency-induced electricity savings resulting from increasing use of LEDs, they will also save as a result of reduced lamps purchases.

This paper examines these lighting efficiency trends, focusing on opportunities in the residential and commercial sectors, which includes indoor and outdoor lighting associated with residential and commercial buildings. Because there is some sectoral overlap in lighting technologies, much of the technology discussion also applies to stationary source applications for industrial and roadway lighting. Section 25.2 introduces lighting concepts used throughout the remainder of the chapter. Section 25.3 discusses the different major lamp technologies by light source type, focusing on factors that affect their energy efficiency and related market trends. Section 25.4 discusses the cost-effectiveness of the different light source technologies from both the societal and consumer perspectives. Section 25.5 describes policies to stimulate energy lighting efficiency improvements. Section 25.6 presents conclusions.

## 25.2 Lighting Concepts

### 25.2.1 Principles of Light Production

Visible light is made up of electromagnetic waves whose wavelengths fall within a narrow band of the electromagnetic spectrum, between 390 and 700 nm. The perceived color of visible light corresponds to its wavelength, with violet and blue light having shorter wavelengths, while orange and red light have longer wavelengths. Light with wavelengths longer than visible light, from 700 nm up to 1 mm, is called *infrared radiation* and is generally perceived as heat. Light with wavelengths shorter than visible light, from 390 nm down to 10 nm is called *ultraviolet radiation*. On an atomic level, light emission occurs in discrete units called *photons*, which are wave packets that carry energy that is inversely proportional to their wavelength.

Common electric light sources use one of two basic physical mechanisms to produce visible light: thermal and atomic emission. The mechanism that has been used longest is *thermal emission*, which is electromagnetic radiation emitted by all objects with temperatures above absolute zero. The spectrum of thermal emission for most objects is very well approximated by the spectrum from a *blackbody*, which is a theoretical object that perfectly absorbs all incident light and emits only thermal radiation. *Blackbody radiation* has a broad spectrum, with an intensity that scales as the fourth power of the object's temperature and a peak wavelength that varies inversely as the temperature. Objects at room temperature emit most of their thermal radiation in the infrared part of the spectrum, and the visible light emitted is too faint to be readily detected. As temperature is increased, the

total power radiated increases rapidly, and the peak of the spectrum shifts toward shorter wavelengths. An object with a temperature of 5000 K will glow brightly, with the peak of its thermal spectrum at visible wavelengths, but since the thermal emission spectrum is very broad, objects with temperatures as low as 750 K emit detectable visible light even though the bulk of their emission occurs in the infrared. The visible light emitted via thermal emission is called *incandescence*.

*Atomic emission* occurs when electrons in atoms are excited to a high-energy configuration via some mechanism and then transition back to a lower-energy configuration via the emission of a photon. Because atomic electrons can only occupy a discrete set of energy levels, the light that is emitted in a particular atomic transition is monochromatic, with a well-defined wavelength that depends on the particular element and the specific energy levels involved in the transition. By mixing various elements and exciting a variety of energy-level transitions, it is possible to create light at a range of wavelengths via atomic emission. The spectral emission peaks can also be broadened by the Doppler effect induced by random motion of the atoms, for example, in a gas. Nevertheless, atomic emission generally produces light with a spectrum made up of one or a number of relatively narrow wavelength peaks (called *emission lines*) in contrast to the relatively broad, smooth spectrum of thermal emission.

Figure 25.5 shows example spectra for blackbody radiation, atomic emission, and, for reference, daylight. Solid lines show the theoretical spectrum of a blackbody at various different temperatures (from bottom to top, 3750 K, 4500 K, 5250 K, and 6000 K). As the temperature rises, the source intensity increases, and the spectral peak shifts to shorter wavelengths. The filled light gray region shows the spectrum of sunlight, whose broad, smooth shape is similar to a blackbody spectrum. The filled dark gray region shows atomic emission from a mercury vapor (MV) lamp, characterized by narrow peaks (emission lines) at characteristic wavelengths. The curves plotted are not on the same scale, except for the relative intensities of the different blackbody temperatures. (Spectral data for sunlight and MV lamp taken from McNamara [8].)

**FIGURE 25.5**

The spectra of different types of light sources at visible and neighboring infrared and ultraviolet wavelengths.

Atomic emission can take many forms, depending on the mechanism by which the electrons are excited. *Fluorescence* occurs when an atom absorbs light at a particular wavelength, which excites an electron, and then emits light at the same or a different wavelength as that electron relaxes to some lower energy level. If the electron relaxes to a higher energy than it had initially, the emitted photon will have a longer wavelength than the absorbed photon; this mechanism is commonly used to convert ultraviolet to visible light, for example, in fluorescent lamps. *Plasma discharge emission* occurs when an electric current passes through plasma (i.e., an ionized gas) in a phenomenon known as an *electric arc*. The free electrons collide with atoms in the gas and excite their electrons, which then transition to lower energy levels and emit photons. This is the primary light-generation method for fluorescent and HID lamps. *Diode emission* from a LED occurs when an electrical current is applied to a semiconductor made of two adjoining materials with different electrical properties. Excited electrons, which are free to move through the semiconducting material, are added to one material and removed from the other by the current. Those electrons that are conducted across the junction between the two materials then relax to the empty energy levels in the electron-depleted atoms, emitting photons in the process.

### 25.2.2 Design of Energy-Efficient Lighting Systems

Residential and commercial lighting systems typically are designed to provide both functional lighting and aesthetic value at the same time. The aim of energy-efficient lighting design is to provide the desired quality of light and other aesthetic properties of the lighting system with the least energy use. Design choices made for aesthetic reasons may in some cases reduce efficiency. For example, adding a diffuser to a luminaire to reduce glare will reduce luminaire efficacy. In other cases, these choices may improve efficiency. For examples, lighting controls used to avoid the delivery of undesirable excess light are aesthetically preferable and save energy.

The goal of energy-efficient lighting design is to provide only as much artificial light as is desirable at the locations where it is needed, when it is needed. The optimal system incorporates daylighting, provides proper illumination for the design application, and addresses changes in occupancy. In the future, systems may even modulate the spectral distribution throughout the day to improve human performance and well-being (see Section 25.2.3).

The key elements of efficient lighting design are (1) making maximum use of natural light, (2) using the most efficient artificial lighting technologies, (3) incorporating automated lighting controls, and (4) controlling high-illumination task lighting separately from lower-illumination ambient lighting. While energy-efficient lighting technologies and controls are addressed at length in the following, this section provides additional background on the benefits and pitfalls of daylighting. Proper daylighting design requires climate-sensitive building design to avoid potential adverse consequences. Specifically, excessive direct penetration of sunlight can result in discomfort from glare and heat loading and increase cooling energy demand, which could offset or outweigh lighting energy savings. On the other hand, because energy-efficient lights produce less heat, they can reduce cooling energy demand, which is an advantage in regions where peak electric loads are dominated by cooling. Achieving an optimal balance requires building energy modeling.

The potential to offset the need for artificial light with daylight is greatly affected by the overall architectural design of a building and the design of the interior space. Passive solar

building design, which optimizes building orientation and window placement and minimizes extreme thermal excursions using appropriately located shading devices, thermal mass, and phase change materials, can facilitate daylighting while avoiding excessive heat loading. Skylights, reflective surfaces inside of and outside of the building, and other measures can be used to bounce natural light farther into a building. Light pipes can be used to provide natural light deeper to the interior. Light pipes may even incorporate a hybrid design that includes artificial lights when natural light is insufficient. Advanced window technologies with dynamic solar control can limit heat losses in winter and avoid excessive heat loading in summer while allowing natural light to enter buildings. The newest technologies incorporate zonal controls that can block glare to building occupants while allowing unaltered light to pass where it will not cause discomfort to occupants. Smart blinds are being developed that automatically adjust to address light level, glare, and thermal loading. Interior design and furnishings that place high light-need activities near windows and that allows the maximum penetration of light from windows into the building interior, can also reduce the need for artificial light during the day.

Another environmentally promising design option that has recently emerged in the market is solar-assisted lighting—products that have integrated photovoltaic (PV) power supply into lighting systems. NexTek Power Systems pioneered this approach with efficient commercial lighting that runs directly off of the direct current (DC) generated by the PV system when PV power is available, and off of rectified alternating current (AC) power when it is not. The approach avoids DC to AC to DC power conversion losses as well as allowing for flexible lighting design. The lights run off of a 24 V bus integrated into the metal grid that supports ceiling tiles in standard commercial drop ceiling (Armstrong Ceiling's DC Flexzone system). The design allows lights to be removed and installed without an electrician and to be placed anywhere on the grid, reducing the cost and greatly enhancing the flexibility of commercial lighting design. At the opposite end of the spectrum, small solar-assisted lighting systems that include a small PV module, a battery, and LED lights (e.g., Fenix International's ReadySet Solar Kit) are now in the market. The systems were designed for developing country markets. While particularly appropriate for off-grid areas, they may also become popular in the many regions with highly unreliable grid power.

### **25.2.3 Lighting, Human Health, and the Environment**

Exposure to light, both natural and artificial, has both beneficial and adverse effects on human health that depend strongly on the wavelength of the light, the timing of exposure, and the organs exposed [9]. Exposure to the natural diurnal cycle of darkness and light promotes mental and physical health by maintaining the body's circadian rhythms [9]. Exposure to blue light in the morning triggers the production of an array of hormones that control stress and impulsive behavior, hunger, and metabolism, and promote reproductive health and alertness. Lack of circadian blue light in the morning can cause sadness, food cravings, decreased energy and libido, anxiety, and depression. The risks of cancer and infectious disease are also increased due to insufficient blue light exposure in the morning and the absence of darkness at night because of disruption of immune response pathways that destroy viruses and cancer.

In addition to being damaging to vision [10], exposure to blue light at night is particularly disruptive to well-being [11–13]. Exposure to darkness stimulates the body's production of hormones that promote sleep, reduce blood pressure, and cellular repair. Eliminating the exposure of geriatric and Alzheimer patients to blue light at night was demonstrated to

improve sleep, reduce illness and blood pressure, reduce aggression, and improve lucidity and social participation in both populations [14].

While to date, lighting design has tended to ignore the health impacts of light color, avoidance of light pollution has become a major issue. The concept is that light should hit its intended target, and it should not shine elsewhere. The BUG System, which quantifies *backlight*, *uplight*, and *glare*, is a system that quantifies undesirable stray light from outdoor lighting [15]. The system was adopted into the Illuminating Engineering Society's Model Lighting Ordinance [16].

While high-end lighting designers have begun in recent years to incorporate spectral dynamics in their lighting systems to alter the mood of spaces throughout the day, off-the-shelf technologies are now becoming available, enabling residential customers to control the hue of lighting. For example, the new Philips Hue lighting system is designed to be controlled by the Apple iPhone. The technologies are likely to become more popular with increased awareness of the impact of lighting on human health and productivity.

---

## 25.3 Lighting Technologies

The following sections discuss the technologies and changing markets of the four major lamp types: incandescent lamps, including halogen (Section 25.3.1); fluorescent lamps (Section 25.3.2), plasma lamps (Section 25.3.3), and LEDs and organic light-emitting diodes (OLEDs) (Section 25.3.4). Following that, two additional technologies are described in the context of their impact on energy efficiency: lighting controls (Section 25.3.5) and luminaires (Section 25.3.6).

### 25.3.1 Incandescent

An *incandescent lamp* produces light by passing an electric current through a conductive filament, which is heated by electrical resistance to the point of incandescence. The filament is generally housed in a glass vessel (bulb) that has been evacuated and typically filled with an inert gas. The bulb typically has a metal base that can be attached to an electrical fixture, most often via a screw-in connection.

#### 25.3.1.1 Technology

Incandescent lamps are the oldest electric lighting technology, having been invented independently by Thomas Edison in the United States and Joseph Swann in England in the late 1800s. In modern lamps, the filament is made of tungsten, although filaments of carbon, tantalum, and osmium were used in early incandescent lamps produced around the turn of the twentieth century. (Upon their introduction, tungsten filaments represented a substantial improvement in efficacy over these earlier filament materials.) Incandescent lamp filaments produce light whose spectrum is well approximated by a blackbody spectrum. Typical incandescent lamps have operating temperatures at which the overwhelming majority of the radiated power (typically 90% or more) falls in the infrared part of the spectrum, where it is sensed as radiant heat rather than visible light. This makes incandescent lamps significantly less efficacious than other lamp types. Nevertheless, incandescent lamps have remained very popular, especially in residential applications.

The continuing popularity of incandescent lamps owes partly to their familiarity but also to a wide range of desirable features. Incandescent lamps have warm color temperatures and excellent color rendering index. They are easily dimmed with no adverse effect on the lamp. Compared with other lighting technologies, incandescent lamps are inexpensive, small, lightweight, and can be used with inexpensive fixtures with no need for ballasts or other controllers. They work equally well on AC or DC power, and they have no need for high-quality power input. In a properly designed fixture, they permit excellent optical control. In addition, incandescent lamps are easy to install and maintain, produce no audible noise, create no electromagnetic interference, and contain few toxic chemicals, allowing their disposal in the general waste stream.

The two primary types of incandescent lamps are general-service and reflector lamps. General-service lamps (also known as A-lamps) are pear-shaped, common household lamps. Reflector lamps are typically conical in shape with a reflective coating applied to part of the bulb surface that has been specially contoured to control the light direction and distribution. Common types of reflector lamps include flood and spot lights, which are often used to illuminate outdoor areas, highlight indoor retail displays and artwork, and improve the optical efficiency of track lights or downlights.

*Halogen lamps* operate on the same principle as standard incandescent lamps, by heating a filament to the point of incandescence, but they are made more efficacious by the utilization of the tungsten-halogen cycle. During operation of a standard incandescent lamp, tungsten is evaporated from the filament and deposited on the interior surface of the glass envelope. This process blackens the bulb over time and causes the filament to grow thinner until it eventually fails. Operating the lamp at a higher temperature would accelerate this process. In a halogen lamp, the filament is surrounded by quartz capsule filled with a small amount of halogen gas, such as iodine or bromine. At moderate temperatures, the halogen gas binds to the tungsten that has evaporated from the filament, preventing deposition onto the quartz capsule. At the higher temperatures found in the vicinity of the filament, the tungsten-halogen bond is broken, and the tungsten is redeposited onto the filament. This tungsten-halogen cycle thus allows halogen lamps to be operated at higher temperatures without adversely affecting their lifetimes (indeed, many halogen lamps have longer lifetimes than standard incandescent lamps). The higher-temperature blackbody spectrum thus emitted by the filament has a larger overlap with the response curve of the human eye, so that more lumens are produced at a fixed power draw, resulting in a higher luminous efficacy.

Even more efficacious than the standard tungsten-halogen lamp is the *halogen infrared reflecting (HIR) lamp*. In such lamps, the halogen capsule, or the lamp reflector, is coated with an optically transparent but infrared-reflective coating, which reflects some portion of the infrared radiation back onto the filament. This increases the operating temperature of the filament without the need for additional watts of electrical power. Because the increased temperature provides more lumens at a fixed wattage, HIR lamps have a higher luminous efficacy than non-HIR halogens. HIR lamps have historically had small market share due to their high initial cost, even though they generally have lifetimes that are two to three times longer than standard halogens.

Because they are operating at higher temperature, halogen lamps produce bright white light with color temperatures slightly higher than those of standard incandescent lamps, with similarly high CRI values. In addition, they tend to have longer rated lifetimes, can be much more compact, are slightly more efficacious, and have better lumen maintenance than standard incandescent lamps. Halogen technology has historically been used heavily in reflector lamps; minimum efficiency standards have led them to capture an increasing

share of this market in the United States and elsewhere. General-service halogen lamps are also available in the market. Historically, these have seen limited use, but recent improvements in their efficacy coupled with new regulatory standards are expected to increase their adoption in the near term.

### **25.3.1.2 Changing Market**

General-service incandescent lamps have long been the workhorse of residential lighting applications, so much so that they are commonly referred to as household light bulbs. Incandescent and halogen reflector lamps have also been widely used in the residential sector, especially for outdoor lighting and directional indoor lighting. They have also seen significant use in the commercial sector in applications that require directional lighting, such as retail display.

There are now a variety of significantly more efficacious substitutes for incandescent and halogen lamp technology. The past two decades have seen a substantial portion of the market for general-service incandescent lamps shift to CFL technology. However, CFLs' unfamiliar appearance, higher price, inferior CRI, and limited capacity for dimming have limited the further growth of their market share. In recent years, LED-based lamps are entering the market intended to be direct replacements for many incandescent lamps. The directional nature of LED sources lends itself to reflector-lamp applications, and such lamps have gained a small foothold in the commercial sector. Recent advances in omnidirectional LED lamps have produced products with similar efficacy and color rendering to CFLs; these can be used as replacements for general-service incandescent lamps. Their very high prices have significantly limited their adoption to date, but as discussed in Section 25.4, LED prices have been falling rapidly. As discussed in Section 25.3.4, the color rendering and efficacy of LED lamps have simultaneously been improving, and LED lamps are expected to capture much of the current market for incandescent lamps over the coming decades [7]. As mentioned earlier, recent efficiency regulations in many markets are phasing out traditional general-service incandescent lamps; so a faster shift toward halogen, CFL, and LED technologies is expected in the general-service market.

## **25.3.2 Fluorescent**

A typical fluorescent lamp system consists of a lamp and an electrical regulating ballast. The lamp is comprised of a glass tube, two electrodes, and a lamp base. The glass tube contains low pressure MV and an inert gas, which is usually argon, and a phosphor coating on the inside of the tube, which determines the light spectrum of the fluorescent lamp and thus its CCT and CRI. The electrodes are made of tungsten wire and are coated with a mix of alkaline oxides that, when heated, emit the electrons that excite and ionize the mercury atoms inside the tube. The base holds the lamp in place and provides the electrical connection to the lamp.

### **25.3.2.1 Technology**

#### **25.3.2.1.1 Ballasts**

A fluorescent ballast provides the necessary voltage to start and maintain the arc in the lamp tube, because the electrical resistance of a plasma goes down as its temperature increases and a ballast is required to regulate the electric current through the lamp. Some ballast types are also designed to provide a specified amount of energy in the form of heat

to the lamp electrodes. This minimizes stress on the electrode coating materials and thus extends lamp lifetime. The current delivered by the ballast to the lamp determines its light output. For a particular lamp-ballast system, light output is characterized by the ballast factor, which is the lumen output of the lamp (or lamps) operated with the ballast, relative to the lumen output of the same lamp (or lamps) operated with a reference ballast. Ballasts can be integral to the lamp or external. For example, medium screw base CFLs have integral ballasts, whereas in most linear fluorescent lamps, the ballast is external to the lamp.

There are two main types of fluorescent ballasts: magnetic and electronic. Magnetic ballasts operate at the electric power system frequency, while electronic ballasts operate at higher frequency and have many advantages over magnetic ballasts. These include higher efficiency, the ability to drive multiple lamps in series or parallel, lower weight, reduced lamp flicker, and quieter operation. These characteristics, as well as regulatory measures, have led to the phase-out of most types of magnetic fluorescent ballasts.

Ballasts are usually categorized by their starting method. Typical starting methods for electronic ballasts are instant start, rapid start, and programmed start. Instant start ballasts use a high voltage to strike the arc of the lamp, without preheating of the electrodes, having a negative impact on lamp life. As a result, instant start ballasts are very energy efficient but are more appropriate for applications with less frequent switching cycles (on–off). Rapid start ballasts heat the electrodes and apply starting voltage at the same time. They use more energy compared to instant start ballasts (~2 W/lamp), but they allow more lamp switching cycles (on–off) before lamp failure. Programmed start ballasts delay the starting voltage until the electrodes are heated to an optimum temperature to minimize the impact of starting on lamp lifetime. They are most suitable for frequent starting applications, such as areas with occupancy sensors. Table 25.2 summarizes characteristics of electronic ballast starting types.

Fluorescent lamps can be dimmed with the use of dimmable ballasts. Dimmable ballasts operate by reducing the electric current through the lamp. While doing so, the ballast must maintain the electrode and starting voltages and regulate electrode heating to maintain rated lamp lifetime. The power required to maintain these functions under dimming conditions can lead to higher ballast energy use at dimmed levels compared to full output levels. However, dimming still typically reduces the overall energy consumption of the lamp-ballast system because of the reduced power consumption of the lamp.

Because fluorescent lamps cannot operate without ballasts, their energy use must account for energy losses in the ballast. Ballast energy use is characterized by two metrics: ballast efficacy factor (BEF) and ballast luminous efficiency (BLE). The BEF, also sometimes referred to as the ballast efficiency factor, is the ratio of a lamp's ballast factor to the ballast input power. BEF is a lamp-ballast performance metric, which accounts for the efficiency of the lamp-ballast system compared to other systems with the same type and number of lamps.

**TABLE 25.2**

Electronic Ballast Starting Type Characteristics

Ballast Starting Type	Start Time (s)	Lamp Switch Cycles
Instant start	<0.1	10,000–15,000
Rapid start	0.5–1.0	15,000–20,000
Programmed start	1.0–1.5	50,000

BEF requires the measurement of several (lamp-related) parameters, which can lead to inaccuracies in its measurement. To reduce measurement variation and testing burden, BLE was introduced in 2012. BLE is immaterial to the lamp and only considers ballast characteristics. It is the total lamp arc power divided by the ballast input power and multiplied by a frequency adjustment factor, which depends on the ballast operating frequency.

#### 25.3.2.1.2 Lamps

The two main categories of fluorescent lamps are linear fluorescent lamps and CFLs. Linear fluorescent lamps, or fluorescent tubes, are typically categorized based on their tube diameter. The most common types of these lamps are T12, T8, and T5 lamps (with tube diameters of 12/8, 8/8, and 5/8 of 1 in., respectively). They are usually available in lengths of 4 ft (1.2 m) lamps and 8 ft (2.4 m) lamps, although 2, 3, 5, and 6 ft lengths can also be found. CFLs have small diameter tubes (typically 1/4 of 1 in.) that are bent into two to six sections or into a spiral shape. The tube(s) are sometimes covered with a diffuser that makes the assembly look more like a general-service incandescent lamp. They have a compact size and various base types, including common household-type screw bases. This allows them to substitute for incandescent lamps in many fixtures.

The physical characteristics (length, diameter, and shape) of fluorescent lamps can influence their efficacy. Several other lamp characteristics, such as the emissive quality of the electrode coatings and the ability of the inert gas fill to improve the mobility of the mercury atoms, can also impact fluorescent lamp efficacy. Another important factor that can significantly affect efficacy, as well as color quality and lumen maintenance, is the phosphor coating. High efficacy fluorescent lamps include *triband* phosphors, which contain oxides of certain rare earth elements—lanthanum, cerium, europium, terbium, and yttrium. Rare earth oxides account for a significant portion of the manufacturing cost of fluorescent lamps. This percentage is higher in high efficacy fluorescent lamps (e.g., 800-series T8 and T5 linear fluorescent), which use 100% triband phosphor coatings, whereas lower efficacy linear fluorescents (700-series) contain only about 30% triband phosphor. Between 2010 and 2011, the price of rare earth oxides increased sharply, causing concerns about the resulting price impacts on high efficacy fluorescent lamps, but has since been reduced considerably. The future trajectory of rare earth oxide prices is highly uncertain and will depend on global supply and demand of rare earth elements.

#### 25.3.2.2 Changing Market

Linear fluorescent lighting is used predominantly in the commercial (and industrial) building sectors. In the residential sector, linear fluorescent lighting is primarily found in specific areas, such as kitchens, bathrooms, garages, and workshops. T12 lamp/ballast systems are less efficacious and more costly to operate compared to T8 and T5 lamp/ballast systems, and thus are currently being phased out of the market. CFLs have seen increased adoption in recent years for residential applications as replacements of incandescent and halogen technologies because of their decreasing first costs, higher efficacies, longer life times, and improved color quality.

Continuous performance improvements and reducing costs of LED-based technologies, in particular in LED troffer luminaires as replacements for linear fluorescents [18], and in reflector and omnidirectional LED lamps as replacements for CFLs, are causing a market shift in the fluorescent lamp market to LEDs. LEDs are projected to replace more than 60% of the linear fluorescent market and to reach 70% market penetration in residential applications by 2030 [7].

### 25.3.3 Plasma Lighting

Plasma lamps emit light via plasma discharge emission from electrically excited gases contained within an arc tube. A typical lamp design consists of a ballast, igniter, electrodes, an alumina glass arc tube filled with pressurized gases, and a lamp base. The operation of a plasma lamp is unique, as it involves a warm-up period of 2–10 min and, when power is interrupted, a restrike time of up to 10 min depending on the technology.

#### 25.3.3.1 Technology

##### 25.3.3.1.1 Ballasts

Plasma lighting requires a ballast to initiate the lamp and to regulate the current during operation, similar to fluorescent ballasts. In addition to a ballast, some plasma lamps require an igniter to initiate the necessary high voltage during start-up. As with fluorescent lighting, there are both magnetic and electronic ballast technologies and similarly, electronic ballasts offer improved lamp lifetime, lumen maintenance, ballast efficiency, higher lamp efficacy, and lower ballast losses, offering better light quality and energy savings. For more description on basic ballast function, see fluorescent Section 25.3.2.

Electronic ballast technology offers higher efficiencies for HID technologies over magnetic ballasts, nearly a 15% higher ballast efficiency for some lamp and ballast types [19]. Industry experts agree that there are limited efficacy gains remaining in HID ballast technology, that only a few percent gains are technologically feasible but may be practically infeasible to attain.

In lieu of further efficiency gains, the use of electronic ballasts allows for the implementation of lighting controls, which reduce hours of use and in turn energy consumption. Due to the nature of HID lamp technology, these control systems utilize a stepwise dimming function where discreet dimming levels are designated, instead of continuous systems, as in incandescent and fluorescent lamp systems. Some systems offering dimming capabilities near 40% of total light output, which in certain applications translates to nearly a 30% reduction in energy consumption.

##### 25.3.3.1.2 Lamps

The most common plasma lamps are mercury vapor (MV), high-pressure sodium (HPS), and metal halide (MH); these are classified as HID. Low-pressure sodium (LPS) lamps are also plasma lamps and are often grouped together with HID, since they are high lumen output technologies used in similar applications (exterior and large interior commercial and industrial spaces). LPS lamp technology is not discussed in depth, as it is an older technology that constitutes a very small fraction of commercial and residential markets.\*

MV lamps, first developed in 1901, use ionized mercury as the primary discharge element, producing a bluish light with better CRI than sodium lamps, but with relatively low efficacy. Phosphors can be used to improve the color and CRI of MV lamps' relatively blue light, but they yield relatively poor color rendering compared to other HID technologies. These lamps are now used primarily in legacy lighting designs or special applications, and are being replaced by MH lamps that have twice the efficacy and far better CRI.

HPS lamps and LPS lamps both utilize mixtures of ionized sodium and mercury gases, and this difference in pressure leads to unique light quality characteristics. LPS lamps

---

\* For example, in the United States, LPS constitutes less than half of 1% of the total lumen output of HID lamps [5].

**TABLE 25.3**

Typical Characteristics of Plasma Lamps

Lighting Type	Typical Efficacies (lm/W)	Lifetime (h)	CRI	CCT (K)	Application
LPS	60–150	12,000–18,000	–44 (very poor)	1,800 (warm)	Exterior
HPS	50–140	16,000–24,000	25 (poor)	2,100 (warm)	Exterior
MV	25–60	16,000–24,000	50 (poor to fair)	3,200–7,000 (warm to cold)	Exterior
MH	70–115	5,000–20,000	70 (fair)	3,700 (cool)	Interior/exterior
Light-emitting plasma	60–130	25,000–100,000	70–95 (good)	2,000–10,000 (warm to cold)	Interior/exterior

Sources: luxim.com; Topanga.com; [http://www.eere.energy.gov/basics/buildings/low\\_pressure\\_sodium.html](http://www.eere.energy.gov/basics/buildings/low_pressure_sodium.html); [http://www.eere.energy.gov/basics/buildings/high\\_intensity\\_discharge.html](http://www.eere.energy.gov/basics/buildings/high_intensity_discharge.html).

offer the highest efficacy, but the monochromatic condition of the light spectra reduces the visual acuity in mesopic (relatively low-light) conditions, thus reducing the effectiveness of the light in outdoor applications. HPS produces a broader light spectrum than LPS by subjecting the gas to higher pressures. This broadening of spectral emission creates a better quality light than LPS but with reduced efficacy. The characteristics of available lamps are highlighted in Table 25.3.

MH lamps are similar to MV lamps, but MH gases are added to the mercury gas in the discharge tube, yielding higher lumen output and efficacy with higher CRI. Improvements in the starting technology of MH lamps have had considerable effect on lamp quality. Innovation from probe start, which involves a third electrode to initiate the lamp, to pulse-start, which utilizes an exterior igniter, allows for higher pressures in the arc tube, which leads to a shorter start-up and restrike time, longer lamp life, lumen maintenance, better cold weather operation, and up to a 20% increase in efficacy compared to traditional MH lamps. Ceramic metal halide (CMH) lamps, utilizing a ceramic glass arc tube and the pulse starting method, have some of the highest efficacies for MH lamps.

A new HID technology, known as light-emitting plasma, uses induction starting to excite the gas vapors instead of an electrical discharge. This electrodeless induction lamp utilizes fill gases that are similar to those in MH lamps but uses a solid-state radio frequency driver to excite the gases inside the lamp. Manufacturers report long rated lifetimes of up to 100,000 h, which far exceed those of other HID technologies. Another advantage of this technology is the relatively small size of the lamp capsule, which allows for greater directionality of the light from the luminaire, leading to significantly higher luminaire efficacies than traditional HID luminaires. The induction starting technique allows for a quicker start-up time (45 s) and restrike time (2 min) than other HID lamps, which allows for easier integration of occupancy controls. Light-emitting plasma (LEP) also has dimming functionality that could allow for significant energy savings compared to other HID technologies.

### 25.3.3.2 Changing Market

While HID lamps are primarily used for exterior lighting, they are also widely used for large indoor spaces in the commercial and industrial sectors and in rare cases in the residential sector. In the United States in 2010, 24% of the installed stock of HID lamps served the commercial sector, while only 1% served the residential sector [5]. Commercial lighting applications include exterior security lighting, warehouse high bay and low bay lighting,

walkway lighting, and, more recently, retail lighting due to an influx of smaller sized CMH lamps with high CRI. Residential HID lighting consists mainly of exterior security lighting with rare specialty interior lighting utilizing CMH lamps.

Advancements in HID efficacy have been leveling off in recent years, and with the advancement of LED replacement technology (see [Figure 25.2](#)), HID market share is projected to decrease. LED replacement efficacies are projected to double from 100 lm/W to over 200 lm/W in the next 20 years ([Figure 25.2](#)), offering significant energy savings [4]. LED replacements also have the potential for spectral control, are amenable to occupancy-based controls, and are more conducive to dimming. But in applications where an intense point-source light is needed, LEDs may never replace plasma lamps. With the persistence of these high-output applications and the limitations of current LED technology, continued improvements are expected for MH lamp technology, both traditional and induction, whereas there is no expectation of the same for MV, LPS, and HPS lamps [20].

### 25.3.4 Solid-State Lighting (LED and OLED)

LEDs and OLEDs turn electricity into narrow-band light via diode emission and can produce varying wavelengths ranging from infrared through the visible spectrum to ultraviolet. LEDs consist of a semiconducting die, typically a form of silicon or germanium, a circuit board, and a lens or diffuser. In some cases, phosphors and a heat sink are also utilized depending on the application and desired light output. OLEDs consist of a wide variety of organic light-emitting compounds, electrodes (one usually being transparent), and typically a plastic or glass envelope that holds all of the components in place and acts as a lens or diffuser for the unit.

#### 25.3.4.1 Technology

There are currently three general methods for creating the white light necessary for general-service lighting from LEDs: Phosphor conversion (PC) where phosphors are used in conjunction with blue or violet LEDs to produce white light via fluorescence, color mixing (CM) where LEDs with discrete colors (red, green, blue, and sometimes amber) are mixed in an array to create white light, and hybrid where PC and CM are combined to create white light.

LED lamps utilizing PC are the most common on the market today. Typically, phosphor (or a mixture of phosphors) is deposited directly onto a blue or near-ultraviolet LED die and encapsulated into the LED package. Locating phosphors away from the LED package, known as remote phosphor conversion, allows for better light dispersion and can create larger uniform light-emitting surfaces that better accommodate current form factors of existing luminaires. Phosphor-converted LEDs can have a range of color temperatures ranging from cool to warm white light. Color rendering of PC-LEDs ranges from moderate to excellent, with CRIs ranging from 70 to greater than 90, depending on the phosphors used. Higher CRIs are achieved at the cost of efficacy. Efficacies have been demonstrated as high as 140 lm/W for cool white emitters and 110 lm/W for warm white LEDs [4]. In 2013, lamps were available in the market with efficacies ranging from 75 to 92 lm/W.

Currently, cool-colored LEDs are about 20% more efficacious than warm-colored LEDs, for both CM and PC LEDs, but the gap is decreasing and it is expected to become negligible over the next decade [18]. White light achieved by CM has the potential for higher efficacies owing to fewer conversion losses compared to PC-LED. However, the green and

sometimes amber colored LEDs used for CM currently have a lower efficiency than blue LEDs, which means less light output at a given input power compared to most other LED colors. Improvements made to the efficiency of green and amber LEDs could lead to large improvements in the efficacy of CM white LED lamps. Current mixed-color lamps on the market have efficacies around 90 lm/W. Color rendering of mixed-color lamps is good to excellent: mixed-color lamps currently exist in the market, with CRI greater than 90.

Another unique feature of CM lamps is the ability to tune the CCT of the output light. This ability can allow for color correcting as lamps age, since LEDs of different colors have different rates of lumen depreciation. It can also allow users to change the color of lamps via appropriately integrated controls.

The third approach, the hybrid method, uses PC with the addition of amber LED to fill in gaps in the PC-LED spectrum. This enables high-CRI lamps with greater efficacies. The light mixing can take place at the LED die level or in the luminaire, depending on the application.

The advantages of LEDs compared to incumbent lighting technologies include the following:

- High efficacies, resulting in lower operating costs; long lifetimes, with reported lifetime values of 30,000 h and projections of up to 50,000 h, which lowers annualized life-cycle costs
- Improved operation in low-temperature applications, since LEDs are more efficient at lower temperatures
- Dimmability, with compatible dimmers designed to work with LED drivers
- Ability to tune colors with CM technologies

Disadvantages of LEDs compared to incumbent technologies include the following:

- High first cost, although LED prices have been dropping very quickly
- Changes in color temperature over time
- Heat management issues: LED lifetimes and efficacies are greatly reduced when operating at high temperature, limiting their ability to be used in existing enclosed fixtures
- Incompatibility with incumbent dimmers: Dimmers that operate by varying the incoming line current to an LED lamp or fixture often do not work well with LED lamps
- Flicker problems with some LED lamps, especially when dimming
- High glare, due to the compact nature of LED packages, though this can be remedied by use of a diffuser

Despite the limitations of current LED technology, none of the current disadvantages appear to be technologically insurmountable. Industry is working, often with the support of governments, to address them.

OLEDs use a thin film of organic materials to emit diffuse light over a planar surface. They have been used mainly for displays in handheld electronic devices such as smart phones, but hold potential for general and niche lighting applications, in particular for diffuse lighting. The main difference between OLEDs and LEDs is form factor, the way light emission is distributed. OLEDs produce relatively diffuse light over a large area compared

to the high-intensity compact source of light given off by an LED. OLEDs can be deposited on a number of different substrates including glass, plastic, and metal. This flexibility allows for the creation of luminaires with a wide variety of shapes and sizes. However, there are few OLED luminaires currently on the market and those that are available are not cost-competitive with other lighting technologies.

Currently, OLEDs lag behind LEDs in many performance metrics; in 2012, the best reported efficacies for OLEDs were approximately 60 lm/W. Color rendering by OLEDs is good to excellent, with CRIs up to 95. However, the lifetime of an OLED is only 10,000 h and they are very sensitive to moisture and heat. Care must be taken in the manufacturing process to properly seal OLEDs or their lifetime is shortened dramatically [4,21].

#### **25.3.4.2 Changing Market**

Single colored LEDs, developed in the 1960s, were the original technology used in nongeneral lighting applications such as traffic signals, exit signs, and outdoor displays. In 1993, innovations in blue LEDs made it possible to create products that could serve general purpose lighting applications that require white light as it became possible to create a white light by CM with the newly invented blue LED. As indicated in the introduction, LEDs are poised to become the dominant lighting technology for all general lighting applications as technology improves and prices continue to drop. Manufacturers' commitments to improving incumbent technologies are waning with most of their research and development efforts shifting toward LED lighting and lighting controls. It is currently unclear the role that OLEDs will play in that market.

#### **25.3.5 Lighting Controls**

Lighting controls are used to reduce energy consumption, to enhance security, and for aesthetic design. Lighting controls systems can include motion sensors, infrared sensors, photo sensors, timers, transmitters and receivers, and computer control systems. They can range in complexity from simple on/off switches that control a single luminaire to sophisticated integrated lighting control systems that control the lighting of entire buildings or campuses of buildings.

##### **25.3.5.1 Technology**

There are three main strategies for lighting control: manual controls, sensor-based controls, and scheduled controls. Manual controls are the most simple; they allow users to control light levels either with on/off switches or dimmers to desired levels. Sensor-based controls rely on sensors to initiate changes in light levels. Scheduled controls adjust light levels according to a predetermined schedule.

Although manual controls, in the form of simple on/off switches, have been used since the inception of electric lighting, they are sometimes incorporated in more advanced lighting strategies (e.g., providing the capacity for individuals in large commercial work places to control the light in their own work space). Multiple strategies may also be included in a single luminaire: for example, stair-well lighting with multi-light-level switching controlled by occupancy sensors.

Sensor technologies fall into two main categories: occupancy sensors and photosensors. Occupancy sensors use several different strategies to determine whether a space is occupied.

**FIGURE 25.6**

Energy savings for lighting controls and lighting energy in actual installations. The symbols indicate the maximum, average, and minimum values found in the study. The vertical bars indicated one standard deviation. (From Williams, A. et al., *LEUKOS* 8(3), 161, 2012.)

Passive infrared (PIR) sensors react to moving emitters of infrared radiation at wavelengths near the peak thermal emission given off by people. Ultrasonic and microwave sensors use the Doppler effect to detect movement, by emitting ultrasonic waves and microwaves, respectively, and measuring frequency shifts in the reflected signal to detect movement. Dual technology sensors use both PIR and ultrasonic technology to detect occupancy, which reduces the false triggering events that can occur with either technology used singly.

A recent metastudy of energy savings from lighting controls [22] found that providing the capacity for manual dimming can save as much energy as more advanced lighting strategies. As shown in Figure 25.6, based on field studies of actual energy savings, personal tuning (using dimmers) saved about the same amount of lighting energy (31%, on average) compared to automated controls, including occupancy sensors (saved 24%, on average) and daylight sensors (28%, on average). While applying multiple strategies simultaneously saved somewhat more energy (38%, on average), the biggest savings are obtained by the first control installed.

### 25.3.5.2 Changing Market

The market for lighting controls is expected to grow rapidly in the coming decades. Building codes have recently begun to incorporate requirements for lighting controls as a means to reduce lighting energy use beyond the more traditional lighting power density limits.

**FIGURE 25.7**

U.S. Department of Energy projections of the total annual commercial lighting capacity and the capacity projected to be under lighting controls. (From DOE, GSFL-IRL preliminary analysis technical support document, Appendix 9A, Lighting controls, U.S. Department of Energy, 2013, <http://www.regulations.gov/#/documentDetail;D=EERE-2011-BT-STD-0006-0022>, accessed February 28, 2013.)

For example, based primarily on building code requirements now in place, the United States Department of Energy estimates that lighting controls will cover approximately 75% of U.S. commercial floorspace by 2050, up from approximately 30% in 2012, see Figure 25.7 [23].

### 25.3.6 Luminaires

A number of factors can affect lighting efficiency at the luminaire level: the choice of light source type (as described earlier), the design of luminaire optical elements (reflectors, lenses, shades, and louvers), and the use of luminaire-based controls. In addition to energy efficiency, light quality must be considered in luminaire design (e.g., the need for glare control in certain applications). While there can be trade-offs between efficiency and light quality—for example, diffusers, which control glare, also reduce efficiency—advanced lighting technologies may eliminate such trade-offs (e.g., by using an inherently diffuse and efficiency light sources, like OLEDs). Similarly, the incorporation of increasingly advanced controls may allow the customization of light levels that reduce energy use.

Various metrics have been developed to quantify luminaire efficiency, and they have become increasingly sophisticated. The simplest metric is luminaire efficiency, the ratio of light leaving the fixture to the light emitted by its light source(s), which accounts for light absorbed in the luminaire. The luminaire efficacy rating (LER) system, developed by the National Electrical Manufacturers Association (NEMA), also accounts for light absorbed in the luminaire, but the metric is quantified as the light output from the luminaire (lumens)

divided by the power input to the luminaire.\* In 2008, NEMA introduced its target efficacy rating (TER) system, which was designed to supersede LER [24]. TER, also quantified in lumens per watt, credits only light that hits its intended target surface. TER covers 22 widely used types of commercial, residential, and industrial luminaires.

Because luminaire efficacy depends on lamp efficacy, luminaire efficacy must be measured with lamps in place. If those lamps are replaced by consumers with lamps that have a different efficacy, the luminaire will no longer perform at the rated level. Luminaire design can protect against this possibility to a significant degree—a factor that is worth considering in the design of lighting efficiency policies and programs. Luminaires with integral LED lighting (also called inseparable solid-state lighting) do not have replaceable lamps, so their efficacies are known with a high degree of certainty over their lifetimes. The socket type used in the luminaire may also ensure that lamp replacement cannot result in large efficiency losses. For example, ANSI Standard ANSI/ANSI C81.62-2009, GU-24 bases are not allowed to be used for incandescent lamp technologies; therefore, the efficacies of replacement lamps will be at least at the fluorescent or LED levels.

---

## 25.4 Cost-Effectiveness of Efficient Lighting Technology

### 25.4.1 Life-Cycle Cost

While lighting provides obvious benefits to consumers, it also imposes costs to society, only some of which are borne by the consumer. While the costs of production are typically included in the price paid by the consumer, environmental and social costs are typically not included in the price. Therefore, lighting policies are increasingly incorporating, to the degree possible, total life-cycle costs.

The environmental costs of lighting depend on lamp technology. The U.S. Department of Energy has produced a three-part study of the life-cycle environmental and resource costs in the manufacturing, transport, use, and disposal of LED lighting products in relation to comparable traditional lighting technologies.† [Figure 25.8](#), from part 3 of that series [25], compares the life-cycle impacts of different CFLs and LED lamps manufactured in 2012, and those expected to be in the market by 2017, relative to those of general-service incandescent lamps. The life-cycle environmental impacts of the current generation of LEDs are approximately comparable to the impacts of CFLs, but the impacts of the next generation of LED technology are expected to be significantly smaller.

### 25.4.2 Current Cost of Ownership of Different Lamp Technologies

In contrast to policymakers, typical lighting consumers generally consider only those costs associated with the ownership of lighting: the purchase price and possibly, if relevant information is available, the costs associated with operation, maintenance, and disposal. This section compares the current cost of ownership of different general-service lighting technologies.

High-efficacy lighting technologies, (e.g., fluorescent or LED) lamps generally have longer lifetimes ([Table 25.1](#)) and higher prices than lower-efficacy (incandescent) options.

---

\* The LER system was developed by the National Electrical Manufacturers Association. The method for measuring LER was published as a series of three standards for fluorescent lighting (LE5), for commercial and residential downlights (LE5A), and for HID industrial luminaires (LE5B).

† These reports are available online at [http://www1.eere.energy.gov/buildings/ssl/tech\\_reports.html](http://www1.eere.energy.gov/buildings/ssl/tech_reports.html).

**FIGURE 25.8**

Life-cycle impacts of different general-service lamp technologies normalized to the impact of an incandescent lamp. (From Tuegne, J. et al., Life-cycle assessment of energy and environmental impacts of LED lighting products, Part 3: LED environmental testing, U.S. Department of Energy, Solid State Lighting Program, 2013, [http://apps1.eere.energy.gov/buildings/publications/pdfs/ssl/lca\\_webcast\\_03-28-2013.pdf](http://apps1.eere.energy.gov/buildings/publications/pdfs/ssl/lca_webcast_03-28-2013.pdf), accessed March 23, 2013.)

Determining the cost-effectiveness of a given technology, by balancing the higher initial price of a lamp against its energy cost savings and longer service life, can be a complex task for the consumer. Different technologies also often have different typical lumen outputs, further complicating the comparison. As a simplifying approach to determine the cost-effectiveness of a particular lighting technology, one can compare the total cost *per year* and *per unit light output* of owning and operating a particular lamp. Additional technical considerations, such as the need for a particular light distribution, CRI, or color temperature, must also be taken into account when choosing a lighting technology, but this approach can be used to compare the cost-effectiveness of a set of lighting options that have been prescreened to meet the technical needs of a particular application.

To determine the total cost of owning and operating a lamp, one first estimates the number of hours for which the lamp will be used in the course of a year. Since lamp lifetimes are typically measured in hours, this roughly determines the lamp's lifetime in years (although the calculation can be more complicated for technologies, like fluorescent lamps, whose lifetimes are shortened by short-term and intermittent use). The annual energy cost is then calculated by multiplying the lamp wattage by the annual hours of use and by the price per watt-hour of electricity. The lifetime operating cost is determined by summing the annual energy cost over the lifetime of the lamp, often multiplied by a discount factor that accounts for the reduced value of future savings compared to up-front costs (e.g., owing to financing costs). The total cost of ownership is then the sum of the price, the

**FIGURE 25.9**

Relative cost-effectiveness of different general-service lighting technologies.

lifetime operating cost, and any end-of-life disposal costs. This value can then be divided by the lamp's lifetime in years and the lamp's total light output in kilolumens to produce a value that can be used to compare the cost of different lighting technologies on an equal basis. Cost per kilolumen-year is a particularly convenient set of units, because it typically yields values in the order of \$1–\$10 to be used for comparison (Figure 25.9).

For the purposes of the figure, we have assumed 1095 annual hours of use, corresponding to 3 h/day, which is an industry-standard value for computing lamp lifetimes and is fairly typical in residential applications. As shown in the figure, linear fluorescent lamps are the most cost-effective and efficacious general-service lighting technology in 2013, yielding a significant savings in both energy and cost over incandescent technologies and a small savings compared to CFL and LED lamps. LED lamps are evolving rapidly, however, and have seen extremely rapid improvements in both cost and efficacy in recent years, as illustrated by the dotted region in the figure. They are expected over the coming decade to surpass all competing technologies in both efficacy and cost. Zero discounting of future energy savings has been assumed in this figure, since the particular choice of discount rate is highly dependent on the individual consumer. Zero disposal cost is also assumed, which is typical in most applications. The impact of discounting would be to slightly reduce the cost-effectiveness of longer-lifetime technologies relative to shorter-lifetime technologies, so that, for example, LEDs would become slightly less cost-effective relative to CFLs. For typical discount rates, however, the overall ranking of the technologies by cost-effectiveness shown in the figure would not change.

## 25.5 Policy Approaches to Improve Lighting Energy Efficiency

Many governments have implemented policies to promote the adoption of energy-efficient lighting because of the large potential for energy, economic, and environmental savings. The primary policy instruments that have been applied to lighting are the following:

- Minimum energy performance standards (MEPSs)
- Labeling and certification
- Economic and fiscal incentives
- Bulk purchasing and procurement specifications
- Building codes

The primary policy instruments are briefly reviewed in the following text. For more information on how lighting policies have been applied in different countries, see *en.lighten* [26,27] and Collaborative Labeling & Appliance Standards Program [28].

### 25.5.1 Minimum Energy Performance Standards

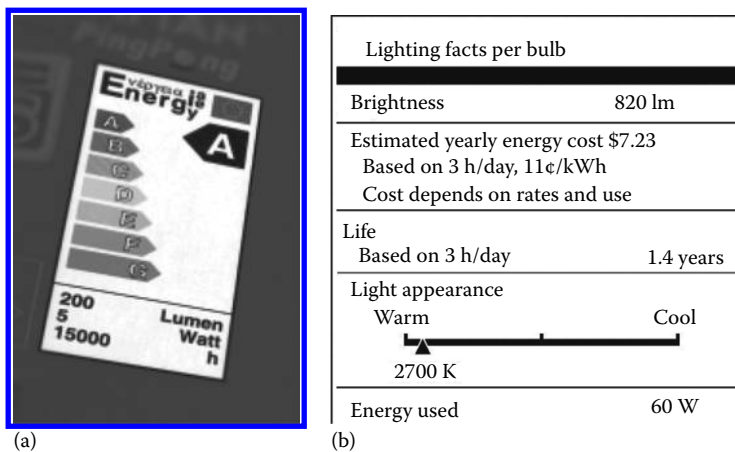

Many nations and states have set MEPSs, also known as efficacy standards, for lighting. Conventionally, such standards have been set for relatively narrow classes of lamps that prevent different light source technologies from competing against each other (e.g., 4 ft fluorescent lamps, CFLs, or general-service incandescent lamps). When standards operate on broader categories of lighting equipment, like luminaires or general-service lamps, larger gains are possible.

Recently, a significant number of nations have adopted such standards on general-service lamps that have the effect of eliminating conventional incandescent lamps from the market. The International Energy Agency's 4E program examined the early impact on the lighting market of such these standards in nine countries and the European Union [29]. IEA concluded that the standards were proving successful in Australia, Korea, and the United Kingdom, with the average efficacy of lamp sales having risen by up to 50% in 3 years, with no significant effect observable at the time in the other jurisdictions, although it is important to note that the requirements had not yet gone into force in some jurisdictions. Minimum efficacy standards for luminaires could have a similar effect, necessitating widely used luminaires to use high efficacy lamps, incorporate lighting controls, or both.

Also relatively new are standards for LED lamps, which in some cases also include quality standards [26]. For example, the International Electrotechnical Commission (IEC)'s IEC/PAS 62612 standard contains performance requirements for *self-ballasted* LED lamps (LEDs lamps with integrated drivers) for general-service lighting. Quality standards can be important to avoid the LED market being spoiled by flooding with low-quality products that undermine consumer confidence.

### 25.5.2 Labeling and Certification

Labeling and certification programs educate the public about the efficiency of lighting products and provide assurance that products perform as advertised. Information programs include mandatory and voluntary product labeling and certification.

**FIGURE 25.10**

(a) EU energy label for a high-efficiency lamp. (b) Lighting Facts label developed by the U.S. FTC, required for use on general-service lamps sold in the United States.

Certification programs like U.S. Energy Star and Brazil's Selo Procel brand efficient products with an easily recognized symbol ensuring consumer that the product is efficient [30,31]. Energy-efficiency labels, on the other hand, provide information on the efficiency of the actual efficiency of the product or how that efficiency compares with other products.

There has been much discussion about appropriate labeling protocols for lighting, because residential customers in particular are unfamiliar with the lumen metric, and have generally used wattage as an indicator of brightness. With the increased using of high efficiency, low wattage lamps, consumers need clearly conveyed information on brightness and efficiency. Comparative labels, like the European Union's EU Energy Label (Figure 25.10a), clearly indicate the performance of the labeled product relative to other products in the market. The label assigns a letter grade, with high grades corresponding to high efficacy. The consumer does not need to understand efficacy units to understand the performance of the lamps relative to other products in the market. While the Federal Trade Commission's (FTC) Light Facts label (Figure 25.10b) provides information on light output (lumens) and energy consumption (watts), to determine the efficacy, the consumer would need to know to divide the two and then would not know how this product performs relative to other products in the market. The FTC label does provide easily understood information on color temperature, however.

### 25.5.3 Economic and Fiscal Incentives

Many jurisdictions offer fiscal incentives for the adoption of high-efficiency lighting. Rebates are the most common incentive for efficient lighting, which are often implemented as part of utility demand-side management programs. In recent years, rebates have begun to focus on lighting controls as well as on efficient lamps. Low interest loans for commercial and residential lighting systems upgrades are also widely available. Tax incentives are also widely offered at the state and federal levels for lighting system upgrades. The Database of State Incentives for Renewables and Efficiency

(DSIRE) compiles information online on the panoply of economic and fiscal incentives available to residential and commercial customers in U.S. states.

#### **25.5.4 Bulk Purchasing and Procurement Specifications**

Many governments (national, regional, and municipal) use bulk purchasing and procurement specifications to stimulate production and therefore reduce the cost of energy-efficient lighting, with the intention of inducing a shift toward more efficient products in the larger on-governmental market (e.g., in Vietnam and the United States, see Energy Sector Management Assistance Program [32] and Department of Energy [33]).

#### **25.5.5 Building Codes**

Energy codes are a subset of building codes, which govern the design and construction of residential and commercial structures. Energy codes generally include lighting provisions. Code provisions are generally applicable only to new construction and to renovations that affect some threshold fraction of a building's floor area. Therefore, incorporation of code provisions into the building stock depends on construction and renovation rates, which can result in relatively slow penetration rates, depending on economic conditions. On the other hand, building codes have the advantage of being able to address lighting efficiency at the application level, accommodating different lighting needs in different spaces.

Lighting provisions in building codes may be prescriptive or performance based. The prescriptive approach stipulates minimum efficacy requirements for lighting products used in different spaces. The more flexible, performance-based approach specifies the maximum allowable lighting power density in watts/square meter (square foot) for different spaces. The lighting designer can then choose any equipment that together meets the overall requirement for the space.

Lighting controls have been increasingly incorporated in building code requirements. This includes increasing the building space required to incorporate lighting controls, incorporation of increasingly sophisticated controls, and the layering of multiple types of controls. See, for example, updates to ASHRAE/IESNA 90.1 [34,35]. In some cases, lighting controls have been used as an alternative compliance path, allowing the use of less efficient lamps. For example, the State of California's Title 24 provisions require that all permanently installed outdoor luminaires using lamps rated over 100 W either have a lamp efficacy of at least 60 lm/W or that they be controlled by a motion sensor [36].

Because all of these policy instruments described earlier rely on accurate ratings of product efficiency, a sound underlying national infrastructure of product testing, monitoring, and enforcement is needed for lighting policies to be effective.

Governments may also support product development to spur efficiency innovations. The L-Prize is creative and highly successful example, in which the U.S. Department of Energy offered a \$10 M cash prize for the development of a 90 lm/W solid-state lamp to replace the standard A19 60-W incandescent. This represented an enormous advancement in LED efficiency when the prize was announced in May 2008. The L-Prize resulted in a fierce competition, which Philips won in August 2011. But the benefits of the competition continued after the prize was won. Today there are eight products in the market that are certified by DOE's Lighting Facts program to meet or exceed the 90 lm/W requirements, with the best omnidirectional A-lamps achieving almost 100 lm/W.

---

## 25.6 Conclusions

With the advent of LED lighting, efficiency improvements can now be achieved without the degradation of light quality. Indeed, new LED lighting technologies can improve light quality by offering color-tuning capacity as well as all of the conventional standard and automated controls. Not only aesthetically pleasing, this feature could offer a potent tool to provide light that is health enhancing, by better mimicking the color dynamics of the diurnal cycle of natural light, essential for well-being.

While at this point falling prices and improved light quality alone may be enough to induce the shift to an LED lighting future, well-crafted lighting policies can continue to drive energy and environmental savings. Energy efficiency standards, coupled with quality standards, can ensure that low-efficiency and low quality LEDs are removed from the market. Bulk purchasing requirements, building codes, and luminaire standards can be used to drive the adoption of lighting controls and earlier adoption of high-efficiency lamps.

In conclusion, global lighting is poised for great increases in energy efficiency and reductions in total life-cycle costs, as a result of solid-state lighting products entering the market and policies aimed at removing low-efficiency incandescent lamps from the market. This is especially true in the residential market where new LED lamps are more than six times as efficient as the incumbent incandescent lamps. Increased use of lighting controls is also likely to significantly reduce energy use. Further opportunities to reduce environmental impacts are available by integrating PV power into lighting systems. Taken together, these opportunities suggest a bright future for lighting.

---

## Glossary

**Color rendering index (CRI)** is a measure of the degree of color shift objects undergo when illuminated by the light source as compared with the color of those same objects when illuminated by a reference source of comparable color temperature. [RP-16-10] CRI is used to quantify how well a light source renders color across the color spectrum. For color temperatures below 5000 K (which applies to most indoor lighting), the reference source is a blackbody radiator, which is most nearly approximated by an incandescent lamp. For color temperatures above 5000 K, the reference source is a standard daylight condition of the same color temperature. Therefore, effectively, this metric quantifies how closely other light source types mimic an incandescent light source or a daylight source.

**Correlated color temperature (CCT)** is the absolute temperature of a blackbody radiator, expressed in degrees Kelvin, whose chromaticity (color appearance) most nearly resembles that of the light source [adapted from RP-16-10]. In lighting design, this metric is used to describe how warm or cool a light source appears. Light with a CCT at or above 4000 K, with a greater proportion of its flux at shorter (blue-violet) wavelengths, is considered cool. Light with a CCT at or below 3000 K, with more flux at longer (red-yellow) wavelengths, is considered warm.

**Efficacy is the ratio of the lumens to the power (watts)** drawn by a lighting system. The concept may be applied to the lamp alone (lamp efficacy), to the lamp-and-ballast system (system efficacy) for fluorescent or HID systems, to the lamp-and-driver

system for LED lamps (system efficacy), or to the luminaire (luminaire efficacy). The distinction between these is which luminous flux is included and where the power input is measured.

**Lumen (lm)** is the SI unit for measuring luminous flux.

**Lumen maintenance** is the lumen output at a given time in the life of the lamp and expressed as a percentage of the initial lumen output of the light source.

**Luminaire** is a complete lighting unit consisting of the light fixture, in combination with its light source(s), any necessary ballasts or drivers, and all parts connecting the power source to the light source, including any integrated controls.

**Luminous Flux** is the rate of flow of electromagnetic radiation emitted by a light source in all directions, weighted by the spectral sensitivity of the human visual system [37].

## 26.1 Introduction

The annual electricity consumption in the U.S. residential sector in 2012 was 3.76 billion kW h/day. By the end of 2013, the total was 3.77 billion kW h/day. In 2014, the U.S. residential sector used approximately 3.73 billion kW h/day. The average annual residential electricity usage per customer in 2012 was 10,834 kW h. By the end of 2013, it was approximately 10,786 kW h and in 2014, it was 10,612 kW h (EIA short-term outlook, October 2013). That is roughly an annual cost of \$1200.00 in 2012, \$1300.00 in 2013, and \$1320.00 in 2014.

The U.S. Energy Information Administration (EIA) uses the British thermal unit (Btu) as a common energy unit to compare or add up energy consumption across the different energy sources that produce electricity. The United States uses several kinds of energy (petroleum, coal, natural gas, propane, nuclear, hydroelectric, wind, wood, biomass waste, geothermal, and solar). It is much easier to convert the various types of energy into Btus and come up with a total for electricity consumption for the various sectors and products.\*

In April, 2013, the EIA came out with a scenario for the next 30 years of electrical consumption in the residential sector indicating that the United States will be consuming more electricity. This does not mean that our products are consuming more electricity; it means that there are going to be more homes, people,<sup>†</sup> and electrical products over the next 30 years (see [Table 26.1](#)).

Reducing the energy consumption of residential appliances and space conditioning equipment depends on replacing older equipment with the much more efficient models available now and on continuing to design even more energy-efficient appliances. National energy efficiency standards for appliances have driven efficiency improvements over the last 20 years, and appliances have become significantly more efficient as a result. Further improvement of appliance efficiency represents a significant untapped technological opportunity.

\* Electricity 1 kilowatt hour (kW h) = 3412 Btu (but on average, it takes about three times the Btu of primary energy to generate the electricity [EIA]).

<sup>†</sup> U.S. population will kept increasing, see <http://www.census.gov/popclock/>.

Source: 2010 and 2011 consumption based on: U.S. Energy Information Administration (EIA), Annual Energy Review 2011, DOE/EIA-0384(2011) (Washington, DC, September 2012). 2010 and 2011 degree days based on state-level data from the National Oceanic and Atmospheric Administration's Climatic Data Center and Climate Prediction Center.

Projections: EIA, AEO2013 National Energy Modeling System run ref2013.d102312a.

Note: Totals may not equal sum of components due to independent rounding. Data for 2010 and 2011 are model results and may differ slightly from official EIA data reports. Btu = British thermal unit. -- = Not applicable.

<sup>a</sup> Does not include water heating portion of load.

<sup>b</sup> Includes televisions, set-top boxes, and video game consoles.

<sup>c</sup> Includes desktop and laptop computers, monitors, printers, speakers, networking equipment, and uninterruptible power supplies.

<sup>d</sup> Includes small electric devices, heating elements, and motors not listed above. Electric vehicles are included in the transportation sector.

<sup>e</sup> Includes such appliances as outdoor grills and mosquito traps.

<sup>f</sup> Includes wood used for primary and secondary heating in wood stoves or fireplaces as reported in the Residential Energy Consumption Survey 2005.

<sup>g</sup> Includes kerosene and coal.

<sup>h</sup> Includes all others not listed above.

<sup>i</sup> Consumption determined by using the fossil fuel equivalent of 9756 Btu/kW h.

## 26.2 Description of Major Appliances and Space Conditioning Equipment

### 26.2.1 Refrigerator-Freezers and Freezers

Refrigerators, refrigerator-freezers, and freezers keep food cold by transferring heat from the air in the appliance cabinet to the outside of the cabinet. A refrigerator is a well-insulated cabinet used to store food at 34°F (1.1°C) or above, a refrigerator-freezer is a refrigerator with an attached freezer compartment that stores food below 0°F (−17.7°C), and a standalone freezer is a refrigerated cabinet to store and freeze foods at −12°F (−24.4°C) or below. Almost all refrigerators are fueled by electricity. The refrigeration system includes an evaporator, a condenser, a metering device, and a compressor. The system uses a vapor compression cycle, in which the refrigerant changes phase (from high pressure vapor to high pressure liquid and back to low pressure vapor) while circulating in a closed loop system. The refrigerant absorbs or discharges heat as it changes phase. Although most refrigerants and insulating materials once contained chlorofluorocarbons (CFCs), all U.S. models sold after January 1, 1996, are CFC-free. Under the Montreal Protocol, in 1996, refrigerator-freezer manufacturers are using R134a (1,1,1,2-tetrafluoroethane) as the replacement for R-12 (dichlorodifluoromethane) refrigerant. R134a is also sold under other names such as: Dymel 134a, Forane 134a, Genetron 134a, HFA-134a, HFC-134a, R-134a, Suva 134a, and Norflurane.

There are over 170 million refrigerators and refrigerator-freezers currently in use today in U.S. homes with over 60 million refrigerators over 10 years old and are costing consumers billions in excessive energy costs.

### 26.2.2 Water Heaters

A water heater is an appliance that is used to heat potable water for use outside the heater upon demand. Water heaters supply water to sinks, bathtubs and showers, dishwashers, and clothes washing machines. Most water heaters in the United States are storage water heaters, which continuously maintain a tank of water at a thermostatically controlled temperature. The most common storage water heaters consist of a cylindrical steel tank that is lined with glass in order to prevent corrosion. Most hot water tanks manufactured today are insulated with polyurethane foam and wrapped in a steel jacket. Although some use oil, almost all storage water heaters are fueled by natural gas (or LPG) or electricity.

Rather than storing water at a controlled temperature, instantaneous water heaters (tankless) heat water as it is being drawn through the water heater. Both gas-fired and electric instantaneous water heaters (tankless) are available. Instantaneous water heaters are quite popular in Europe and Asia. Although they are not commonly used in the United States, their presence does seem to be increasing.

Like refrigerators, water heaters are present in almost all U.S. households. Approximately 54% of households have gas-fired water heaters, and approximately 38% have electric water heaters. Hot water use varies significantly from household to household, mostly due to differences in household size and occupant behavior.

The Department of Energy (DOE) final rule effective on April 16, 2015, mandates will require higher energy factor (EF) ratings on virtually all residential gas, electric, oil, and tankless gas water heaters. The EF is the ratio of useful energy output from the water heater to the total amount of energy delivered to the water heater. The higher the EF, the more efficient is the water heater (see [Table 26.2](#)).

**TABLE 26.2**

2015 Energy Conservation Standards for Residential Water Heaters

Product Classes Affected by Change	Rated Storage Volume/Inputs Affected by Change	New EF Requirements
Electric	$\geq 20$ and $\leq 55$ gal, $\leq 12$ kW input	$0.960 - (0.0003 \times V)$
	$> 55$ and $\leq 120$ gal, $\leq 12$ kW input	$2.057 - (0.00113 \times V)$
Gas fired	$\geq 20$ and $\leq 55$ gal, $\leq 75,000$ Btu/h	$0.675 - (0.0015 \times V)$
	$> 55$ and $\leq 100$ gal, $\leq 75,000$ Btu/h	$0.8012 - (0.00078 \times V)$
Oil fired	$\leq 50$ gal, $\leq 105,000$ Btu/h	$0.68 - (0.0019 \times V)$
Instantaneous electric <sup>a</sup>	$\leq 2$ gal, $\leq 12$ kW input	$0.93 - (0.00132 \times V)$
Instantaneous gas fired	$\leq 2$ gal, $\leq 200,000$ Btu/h	$0.82 - (0.0019 \times V)$

<sup>a</sup> No change.

### 26.2.3 Furnaces and Boilers

Furnaces and boilers are major household appliances used to provide central space heating. Both fuel-burning and electric furnaces and boilers are available. A typical gas furnace installation is composed of the following basic components: (1) a cabinet or casing; (2) heat exchangers; (3) a system for obtaining air for combustion; (4) a combustion system including burners and controls; (5) a venting system for exhausting combustion products; (6) a circulating air blower and motor; and (7) an air filter and other accessories. (Furnaces that burn oil and liquid petroleum gas (LPG) are also available, though not as common.) In an electric furnace, the casing, air filter, and blower are very similar to those used in a gas furnace. Rather than receiving heat from fuel-fired heat exchangers, however, the air in an electric furnace receives heat from electric heating elements. Controls include electric overload protection, contactor, limit switches, and a fan switch. Furnaces provide heated air through a system of ducts leading to spaces where heat is desired. In a better system, hot water or steam is piped to terminal heating units placed throughout the household. The boiler itself is typically a pressurized heat exchanger of cast iron, steel, or copper in which water is heated.

According to the U.S. Census Bureau in its report *Annual 2012 Characteristics of New Housing* report, 59% of new family homes completed in 2012 used natural or LPG gas for heating, followed by 39% that use electricity for heating, 1% that use oil, and 2% that use other forms.

### 26.2.4 Central Air Conditioning, Room Air Conditioners, and Ductless Minisplit Air Conditioners

A central air conditioning (AC) system is an appliance designed to provide cool air to an enclosed space. Typically, central AC systems consist of an indoor unit and an outdoor unit (split system). Central air conditioning (AC) units are also available in a package unit. A packaged unit air conditioning system has all of the components contained in one unit. This type of air conditioning unit can be installed on a rooftop with duct work added. A package unit air conditioner operates the same as a central unit. The outdoor condenser unit contains a compressor, condenser coil (outdoor heat exchanger coil), condenser fan, and condenser fan motor; the indoor unit consists of an evaporator coil (indoor heat exchanger coil) and a refrigerant flow control device (a capillary tube, thermostatic expansion valve, or orifice) residing either in a forced-air furnace or an air handler. Refrigerant tubing connects the two units. A central AC system provides conditioned air by drawing warm air from the living area space and blowing it through the evaporator coil; as it is passing through

the evaporator coil, the air gives up its heat content to the refrigerant. The conditioned air is then delivered back to the living area space (via a ducted system) by the blower residing in the furnace or air handler. The compressor takes the vaporized refrigerant aiming out of the evaporator and raises it to a temperature exceeding that of the outside air. The refrigerant then passes on to the condenser unit (outside coil), where the condenser coil rejects the heat from the refrigerant to the cooler outside air, and condenses. The liquid refrigerant passes through the flow control device, and its pressure and temperature are reduced. The refrigerant reenters the evaporator coil, where the refrigeration cycle is repeated.

Unlike the two-unit, central AC system, a room air conditioner is contained within one cabinet and is mounted in a window or a wall so that part of the unit is outside the building and part is within the occupied space. The two sides of the cabinet are typically separated by an insulated divider wall in order to reduce heat transfer. The components in the outdoor portion of the cabinet are the compressor, condenser coil, condenser fan, fan motor, and capillary tube. The components in the indoor portion of the cabinet are the evaporator coil and evaporator fan. The fan motor drives both the condenser and evaporator fans. A room AC provides conditioned air in the same manner described for a central AC system but without air ducts.

Like conventional central air conditioners, minisplit air conditioners use an outside compressor/condenser unit and an indoor evaporator coil/ductless air handler unit. The difference is that each room or zone to be cooled has its own ductless air handler. Each indoor ductless air handler unit is connected to the outdoor condensing unit via a conduit carrying the electrical power, refrigerant lines, and condensate lines. The primary advantage is that by providing dedicated units to each occupied space or zones, it is easier to meet the varying comfort needs of different rooms of the residence. By avoiding the use of ductwork, minisplit AC also avoid energy losses associated with central AC. Some minisplit air conditioner condensers are designed to handle up to five ductless air handlers at one time.

Approximately 89% of U.S. households had an AC system in 2009; room ACs is used in 6% of households, and 5% without AC. According to the U.S. Census Bureau in its report *Annual 2012 Characteristics of New Housing* report, 89% of new family homes completed in 2012, followed by 11% completed without AC installed.

AC manufacturers are beginning to offer HFC-410A refrigerant in AC systems as an alternative to HCFC-22 (R-22) refrigerant units. The EPA has established the phase-out of the HCFC-22 refrigerant with no production or importing beginning in 2020. However, manufacturers of AC equipment must phase out the use of HCFC-22 refrigerant in new AC equipment by January 1, 2010. In general, existing R-22 systems will probably be converted to R-407C, an alternative refrigerant; however, new AC equipment will be designed to operate on R-410A.

### 26.2.5 Heat Pumps

Unlike air conditioners, which provide only space cooling, heat pumps use the same equipment to provide both space heating and cooling. A heat pump draws heat from the outside air into a building during the heating season and removes heat from a building to the outside during the cooling season. An air source heat pump contains the same components and operates in the same way as a central AC system but is able to operate by reversing the refrigerant directional flow as well, in order to provide space heating. In providing space heat, the indoor coil acts as the condenser while the outdoor coil acts as the evaporator. When the outside air temperature drops below 2°C (35.6°F) during the heating season, the available heat content of the outside air significantly decreases; in this

case, a heat pump will utilize supplementary electric-resistance backup heat. A ground-source heat pump operates on the same principle as air-source equipment except that heat is rejected or extracted from the ground instead of the air. Since ground temperatures do not vary over the course of a day or a year as much as the ambient air temperature, more stable operating temperatures are achieved. The ground loop for a ground-source heat pump is a closed system that uses a pressurized, sealed piping system filled with a water/antifreeze mixture. The indoor mechanical equipment of a ground-source system includes a fan coil unit with an indoor coil, a compressor, and a circulation pump for the ground loop. Almost all heat pumps are powered by electricity.

Heat pumps were used in approximately 11% of U.S. households in 2001. The energy consumption of heat pumps varies according to the same user characteristics discussed earlier for AC systems. According to the U.S. Census Bureau in its report *Annual 2012 Characteristics of New Housing* report, 38% of new family homes completed in 2012 have heat pump units installed.

The EPA has established the phase-out of the HCFC-22 refrigerant for heat pumps with no production or importing beginning in 2020. However, manufacturers of heat pump equipment must phase out the use of HCFC-22 refrigerant in new heat pump equipment by January 1, 2010. In general, existing R-22 systems will probably be converted to R-407C, an alternative refrigerant; however, new heat pump equipment will be designed to operate on R-410A.

### 26.2.6 Clothes Washers

A clothes washer is an appliance that is designed to clean fabrics by using water, detergent, and mechanical agitation. The clothes are washed, rinsed, and spun within the perforated basket that is contained within a water-retaining tub. Top-loading washers move clothes up and down, and back and forth, typically about a vertical axis. Front-loading machines move clothes around a horizontal axis. Electricity is used to power an electric motor that agitates and spins the clothes, as well as a pump that is used to circulate and drain the water in the washer tub. Some washer models use a separate water heater element to heat the water used in the washer.

Approximately 84% of households had clothes washers in 2009. Most of the clothes washers sold in the United States are top-loading, vertical-axis machines. The majority of energy used for clothes washing (85%–90%) is used to heat the water. User behavior significantly affects the energy consumption of clothes washers. The user can adjust the amount of water used by the machine to the size of the load, and thereby save water and energy. Choosing to wash with cold water rather than hot water reduces energy consumption by the water heater. Similarly, rinsing with cold water rather than warm can reduce energy consumption. Energy consumption depends on how frequently the washer is used. The DOE's test procedure assumes clothes washers are used 300 times a year on average. According to the U.S. Energy Star program, if every washer purchased in the United States in 2013 earned the Energy Star rating, we would save about \$250 million in electricity, water usage, and gas every year thereafter.

### 26.2.7 Clothes Dryers

A clothes dryer is an appliance that is designed to dry fabrics by tumbling them in a cabinet like drum with forced-air circulation. The source of heated air may be powered either by electricity or natural gas. The motors that rotate the drum and drive the fan are powered by electricity. Approximately 79% of U.S. households have automatic clothes dryers and 21% do not use a clothes dryer in 2009. An automatic dryer in U.S. homes consists of 80% electric dryers, 19% natural gas dryers, and 1% propane gas (LPG) dryers.

### 26.2.8 Dishwashers

A dishwasher is an appliance that is designed to wash and dry kitchenware by using water and detergent. Typically, in North America, hot water is supplied to the dishwasher by an external water heater. In addition, an internal electric heater further raises the water temperature within the dishwasher. Electric motors pump water through spray arms impinging on the kitchenware in a series of wash and rinse cycles. An optional drying function is also enabled by electric heaters and sometimes a fan. In recent years, some dishwashers incorporate soil sensors that determine when the dishes are clean and the washing cycle can be stopped. Approximately 69% of U.S. households had dishwashers in 2011.

### 26.2.9 Cooktops and Ovens

A cooktop is a horizontal surface on which food is cooked or heated from below; a conventional oven is an insulated, cabinet like appliance in which food is surrounded by heated air. When a cooktop and an oven are combined in a single unit, the appliance is referred to as a range. Both gas and electric ranges are available. Cooktops and ovens are present in almost all households. Almost 60% of households use electric cooktops and ovens, and the remaining 40% of households use gas cooktops and ovens.

In a microwave oven, nonionizing microwaves directed into the oven cabinet cavity cause the water molecules inside the food to vibrate. Movement of the water molecules heats the food from the inside out. The fraction of households with microwave ovens has increased dramatically in recent years. Appliance manufacturers have sold over 5 million microwave ovens in 2013.

---

## 26.3 Current Production

Table 26.3 shows the number of various appliances that was shipped by manufacturers in 2012 and 2013. Shipments have been increasing for most of the major appliances and air conditioners.

---

## 26.4 Efficient Designs

State and federal standards requiring increased efficiency for residential appliances, utility programs, and labels (such as Energy Star) have improved appliance efficiency dramatically since the late 1970s (Meyers et al., 2004). For example, the annual energy consumption (according to the DOE test procedure) of a new refrigerator in 2003 was less than half the consumption in 1980. Because of the slow turnover rate of appliances, however, the older, less efficient equipment remains in use for a long time. Promising design options for further improving the efficiency of residential appliances are discussed next.

The DOE has set standards and test procedures for appliances and air conditioners and has required manufacturers to comply with their rulings. See website for further details on the appliances and air conditioners listed in this chapter at: [http://www1.eere.energy.gov/buildings/appliance\\_standards/standards\\_test\\_procedures.html](http://www1.eere.energy.gov/buildings/appliance_standards/standards_test_procedures.html).

**TABLE 26.3****Shipments of Major Appliances and Space Conditioning Equipment in the United States**

	YTD-2012	YTD-2013	%Chg
<i>Major home appliances and space conditioning equipment (thousands of units)</i>			
All major appliances	36,981.10	37,971.10	2.70
Cooking—total	9,014.60	9,166.70	1.70
Electric cooking—total	2,386.60	2,555.60	7.10
Electric ranges	1,902.70	2,009.00	5.60
Electric ovens	316.5	365.9	15.60
Surface cooking units	167.4	180.7	8.00
Gas cooking—total	1,412.80	1,521.50	7.70
Gas ranges	1,228.30	1,304.20	6.20
Gas ovens	17.1	17.7	3.70
Surface cooking units	167.5	199.5	19.20
Microwave ovens	5,215.20	5,089.70	-2.40
Home laundry—total	7,320.90	8,258.00	12.80
Automatic washers	4,104.40	4,591.90	11.90
Dryers—total	5,215.20	3,666.00	14.00
Electric	2,615.80	2,963.50	13.30
Gas	600.7	702.5	17.00
Kitchen cleanup—total	6,621.40	7,253.00	9.50
Disposers	3,419.80	3,725.00	8.90
Dishwashers—total	3,181.30	3,505.00	10.20
Built in	3,153.70	3,480.20	10.40
Portable	27.6	24.8	-10.10
Compactors	20.3	23	12.90
Food preservation—total	5,976.30	6,090.00	1.90
Refrigerators 6.5 and over	4,897.90	5,134.10	4.80
Freezers—total	1,078.50	955.9	-11.40
Chest	714.1	581.2	-18.60
Upright	364.4	374.6	2.80
Gas water heaters—total	3,186.50	3,535.50	11.00
Electric water heaters—total	3,077.30	3,330.70	8.20
Gas furnaces—total	1,787.30	2,093.90	17.20
Oil furnaces—total	25,567.00	24,593.00	-10.80
Air conditioners and heat pumps—total	5,019.00	5,540.40	10.40
Air conditioners only—total	3,526.60	3,807.50	8.00
Heat pumps only—total	1,492.30	1,732.90	16.10
Home comfort—total	8,047.90	7,206.50	-10.50
Room air conditioners	7,224.70	6,436.10	-10.90
Dehumidifiers	823.2	770.4	-6.40

Notes: Figures (in units) include shipments for the U.S. market, whether imported or domestically produced. Export shipments are not included; Industry figures are estimates derived from the best available figures supplied by a sample of AC manufacturers and are subject to revision.

### **26.4.1 Refrigerators and Freezers**

Relative to the 2001 U.S. federal efficiency standard, achieving a 15% energy use reduction for refrigerator-freezers is possible with the use of a high-efficiency compressor, high-efficiency motors for the evaporator and condenser fans, and adaptive defrost control. Models at this level of efficiency account for a modest market share in the United States. Achieving a 25% energy use reduction generally would require a reduction in load transmitted through the unit's walls and doors, which might require the use of vacuum panels.

### **26.4.2 Improved Fan Motors**

The evaporator and condenser fans of large refrigerators are powered by motors. The most common motor used for this purpose is a shaded-pole motor. Large efficiency gains are possible in refrigerators and freezers by switching to electronically commutated motors (ECMs), also known as brushless permanent-magnet motors, which typically demand less than half as much power as shaded-pole motors.

### **26.4.3 Vacuum Insulation Panels**

The use of vacuum insulation panels (VIPs) can significantly reduce heat gain in a refrigerated cabinet and thereby decrease the amount of energy necessary to maintain a refrigerator or freezer at a low temperature. When using VIP, a partial vacuum is created within the walls of the insulation panels. Because air is conductive, the amount of heat transfer from the outside air to the refrigerated cabinet is reduced as the amount of air within the panels is reduced. Evacuated panels are filled with low-conductivity powder, fiber, or aerogel in order to prevent collapse. Energy savings associated with the use of vacuum panel insulation range from 10% to 20%. Vacuum panel technology still faces issues regarding cost and reliability before it can come into widespread use in refrigeration applications (Malone and Weir, 2001).

### **26.4.4 Water Heaters**

#### **26.4.4.1 Gas-Fired Storage Water Heater**

The current models of gas-fired storage water heaters have a central flue that remains open when the water heater is not firing. This leads to large off-cycle standby losses. It should be possible to dramatically reduce off-cycle losses with relatively inexpensive technical modifications to the water heater. Energy savings derived from models with these modifications are expected to be about 25% compared to the 2004 U.S. standards.

The amount of heat extracted from the fuel used to fire a gas appliance can be increased by condensing the water vapor in the flue gases. In a condensing storage water heater, the flue is lengthened by coiling it around inside the tank. The flue exit is located near the bottom of the tank where the water is coolest. Because the flue gases are relatively cool, a plastic venting system may be used. A drain must be installed in condensing systems. Energy savings associated with the use of a gas-fired condensing water heater are approximately 40% compared to the 2004 efficiency standard. At this time, the high cost of the water heater results in a payback time that exceeds the typical lifetime of a water heater, but it is reasonable to assume that the cost could be reduced to the point that the water heater would be cost effective. In applications with heavy hot water use, such as laundromats or

hotels, they may already be cost effective. Currently, a few companies produce condensing storage water heaters for commercial markets and they are sometimes sold as combined water heater/space heating systems for residential use.

#### **26.4.4.2 Heat Pump Water Heaters**

Heat pumps used with water heaters capture heat from the surrounding air or recycle waste heat from AC systems and then transfer the heat to the water in the storage tank. In this way, less energy is used to bring the water to the desired temperature. The heat pump can be a separate unit that can be attached to a standard electric water heater. Water is circulated out of the water heater storage tank, through the heat pump, and back to the storage tank. The pump is small enough to sit on the top of a water heater but could be anywhere nearby. Alternatively, the heat pump can be directly integrated into the water heater. Research indicates that this technology uses 60%–70% less energy than conventional electric resistance water heaters. Field and lab tests have been completed for several prototypes. A few models are currently available for sale.

#### **26.4.4.3 Solar Water Heaters**

Technological improvements in the last decade have improved the quality and performance of both passive and active solar water heaters. Research indicates that, in general, solar water heaters use 60% less energy than conventional electric resistance water heaters. There are several types of solar water heaters commercially available today.

### **26.4.5 Furnaces**

#### **26.4.5.1 Condensing Furnaces**

The efficiency of a conventional gas furnace can be increased by using an additional heat exchanger to capture the heat of the flue gases before they are expelled to the outside. The secondary heat exchanger is typically located at the outlet of the circulating air blower, upstream of the primary heat exchanger. A floor drain is required for the condensate. A condensing furnace has efficiency up to 96% AFUE, well above the 80% AFUE rating of a standard noncondensing gas furnace. Condensing furnaces have been on the market since the 1980s and now constitute one-third of all gas furnace sales. They are particularly popular in colder areas of the United States, where the cost of heating is high. An early technical problem, corrosion of the secondary heat exchanger, has been resolved by the industry.

#### **26.4.5.2 Integrated Water Heaters and Furnaces**

Traditionally, water heating and space heating have required two separate appliances—a hot water heater and a furnace. Combining a water heater and a furnace into a single system can potentially provide both space heating and hot water at a lower overall cost. Integrated water and space heating is most cost effective when installed in new buildings, because gas connections are necessary for only one appliance rather than two.

Combination of space- and water-heating appliances fall into two major classes: (1) boiler/tankless-coil combination units, and (2) water-heater/fancoil combination units. A great majority of boiler/tankless-coil combination units are fired with oil, whereas most water-heater/fancoil combination units are fired with natural gas. In the latter units, the primary

design function is domestic water heating. Domestic hot water is circulated through a heating coil of an air-handling system for space heating. Usually the water heater is a tank-type gas-fired water heater, but instantaneous gas-fired water heaters can be used as well.

The efficiencies of these integrated systems are determined largely by the hot water heating component of the system. Compared to a system using a standard water heater or boiler, an integrated system using a condensing water heater or condensing boiler can reduce energy consumption by as much as 25%.

#### **26.4.6 Central Air Conditioning, Room Air Conditioners, and Ductless Minisplit Air Conditioners**

##### **26.4.6.1 Electric Variable-Speed Air Conditioning**

Variable-speed central air conditioners use ECMs, which are more efficient than the induction motors used in a single-speed system. In addition, the speed of the ECM can be varied to match system capacity more precisely to a building load. Cycling losses, which are associated with a system that is continually turned off and on in order to meet building load conditions, are thus reduced. Unlike induction motors, ECMs retain their efficiency at low speeds; consequently, energy use is also reduced at low-load conditions. A variable-speed AC system uses approximately 40% less energy than a standard single-speed AC system. Although these AC systems are now available from major manufacturers, they account for a small fraction of sales.

##### **26.4.6.2 Electric Two-Speed Air Conditioning**

Two-speed induction motors are not as efficient as variable-speed ECMs, but they are less expensive. Like variable-speed air conditioners, two-speed air conditioners reduce cycling losses. When two-speed induction motors are used to drive compressor and fans, the system can operate at two distinct capacities. Cycling losses are reduced, because the air conditioner can operate at a low speed to meet low building loads. In some models, two-speed compressors are coupled with variable-speed indoor blowers to improve system efficiency further. A two-speed AC system reduces energy consumption by approximately one-third. Although these AC systems are available from several major manufacturers, they account for a small fraction of sales.

##### **26.4.6.3 Room Air Conditioners**

The most efficient room air conditioners have relatively large evaporator and condenser heat-exchanger coils, high-efficiency rotary compressors, and permanent split-capacitor fan motors. Compared to standard room ACs, highly efficient room ACs reduce energy consumption by approximately 25%. Such room ACs are available from several manufacturers. Units with Energy Star designation, which must exceed federal minimum efficiency standards by 10%, accounted for 35% of sales in 2004.

##### **26.4.6.4 Ductless Minisplit Air Conditioners**

Ductless minisplit air conditioners are available in numerous mix-and-match capacities and configurations. This type of AC system does not require bulky ductwork or complicated installation or expensive modifications to be installed in a home or office. Multiple

indoor units (zones) with varying capacities can be connected to one condenser unit. These units are available in heat and/or cool. These high-efficiency air conditioners can save up to 20% energy usage.

### **26.4.7 Heat Pumps**

#### ***26.4.7.1 Variable-Speed and Two-Speed Heat Pumps***

Like central air conditioners, heat pumps can be made more efficient by the use of two-speed and variable-speed motors (see the earlier discussion of efficient central air conditioners). Both two-speed and variable speed air-source heat pumps are available; variable-speed ground-source heat pumps are not commercially available at this time. Compared to standard models, two-speed air-source heat pumps reduce energy consumption by approximately 27%, variable-speed air-source heat pumps reduce energy consumption by 35%, and two-speed ground-source heat pumps reduce energy consumption by 46%. Variable-speed and two-speed air-source heat pumps are made by the same companies that make variable speed and two-speed AC systems. Several manufacturers produce efficient air-source and two-speed ground-source heat pumps, but they account for a small fraction of all heat pump sales.

#### ***26.4.7.2 Gas-Fired Heat Pumps***

Currently, all residential heat pumps are electric, but researchers have been developing gas heat pumps. The Gas Research Institute (GRI) and a private corporation jointly developed a natural gas, engine-driven, variable-speed heat pump in which the compressor is driven by an internal combustion spark-ignition engine and heat is recovered in the space-heating mode. This engine-driven heat pump was put on the market in 1994, but was withdrawn in the late 1990s due to lack of a maintenance infrastructure. In addition, the DOE has been funding the development of a gas-fired ammonia-water absorption-cycle heat pump. Gas-driven heat pumps have the potential to reduce heat pump energy consumption by approximately 35%–45%.

### **26.4.8 Distribution Systems**

When assessing the efficiency of a space conditioning system, it is important to consider the efficiency of the distribution system as well as the appliance. It is not uncommon for air ducts to have distribution losses of 20%–40% due to conduction as well as leakage. Better insulation as well as more careful duct sealing can reduce these losses. In general, the most effective strategy for reducing distribution losses is to include the distribution system in the conditioned space so that any losses due to conduction or air leakage go directly into the space to be conditioned. This requires careful attention by the architect in the design of new buildings and is typically expensive as a retrofit measure.

### **26.4.9 Clothes Washers**

#### ***26.4.9.1 Horizontal-Axis Washers***

Although horizontal-axis clothes washers dominate the European market, the vast majority of clothes washers sold in the United States are top-loading, vertical-axis machines. However, this is expected to change by 2007 when more stringent minimum efficiency

regulations on clothes washers will take effect. Horizontal-axis washers, in which the tub spins around a horizontal axis, use much less water than their vertical-axis counterparts, and less hot water is therefore required from water heaters. As mentioned earlier, the majority of energy used for clothes washing is used for heating water, so a significant amount of energy can be saved by using horizontal-axis washers. Research has indicated that horizontal-axis washers are more than twice as efficient as vertical-axis washers of comparable size (U.S. Department of Energy, 2000).

#### **26.4.9.2 High-Spin-Speed Washers**

Clothes washers can be designed so that less energy is required to dry clothes after they have been washed. Extracting water from clothes mechanically in a clothes washer uses approximately 70 times less energy than extracting the water with thermal energy in electric clothes dryer. Thus, by increasing the speed of a washer's spin cycle, one can reduce the energy required to dry clothes.

Because gas clothes dryers require so much less energy than electric dryers, based on energy consumption including that consumed at the electric power station, energy savings are much more significant when a high-spin-speed washer is used with an electric dryer. In a vertical-axis clothes washer, an increase in spin speed from 550 to 850 rpm reduces moisture retention from 65% to 41%. In an electric dryer, this reduces the energy consumption by more than 40%. In a horizontal-axis washer, an increase in spin speed from 550 to 750 rpm reduces moisture retention from 65% to 47%; in an electric dryer, energy consumption is reduced by more than 30%. High-spin-speed washers have been common on European horizontal axis machines for some time, and are becoming more common in the United States.

### **26.4.10 Clothes Dryers**

#### **26.4.10.1 Microwave Dryers**

In conventional clothes dryers, hot air passes over wet clothes and vaporizes the surface water. During the later stages of drying, the surface dries out and heat from the hot air must be transferred to the interior, where the remaining moisture resides. In contrast, in microwave drying, water molecules in the interior of a fabric absorb electromagnetic energy at microwave wavelengths, thereby heating the water and allowing it to vaporize. Several U.S. appliance manufacturers have experimented with microwave clothes dryers, and a few small companies have built demonstration machines. Issues of arcing on metal objects and possible fire within the dryer would need to be resolved before microwave clothes dryers are likely to be sold.

#### **26.4.10.2 Heat Pump Dryers**

A heat pump dryer is essentially clothes dryer and an air conditioner packaged as one appliance. In a heat pump dryer, exhaust heat energy is recovered by recirculating all the exhaust air back to the dryer; the moisture in the recycled air is removed by a refrigeration–dehumidification system. A drain is required to remove the condensate; because washers and dryers are usually located side by side, a drain is generally easily accessible. Heat pump dryers can be 50%–60% more efficient than conventional electric dryers. Introduced in Europe in 1999, heat pump dryers are available both in the United States and Europe.

## 26.5 Cost Effectiveness of Energy-Efficient Designs

The cost effectiveness of energy-efficient designs for major appliances and space conditioning equipment depends on consumer energy prices and also on per-unit costs when new technologies are manufactured on a large scale. Therefore, the cost effectiveness of such designs varies.

A U.S. study, conducted in 2004 for the National Commission on Energy Policy (NCEP), reviewed the literature on energy-efficient designs for major appliances and space conditioning equipment and estimated their costs and energy savings relative to baseline designs (Rosenquist et al., 2004). For a number of products, it determined the efficiency level that provides users with the lowest life-cycle cost over the appliance lifetime. Table 26.4 lists the selected efficiency levels (expressed in terms of annual energy consumption in some cases), along with their associated cost of conserved energy (CCE) for consumers. The CCE in terms of \$/kW h or MBtu (gas) is an expression of the extra first cost incurred to save a unit of energy. Calculation of CCE requires application of a present worth factor (PWF) to spread the initial incremental cost over the lifetime of the equipment. The PWF uses a discount rate to effectively amortize costs over time. The CCEs for electric appliances in Table 26.4 are all below the average U.S. residential electricity price.

## 26.6 Conclusion

Residential appliances consume significant amounts of electricity and natural gas. This chapter described the basic engineering principles of the major appliances and space conditioning equipment as well as promising energy-efficient designs.

Significant potential energy savings are possible beyond the models typically sold in the marketplace today. Among the various end-uses, energy savings range from 10% to 50%. Many of these efficient appliances appear to be cost effective at currently projected

**TABLE 26.4**

Cost Effectiveness of Efficient Designs for Selected Appliances and Space Conditioning Equipment

Product	Baseline Technology	Efficient Technology	CCE <sup>a</sup>
Refrigerator	484 kW h/year	426 kW h/year	4.9 cents/kW h
Room air conditioner	9.85 EER	10.11 EER	5.2 cents/kW h
Electric water heater	92 EF	Heat pump	3.9 cents/kW h
Clothes washer <sup>b</sup>	3.23 kW h/cycle	Horizontal axis and high spin speed (1.87 kW h/cycle)	5.0 cents/kW h
Gas furnace <sup>c</sup>	80% AFUE	Condensing furnace (90% AFUE)	\$9.30/MBtu

<sup>a</sup> The CCE may be compared to expected residential energy prices. In the United States, long-term forecasts (as of 2005) place average prices in the range of 8.5–9.0 cents/kW h for electricity and \$7.7–\$8.4/MBtu for natural gas.

<sup>b</sup> Includes the energy for water heating and drying associated with clothes washing. Refers to electric water heater and dryer. Baseline refers to the 1994 DOE standard level. Additional consumer benefits derive from reduction in water usage.

<sup>c</sup> The CCE value is a U.S. national average. In cold climates, the amount of saved energy is higher, so the CCE is lower by a third or more.

manufacturing costs, with simple payback times that are shorter than the typical appliance lifetimes of 10–20 years. If costs of efficiency improvements decrease, or if future energy prices increase, more of the potential energy savings that are already technically possible will become economically attractive. In addition, future research is likely to identify additional technological opportunities to save energy.

### 27.1 Heat Pump Concept

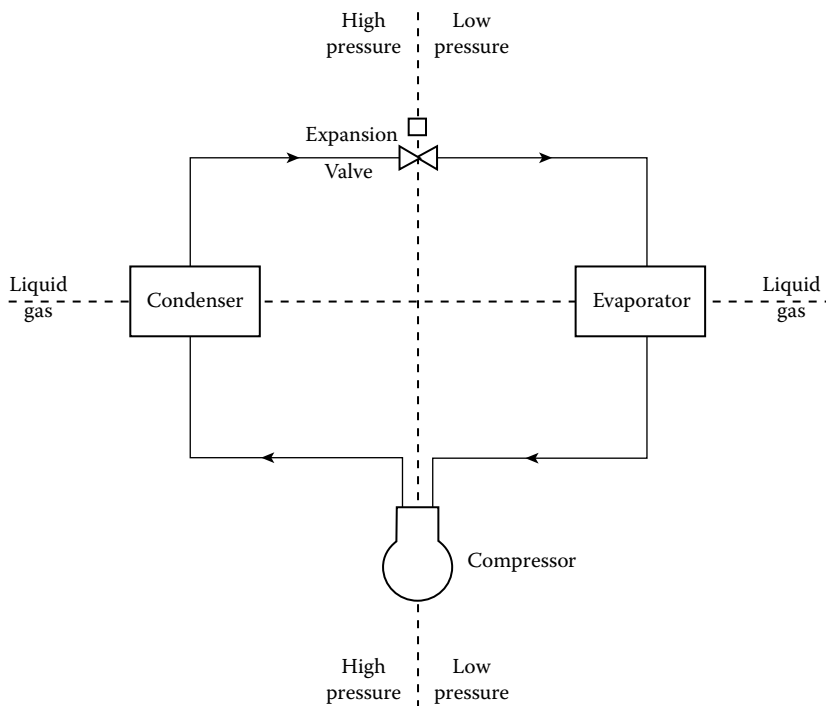

*Heat pumps are reverse cycle building heating/cooling units or systems that can extract heat from a building and reject that heat to the environment, providing cooling for a building, and can switch from providing cooling to providing heating by extracting heat from the environment and rejecting that heat into a building.* This heat transfer cycle can be accomplished using a vapor-compression refrigeration cycle or an absorption refrigeration cycle; though by far, vapor-compression systems are more widely used (see Section 27.4 for more discussion of absorption cycle systems).

All refrigeration cycles hinge on one common physical characteristic: if a chemical compound (which we can call a *refrigerant*) changes phase from a liquid to a gas, a process called *evaporation*, the compound must absorb heat to do so. Likewise, if refrigerant changes phase back from a gas to a liquid, the process of *condensation*, the absorbed heat must be rejected. Thus, all refrigeration cycles depend on circulating a refrigerant between a heat *source* (from which heat is removed, thus producing cooling) and heat *sink* (somewhere to which the collected heat can be rejected).

The *vapor-compression refrigeration cycle*, wherein a chemical substance alternately changes from liquid to gas and from gas to liquid, actually consists of four distinct steps:

1. *Compression*: Low-pressure, low-temperature refrigerant gas is compressed, thus raising its pressure by expending mechanical energy. There is a corresponding increase in temperature along with the increased pressure.
2. *Condensation*: The high-pressure, high-temperature gas is cooled by air or water that serves as a *heat sink* and condenses into liquid form.
3. *Expansion*: The high-pressure, high-temperature liquid flows through an orifice in the expansion valve, thus reducing both liquid pressure and temperature.
4. *Evaporation*: The low-pressure, low-temperature liquid absorbs heat from an air or water that serves as a *heat source* and evaporates as a gas or vapor. The low-pressure, low-temperature vapor flows to the compressor and the process repeats.

As shown in Figure 27.1, the vapor-compression refrigeration system consists of four components that perform these four steps. The *compressor* raises the pressure of the initially low-pressure refrigerant gas. The *condenser* is a heat exchanger that cools the high-pressure gas so that it changes phase to liquid. The *expansion valve* (or other pressure-reducing device) controls the pressure ratio, and thus flow rate, between the high- and low-pressure regions of the system. The *evaporator* is a heat exchanger that heats the low-pressure liquid, causing it to change phase from liquid to vapor.

**FIGURE 27.1**  
Schematic of basic vapor-compression refrigeration cycle.

For any heat pump utilizing the vapor-compression refrigeration cycle, there is a fifth element required: a *reversing valve*. This allows the condenser and evaporator heat exchangers to switch roles as the system switches from providing cooling to providing heating and vice versa by reversing the direction of refrigerant flow between these two components.

The amount of energy consumed by the compressor is dictated by the *lift* or pressure increase that the compressor must provide to raise the pressure/temperature of the low-pressure, low-temperature vapor that enters to the high-pressure, high-temperature vapor that leaves. On the low-pressure, low-temperature side of the system, refrigerant conditions depend on the temperature needed to provide required sensible cooling and dehumidification (typically about 45°F [7°C]), while the high-pressure/hot side refrigerant must be at conditions that allow it to condense at ambient temperatures of 105°F–125°F (51°C–65°C). If condensing temperatures are lowered to the heat sink's temperature condition, then the required lift is decreased and required energy input to the compressor also decreases.

The *type* of heat pump is typically defined by the environmental component that is used as a heat *source*, from which heat is extracted when providing heating, and heat *sink*, to which heat is rejected when providing cooling. The heat source/sink may be atmospheric air, directly or indirectly; the ground; or large water sources, such as lakes, rivers, or oceans. Subtypes of heat pumps are also sometimes defined on the basis of heat transfer media utilized: air, refrigerant, or water.

Vapor-compression cycle heat pumps have been available since the 1950s and factory-built heat pump units are widely used in residential and light commercial applications in mild climate regions, mostly in the South. However, since the early 2000s, the energy efficiency of these units, both air source and water source, has been improved dramatically:

*Variable air volume supply air:* Variable indoor airflow provided by the use of *electronically commutated motors* (ECMs). ECMs are DC motors that function using a built-in inverter and a magnet rotor and as a result are able to achieve greater efficiency in airflow systems than conventional *permanent split capacitor* (PSC) motors used in the past. Initially, silicon rectifier controllers were added to PSC motors to provide variable speed control. But, as PSC motor speed was reduced, efficiency suffered, falling from 65%–70% to as low as 12%. ECMs, on the other hand, maintain a high level (65%–75%) of efficiency over almost its full speed range. Additionally, unlike PSC motors, ECMs are not prone to overheating and do not require additional measures to offset the generation of heat.

By varying the indoor airflow rate in response to the imposed cooling and heating loads, indoor fan energy consumption is reduced significantly since no heat pump system is required to operate at peak capacity more than a few hours each year. Additionally, when providing cooling, variable airflow results in much better humidity control than provided by older, single-speed systems, a real boon for installations in the South.

*Variable speed compressor(s):* Variable compressor speed/load control provides a better match between the imposed load and the compressor capacity. Older, single-speed compressors cycled on and off as the imposed cooling/heating load was reduced, resulting in thermal losses at the beginning and end of each run cycle. The next level of improvement was to provide two-speed compressors and, for the last 10 years or so, fully variable speed compressors. Some very high-efficiency systems even use multiple variable speed compressor configurations in which one compressor is used during normal *part load* operation and the second is used only during *peak load* conditions.

*Variable heat sink/source medium flow:* For both air-source and water-source heat pumps, variable sink/source flow is being applied to reduce energy consumption required for air or water transport.

*Demand defrost control:* For air-source heat pumps, demand defrost control is incorporated to minimize energy losses associated with the buildup of frost or ice on the outdoor heat exchanger when the unit is providing heating.

And vapor-compression cycle heat pumps now typically utilize R-410A or R-134a refrigerant in lieu of the older R-22 refrigerant that is no longer available, significantly reducing the potential for atmospheric ozone depletion and warming in the event of a refrigerant leak. The refrigerant change has resulted in the heat transfer area of both indoor and outdoor heat exchanges being increased, improving both cooling/heating performance and energy consumption even further.

---

## 27.2 Air-Source Heat Pumps

*Air-source* heat pumps utilize atmospheric (outdoor) air as their ultimate heat source/sink, either extracting heat from outdoor air to provide heating or rejecting excess heat into it when cooling. Thus, the performance and seasonal efficiency of these heat pumps is significantly impacted by outdoor air temperature.

### 27.2.1 Premium Efficiency Air-Source Heat Pumps

Standard 90.1-2010, promulgated by the American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc. (ASHRAE), forms the basis of most current energy conservation building codes in the United States. For air-source heat pumps, this standard defines efficiency on the basis of specific required minimum performance measurements:

For cooling by units rated with a cooling output of less than 65,000 Btu/h (19 kW), *seasonal energy efficiency ratio* (SEER) is defined as the total cooling output of the heat pump during its normal cooling usage period (in Btu) divided by the total electric energy input during that same period (in watt hours).

For cooling by units rated with a cooling output of 65,000 Btu/h (19 kW) or greater, *energy efficiency ratio* (EER) is defined as the ratio of net cooling capacity (in Btu/h) to the total rate of electrical input (in watts) under designated operating conditions.

For heating by units rated with a cooling output of less than 65,000 Btu/h (19 kW), *heating seasonal performance factor* (HSPF) is defined as the total heating output of the heat pump during its normal heating usage period (in Btu) divided by the total electric energy input during that same period (in watt hours).

For heating by units rated with a cooling output of 65,000 Btu/h (19 kW) or greater, heating efficiency is defined in terms of *coefficient of performance* (COP). COP is a dimensionless value defined as the net heating capacity of the heat pump (in Btu/h [kW]) divided by the energy input (in Btu/h [kW]) under designated operating conditions.

ASHRAE has established current minimum performance requirements for packaged (all components in one outdoor enclosure) and split system (separate indoor and outdoor components) air-source heat pumps at SEER = 13.0 and HSPF = 7.7 for heat pumps rated with a cooling output of less than 65,000 Btu/h (19 kW). All air-source heat pumps with a cooling output of less than 65,000 Btu/h (19 kW) available from larger equipment manufacturers will meet or exceed the minimum ASHRAE performance standards. Additionally, most manufacturers offer *high*-efficiency units that have SEER = 15–16 and HSPE = 8–9 and some offer *premium* efficiency units that have SEER = 19–20 and HSPE = 9–10, which comply generally with the EPA's Energy Star requirements.

For larger-capacity air-source heat pump units, the following table summarizes ASHRAE's current minimum requirements:

System Cooling Capacity (Btu/h)	Minimum Cooling	Minimum Heating
	Performance (EER)	Performance (COP)
65,000–134,999 (19–39 kW)	11.0	3.3 at 47°F (9°C)/2.25 at 17°F (–8°C)
135,000–239,999 (40–70 kW)	10.6	3.2 at 47°F (9°C)/2.05 at 17°F (–8°C)
≥240,000 (≥70 kW)	9.5	

Again, though, manufacturers typically offer larger-capacity premium efficiency equipment with EER = 12–12.5 and COP (at 47°F [9°C]) = 3.5–4.5.

An additional important part of achieving high-efficiency air-source heat pump energy performance is to select each heat pump capacity as close as possible to the anticipated peak load. Since most heat pumps are installed in mild climate areas where cooling is more of a consideration than heating, units are typically selected on the basis of the peak imposed cooling load in order to minimize oversizing and loss of cooling efficiency. For example, a residence or commercial area may require 40,800 Btu/h (12 kW) or 3.4 tons of cooling. Because heat pump units are manufactured in specific capacity ranges, typically 2–6 tons at 1 ton increments, 7-1/2 tons, and 10 tons, contractors would normally recommend installation of a 4.0 tons heat pump for this example.

But the more efficient and less costly approach would be to install a 3.0 tons heat pump. Doing so would result in better match between imposed load and available capacity during part load operating periods, reducing energy consumption. The shortfall in capacity at peak load may result in indoor temperatures rising 1°F–2°F (1°C) above cooling set point temperature, but since the peak cooling period occurs for only a few hours each year, the negative comfort impact is minimal.

For applications located where heating requirements are more significant, sizing the heat pump unit on the basis of heating need rather than cooling need may result in improved heat pump performance and improved energy efficiency. While this selection may result in some oversizing relative to cooling and a small loss in cooling efficiency, the larger system will be able to provide compressor-based heating for longer periods, reducing the amount of low-efficiency supplement heating required, saving energy, and reducing operating costs.

Careful review of imposed heating and cooling loads is required to select an air-source heat pump unit and maximize energy efficiency. It is important that consumers and designers evaluate alternative unit selections and make the final decision on the basis of the lowest life-cycle cost, considering both first cost and anticipated energy costs of the anticipated life of the unit, typically 15 years.

### 27.2.2 Cold Climate Air-Source Heat Pumps

For all air-source heat pumps, and based on system thermodynamics, as the outdoor air temperature falls, the heat pump is able to extract less and less heat from the environment, while requiring more and more energy input to the compressor. Ultimately, the heat pump will be unable to extract the amount of heat needed to offset building losses and additional *supplemental* heating will be required. Typically, the supplemental heating capacity is provided by electric resistance heating coils that, by themselves, have a COP = 0.98. When the outdoor air is too cold for the refrigerant to extract any heat from it, there is no need to operate the compressor at all and all of the heating is done by the supplemental heater, at low efficiency and high expense.

However, since the 1990s, research to develop an air-source heat pump that would work in colder climates has been underway. One manufacturer now offers a cold-climate heat pump that features a two-speed, two-cylinder compressor for efficient operation, a backup booster compressor that allows the system to operate efficiently down to 15°F (−9°C), and a plate heat exchanger called an *economizer* that further extends the performance of the heat pump to well below 0°F (−18°C).

### 27.2.3 Dual Fuel Air-Source Heat Pumps

An alternative to the use of electric resistance supplemental heating, the dual fuel heat pump, has been in use since about 1980. This type of heat pump utilizes, today, a high-efficiency condensing furnace firing natural gas or LPG (propane) to provide heating when fossil fuel firing is more cost-effective than operating the unit compressor(s) and consuming electricity.

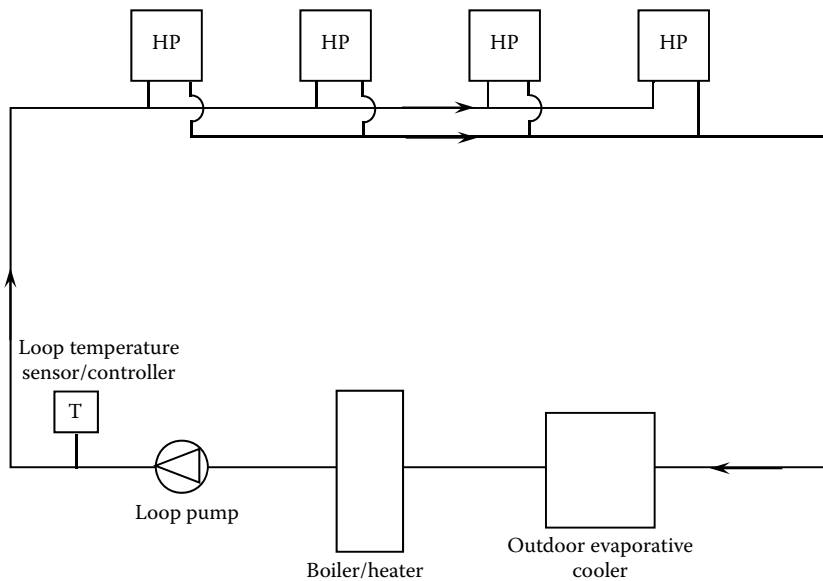

While the COP of a condensing furnace is essentially the same as for electric resistance heating, the much lower cost of natural gas or LPG relative to cost of electricity can result in much more economical heating. For example, with a typical residential electricity cost of \$0.12/kWh, the cost of electric resistance heating will be \$34 per 1,000,000 Btu (\$0.116/kW). In December 2014, residential natural gas sold for \$9.98 (U.S. average) per 1,000,000 Btu (\$0.034/kW). Therefore, the heat pump system must maintain a minimum heating COP of 3.41, well above the ASHRAE minimum, to provide heating at a cost that is equal to or less than the cost of fossil fuel firing. Typically, the *tipping* point for switching from the heat pump's compressor-based heating cycle to fossil fuel-fired heating is when the outdoor temperature falls below about 30°F (−1°C).

---

## 27.3 Water-Source Heat Pumps

Air-source heat pumps units cannot easily be applied to larger, particularly multistoried, buildings that require a large number of independently controlled thermal zones. Larger apartment buildings, hotels, schools, office buildings, etc. simply will not have the outdoor space available for a large number of independent air-source heat pumps.

The alternative, then, is to go to water-source heat pumps. Typically, a water-source heat pump system consists of one or more individual single zone, water-cooled packaged units with a supply fan, indoor air coil, compressor, and water-to-refrigerant heat exchanger, connected to a common water supply system that acts as the heat source/sink for each individual heat pump unit.

**FIGURE 27.2**  
Schematic of basic closed-circuit water-source heat pump system.

### 27.3.1 Closed-Circuit Water-Source Heat Pump Systems

The most common, and very efficient, approach to using water-source heat pumps is to utilize a closed-circuit water heat exchanger as illustrated by Figure 27.2.

In this configuration, each packaged water-source heat pump refrigerant system reverses the direction of refrigerant flow from summer to winter with the following results: during summer, heat is removed from the space via the air coil (evaporator) and rejected to the central circulating water heat exchanger via the water-to-refrigerant heat exchanger (condenser). Excess heat rejected to this heat exchanger is, in turn, rejected to the outdoors through a closed-circuit evaporative cooler in order to maintain the heat exchanger temperature at or below 85°F (29°C).

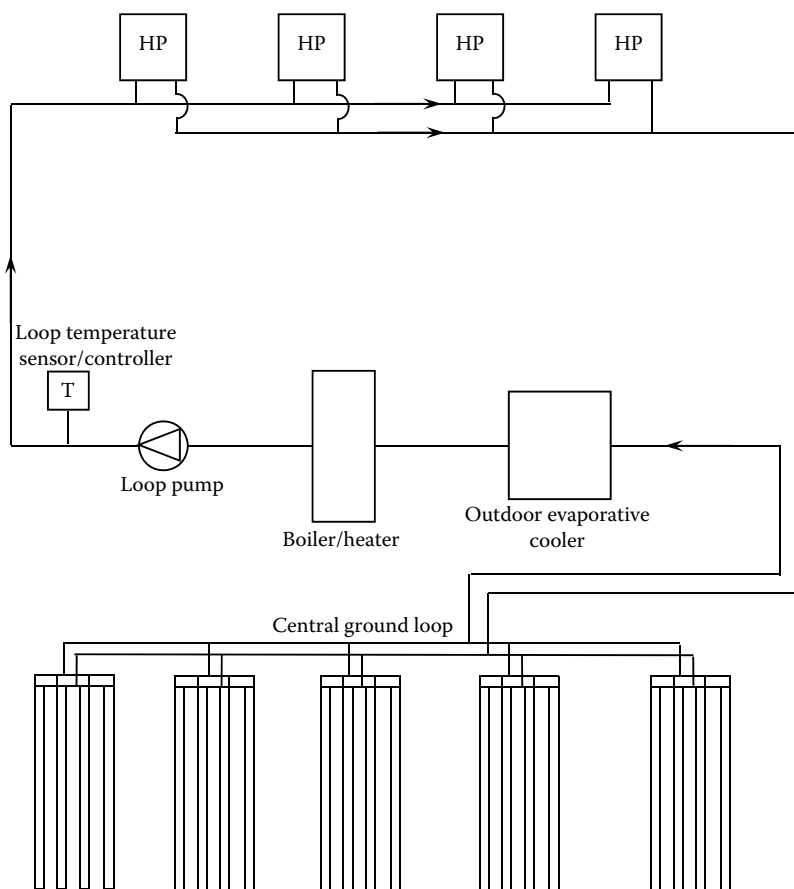

During winter, heat is removed from the circulating water heat exchanger via the water-to-refrigerant heat exchanger (evaporator) and rejected to the space via the air coil (condenser). If enough heat is removed from the heat exchanger to lower its temperature to below 65°F (18°C), an auxiliary heater (typically a high-efficiency condensing hot water boiler) adds supplemental heat to the heat exchanger to maintain the required temperature.

ASHRAE stipulates minimum energy performance requirements only for closed heat exchanger water-source heat pump units of less than 135,000 Btu/h (40 kW) cooling capacity. The minimum requirements are a cooling EER = 12.0 and a heating COP = 4.2. Again, manufacturers offer *premium* performance units that can produce a cooling EER of 16 or higher and a heating COP of almost 5.0.

### 27.3.2 Closed-Circuit Geothermal Heat Pump Systems

Closed circuit geothermal heat pumps are a variation to the basic closed-circuit heat pump system, as discussed in the previous subsection, that are designed to take advantage of the earth (ground) or a large body of water as heat source/sink. The supplemental heater(s)

**FIGURE 27.3**  
Schematic of basic closed-circuit geothermal heat pump system.

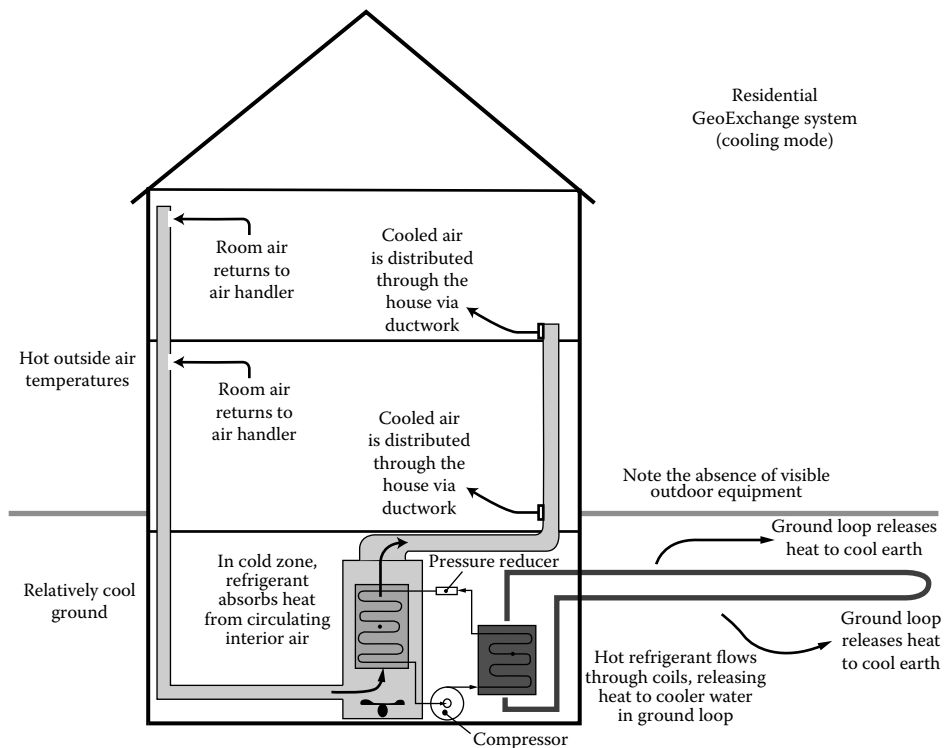

and evaporative cooler(s) that represent the heat source and sink in the basic closed-circuit heat pump system are augmented by a *ground-coupled heat exchanger* or water-coupled heat exchanger that is utilized as the primary system heat source and sink. The supplemental heater(s) and evaporative cooler(s) are maintained to augment the ground-coupled heat exchanger and/or to operate under emergency conditions.

Figure 27.3 illustrates the common ground-coupled geothermal heat pump system configuration.

The ground-coupled heat exchanger may be installed either horizontally directly in the ground or vertically through one or more wells, typically referred to as *boreholes*. The fluid could be either water or a refrigerant.

Geothermal heat pumps take advantage of the natural constant temperature of the ground 5–6 ft [1.5–1.8 m] below grade where the ground mean annual temperature remains between 45°F and 65°F [7°C–18°C], depending on location and water table. The ground temperature is warmer than the air above it in the winter and cooler than the air in the summer, resulting in the need for less compressor lift and more efficient heating and cooling.

The geothermal heat pump system has three major parts: the ground-coupled heat exchanger, the heat pump unit, and the air delivery system (ductwork and air outlets/inlets). The heat exchanger is a system of pipes that is buried in the shallow ground near the

**FIGURE 27.4**

Example of a residential geothermal heat pump configuration in the summer months. (Courtesy of the Geothermal Heat Pump Consortium.)

building. A fluid (usually water or a mixture of water and antifreeze) circulates through the pipes to absorb or deposit heat within the ground (Figure 27.4).

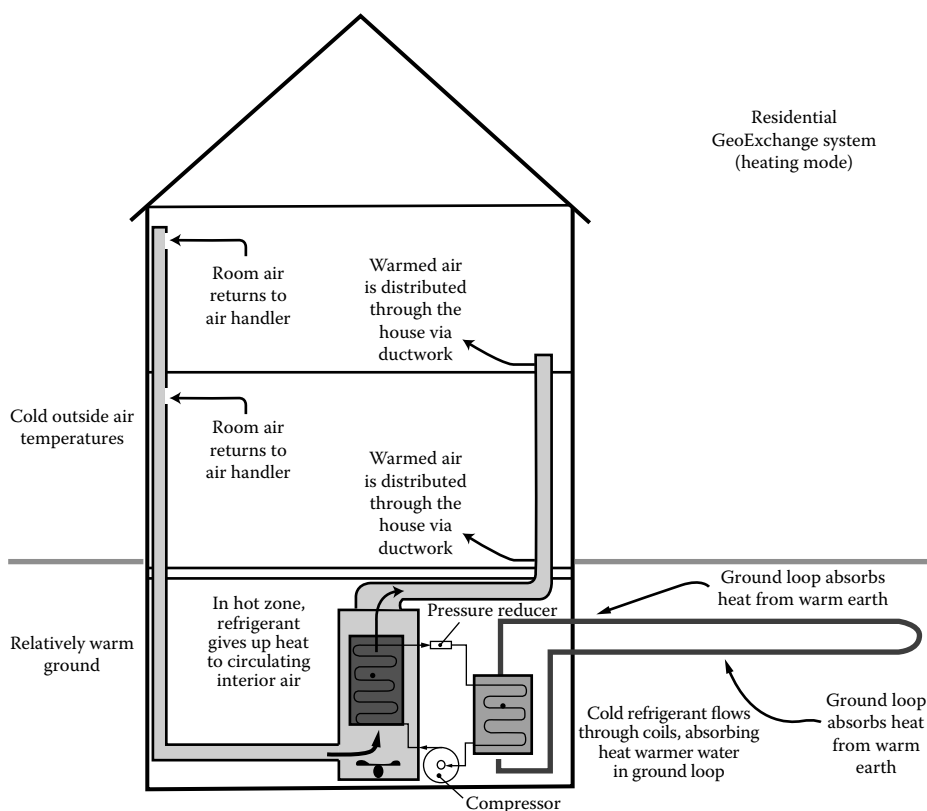

In the winter, the heat pump removes heat from the heat exchanger and pumps it into the indoor air delivery system. In the summer, the process is reversed, and the heat pump moves heat from the indoor air into the heat exchanger. The heat removed from the indoor air during the summer can also be used to heat water (Figure 27.5).

The ground-coupled heat exchanger provides the means of transferring heat to the earth in summer and extracting heat from the earth in winter. Physically, the heat exchanger consists of several lengths of plastic pipe typically installed either in horizontal trenches or vertical boreholes that are backfilled to provide close contact with the earth.

Fluid inside the heat exchanger is pumped through a refrigerant heat exchanger in the geothermal heat pump. In the summer, it absorbs heat from the refrigerant and carries it to the ground through the ground-coupled heat exchanger piping to be rejected. In winter, it absorbs heat from the earth and transfers that heat to be extracted by the refrigerant.

Once installed, the heat exchanger remains out of sight beneath the surface. The ground heat exchanger consists of high-density polyethylene piping with an anticipated service life of at least 50 years.

Horizontal closed heat exchangers are the most cost-effective configuration when (1) adequate land is available, (2) soil conditions are such that trenches are easy to dig (e.g., no rock), and (3) trench depths are not defined by frost lines exceeding 36 in. [1 m] below grade. Trenching machines or backhoes are utilized to dig the trenches normally 5–6 ft

**FIGURE 27.5**

Example of a residential geothermal heat pump configuration in the winter months. (Courtesy of the Geothermal Heat Pump Consortium.)

below finished grade and then lay a series of parallel plastic pipes. Backfilling the trench requires that great care is taken to eliminate sharp rocks or debris that may damage the heat exchanger piping. Typically, compacted sand or a mix of sand and bentonite is back-filled for the first 6–12 in. [15–30 cm] to create good contact between the piping and earth. A typical horizontal heat exchanger will be about 400–600 ft [120–180 m] long per ton of required cooling capacity (Figure 27.6).

**FIGURE 27.6**

Example of a horizontal heat exchanger configuration in a residential installation. (Courtesy of the Geothermal Heat Pump Consortium.)

**FIGURE 27.7**

Example of a *slinky* heat exchanger configuration in a residential installation. (Courtesy of the Geothermal Heat Pump Consortium.)

The pipe may be curled into a slinky shape in order to fit more of it into shorter trenches. While this reduces the amount of land space needed, it may require more pipes (Figure 27.7).

For vertical heat exchangers, boreholes are drilled into the ground from 150 to 450 ft [45–140 m] deep. Each hole contains a single heat exchanger of pipe with a U-bend at the bottom. After the pipe is inserted, the hole is backfilled or grouted with a slurry of mixture of sand and bentonite. Each vertical pipe is then connected to a horizontal pipe, which is also concealed underground. The horizontal pipe then carries fluid in a closed system to and from each geothermal heat pump unit (Figure 27.8).

ASHRAE stipulates minimum performance requirements only for ground-coupled heat pump systems of less than 135,000 Btu/h [40 kW] cooling capacity, requiring a cooling EER = 13.4 and a heating COP = 3.6.

Despite their excellent energy efficiency, the application of ground-coupled heat pump systems has been relatively limited due to a number of *challenges* that significantly reduce their cost effectiveness, especially as conventional air-source and water-source heat pumps continue to improve their energy performance. These challenges include:

*Land type and space for a ground-coupled heat exchanger:* The soil in which a horizontal ground-coupled heat exchanger is installed must be reasonably finely textured, no rock, and soil that contains little clay. The soil in which boreholes and vertical heat

**FIGURE 27.8**

Example of a vertical heat exchanger configuration in a residential installation. (Courtesy of the Geothermal Heat Pump Consortium.)

exchangers are installed are less critical since the borehole is backfilled with a mix of sand and bentonite after the piping is installed to insure good heat transfer with the surrounding undisturbed earth.

Horizontal trench heat exchangers installed with two pipes per trench typically require 2000–4000 ft<sup>2</sup> (600–1200 m<sup>2</sup>) of ground surface area per ton of cooling capacity required. Obviously, that requirement limits the applicability of this type of heat exchanger. Vertical heat exchangers required only about 200–400 ft<sup>2</sup> (60–120 m<sup>2</sup>) of ground surface area per ton of cooling capacity required.

*Costs of ground-coupled heat exchanger:* Horizontal trenching, assuming no rock is present near the ground surface, is relatively inexpensive since it is accomplished by conventional backhoes or trenching machines fairly quickly. Drilling boreholes for vertical heat exchangers is more difficult and expensive than trenching. And, even with vertical heat exchangers, some horizontal trenching is required to connect each borehole piping heat exchanger to a common piping system.

Another cost element associated with vertical heat exchangers is the need to drill a test bore prior to designing the system in order to determine actual subsurface conditions. The soil thermal conductivity can vary as much as 400% depending on the type of soil and rock encountered, ground water hydrology, etc. This means that the number and depth of geothermal boreholes may vary significantly from site to site for the same system capacity.

*Circuit pumping energy consumption:* Geothermal heat pumps require a flow ranging from 2.5 to 3.5 gal/min (9.4–13.2 L/min) for each ton of cooling load. In older systems, the pumps to provide this flow operated at all times at a constant speed and, thus, significant pumping energy was consumed. Today's systems utilized variable flow pumping and the costs of pumping have been reduced.

*System complexity:* Geothermal heat pump systems have more components, more complex controls, and higher maintenance costs than conventional systems.

A more efficient alternative to the ground-coupled heat exchanger is a *water-coupled heat exchanger*. Large ponds, lakes, rivers, and even the ocean represent excellent heat sources/sinks for use with heat pumps. While water temperatures vary in these bodies of water summer to winter, the water temperature swing is always more moderate than for air, rarely falling below about 32°F [0°C] or rising above 85°F [29°C]. Even water that freezes on the surface is above freezing below the ice.

Water-to-water heat exchange is 20%–50% more efficient than water-to-ground heat exchange, significantly improving the efficiency of heat exchange of water-coupled systems over ground-coupled systems, and these systems typically have a cooling EER of 18–20 and a heating COP of 3–4.

Water-coupled heat exchangers may be configured with horizontal coiled piping submerged in the body of water. The alternative is to install a high-efficiency plate-and-frame heat exchanger with closed-circuit flow to the heat pump unit(s) on one side and flow from the body of water on the other. This second configuration, despite having somewhat higher pumping energy consumption, is preferred to avoid the problems with silting, drift, and mechanical damage that can occur to submerged piping loops.

While the applicability of water-coupled heat pump systems is limited simply because availability of usable water sources/sinks is more limited, the systems themselves are both less expensive and more energy efficient than ground-coupled systems and represent a very cost-effective approach when applicable.

### 27.3.3 Open-Circuit Geothermal Heat Pump Systems

Open-circuit geothermal heat pump systems, often called *groundwater heat pump systems*, use two or more groundwater wells for their heat source/sink, one or more wells from which groundwater is withdrawn and one or more wells into which the water is *injected* back into the ground after passing through the heat pump units. These systems are as efficient, sometimes even more so, than water-coupled heat pump systems.

However, these systems have a significant negative environmental impact. Since the water flow rate required for heat pump operation is relatively high, the amount of water withdrawn from an available aquifer amounts for a significant demand on the aquifer. Then, since the water reinjection point is typically far outside the *recharge zone* for the aquifer, simply pumping the water back into the ground really does not benefit the aquifer from which it was removed.

*Since most aquifer levels in the United States have already fallen significantly over the past 50 years and continue to fall, the use of this heat pump system configuration and further stress on aquifers is not recommended.*

### 27.3.4 Gas-Fired Engine-Driven Heat Pumps

To many, the use of electricity as a primary energy source is not desirable. The electrical power industry routinely releases huge quantities of CO<sub>2</sub> into the atmosphere, along with large quantities of SO<sub>2</sub> and NO<sub>x</sub>. On a comparative basis, these poor greenhouse gas emissions make grid electricity a poor sustainable choice for any building heating and cooling system.

In the early 1990s, a U.S. manufacturer introduced a small (5 tons) natural-gas-fired engine-driven packaged air-source heat pump for the residential and light commercial failure. While the engine itself is no more efficient than grid electricity power production, its use of clean-burning natural gas or LPG (propane) resulted in significantly reduced greenhouse gas emissions and a lower operating cost due to the low cost of gas fuels compared to electricity.

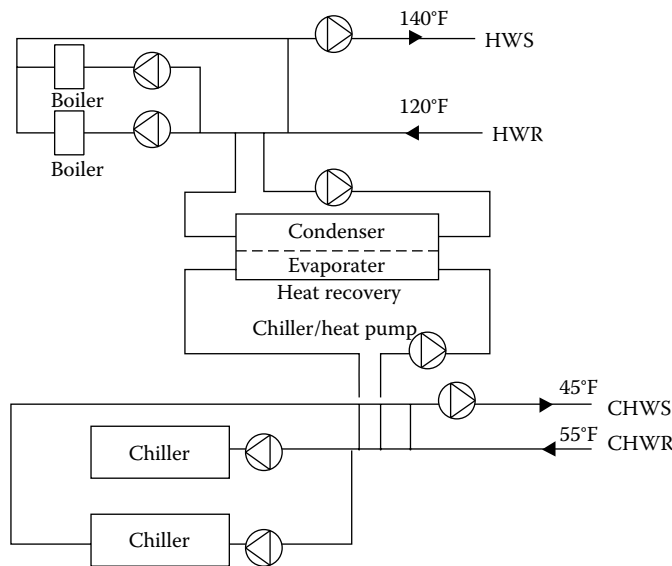

But that heat pump was a dismal failure! Of over 4000 units sold, 100% of the units failed within the first 3 years of their operation and the manufacturer was forced to replace almost all of these systems with conventional units. The problem with this concept was not with the heat pump, but with the engine. In this case, the manufacturer attempted to use a modified engine designed for lawn tractors and small engine-generators designed for 150–500 h annual use in an application that required the engine to operate 4000–5000 h/year.

Theoretically, an engine-driven heat pump, coupled with recovered heat from the engine jacket and exhaust, can achieve a heating COP of 1.4–2.0. And, today, manufacturers have teamed with automotive engine manufacturers to offer gas-engine-driven packaged air-source heat pumps in the 8–20 tons cooling capacity range, primarily for commercial applications. These units have an advertised SEER of 18+ and heating COP of 1.5.

The development of smaller gas-engine-driven systems is reportedly underway in both Japan and at Oak Ridge National Laboratory, and domestic-scale units could be brought to market within a few years.

### 27.3.5 Heat Recovery Chiller/Heat Pump System

Large buildings are often cooled by chilled water systems that circulated water at 40°F–45°F [4°C–7°C] to cooling coils located in air-handling units located throughout the building. While small residential or light commercial buildings require cooling *or* heating, large buildings may require simultaneous cooling *and* heating. And, there is almost always a need to generate service hot water in large buildings.

**FIGURE 27.9**  
Schematic of HRC/heat pump system.

When providing cooling, the chilled water system rejects the excess collected heat to the outdoor air via cooling towers via condenser water at 85°F–95°F [29°C–35°C] temperature. These temperatures are typically too low to allow condenser water to be used for heating, so the *dedicated heat recovery chiller (HRC) heat pump* system is sometimes applied as illustrated by Figure 27.9.

Though not a truly *reverse cycle system*, this system is a heat pump configuration. A *lead HRC* is configured with a primary/secondary piping loop on the chilled water return piping upstream of the remaining cooling-only chillers. The HRC capacity is selected based on the need to provide heating during the summer. Thus, the HRC removes heat from the return chilled water, lowering its temperature, and rejects that heat to the hot water system at 130°F–140°F [54°C–60°C]. The effect is to reduce the imposed load on the cooling-only chillers by *precooling* the return chilled water while simultaneously producing hot water at sufficiently high temperature to be useful.

For this concept to be cost effective, there must be a need for heating during the summer cooling period. This heat may be needed for reheat associated with space temperature or humidity control, service hot water heating, pool heating, etc. To maximize the energy efficiency of this concept, though, there must be a need for chilled water cooling for as long as feasible. This means that the use of airside economizer cycles, required by most energy conservation building codes, needs to be carefully evaluated to determine when it is more efficient to provide mechanical cooling and capture the rejected heat versus using the outdoor air to provide *free cooling* and operating boilers to provide heat.

### 27.3.6 Variable Refrigerant Flow Heat Pump System

Since about 2000, the use of *variable refrigerant flow (VRF)* systems that achieve a better level of thermal zoning in buildings while using a common outdoor air unit has increased significantly. With VRF systems, up to 16 indoor evaporator units of varying capacity can be coupled with a single outdoor condensing unit. Currently widely applied in large buildings

such as offices and hospitals outside the United States, especially in Japan, Europe, and Canada, these systems are just *catching on* in the United States.

These systems use multiple compressors, including inverter-driven variable speed units, and deliver excellent part-load performance and zoned temperature control, resulting in excellent occupant comfort. The basic difference between these systems and conventional HVAC systems is that they circulate refrigerant directly to multiple indoor units, rather than using water (as in a chiller) or air (as in a ducted DX system) to achieve heat transfer to the space.

VRF systems are extremely flexible, enabling a single condensing unit to be connected to a large number of indoor units of varying capacity and configuration. The exact number of indoor units varies according to the manufacturer, but one typical manufacturer allows connection of up to 16 indoor units to one condensing unit or up to 30 indoor units on a single refrigerant circuit supplied by 3 outdoor units.

Typically, each condensing unit uses two or three compressors, one of which is an inverter-driven variable speed compressor. Systems are commonly designed by combining multiple condensing units to achieve system capacities of up to several hundred tons.

Energy savings are due to several factors:

*High part-load efficiency:* Because VRF systems consist of multiple compressors, some of which are variable speed, the system's part load efficiency is excellent. A typical dual-compressor system can operate at 21 capacity steps. Since most HVAC systems spend most of their operating hours between 30% and 70% of their maximum capacity, a load range in which the COP of the system is very high and, thus, the seasonal energy efficiency of these systems is excellent.

*Effective zone control:* Indoor units can easily be turned off in locations needing no cooling, while the system retains highly efficient operation.

*Heat pump operation:* In buildings where simultaneous heating and cooling are needed, such as many office buildings, the system is configured as a three-pipe heat recovery system. In this configuration, refrigerant flow control is used to circulate refrigerant from the discharge of the evaporators in space being cooled to the evaporators of zones needing heat and vice versa. By using refrigerant to move heat between zones, a very high heating COP can be realized (perhaps as high as 4.0).

Because the energy savings of VRF systems are so application dependent, it is difficult to make definitive, general statements about their energy efficiency. Initial estimates of energy savings are in the range of 5%–15%, with higher savings in hot, humid climates, and lower savings in cold climates.

---

## 27.4 Advanced-Technology Heat Pumps

### 27.4.1 Absorption Cycle Heat Pumps

Absorption cycle heat pumps are essentially air-source heat pumps driven not by electricity but by a heat source such as natural gas, propane, solar-heated water, or geothermal-heated water. Because natural gas is the most common heat source for absorption heat pumps, they are also referred to as *gas-fired heat pumps*.

Residential absorption heat pumps use an ammonia–water absorption cycle to provide heating and cooling. As in a vapor-compression cycle heat pump, the refrigerant (in this case, ammonia) is condensed in one heat exchanger to release its heat; its pressure is then reduced and the refrigerant is evaporated to absorb heat.

The absorption cycle heat pump has no compressor. Evaporated ammonia is absorbed into water, and a relatively low-power pump then pumps the ammonia–water solution to a heat exchanger at a slightly higher pressure where heat is added to essentially boil the ammonia out of the water.

The *generator absorber heat exchanger* boosts the efficiency of the unit by recovering the heat that is released when the ammonia is absorbed into the water. Other innovations include high-efficiency vapor separation, variable ammonia flow rates, and low-emissions, variable-capacity combustion of the natural gas.

Absorption cycle cooling only is now commercially available in the 5+ ton capacity range and absorption cycle heat pumps are under development.

### 27.4.2 Solar-Assisted Heat Pumps

Solar-assisted (sometimes called *solar-augmented*) heat pumps utilize rooftop solar heat collectors configured to augment air-source or ground-source geothermal heat exchangers. These systems are generally series configured with solar panels that are arranged to act as an additional heat source for the heat pump.

For air-source or water-source heat pumps, solar panels can provide higher temperature heat during the winter, reducing the need for supplemental heating by electric coils or boilers. This configuration can also reduce surface land requirements for ground-coupled heat pumps, expanding their range of applicability.

## 28.1 Introduction

Motor systems are by far the most important type of electrical load, ranging from small fractional horsepower motors incorporated in home appliances to multi-megawatt motors driving pumps and fans in power plants. Motors consume over half of total U.S. electricity, and in industry they are responsible for about two-thirds of the electricity consumption. In the commercial and residential sectors, motors consume slightly less than half of the electricity. The cost of powering motors is immense, roughly \$100 billion a year in the United States alone. There is a vast potential for saving energy and money by increasing the efficiency of motors and motor systems.

### 28.1.1 Motor Types

Motors produce useful work by causing the shaft to rotate. Motors have a rotating part, the rotor, and a stationary part, the stator. Both parts produce magnetic fields, either through windings excited by electric currents or through the use of permanent magnets (PMs). It is the interaction between these two magnetic fields that is responsible for the torque generation, as shown in Figure 28.1.

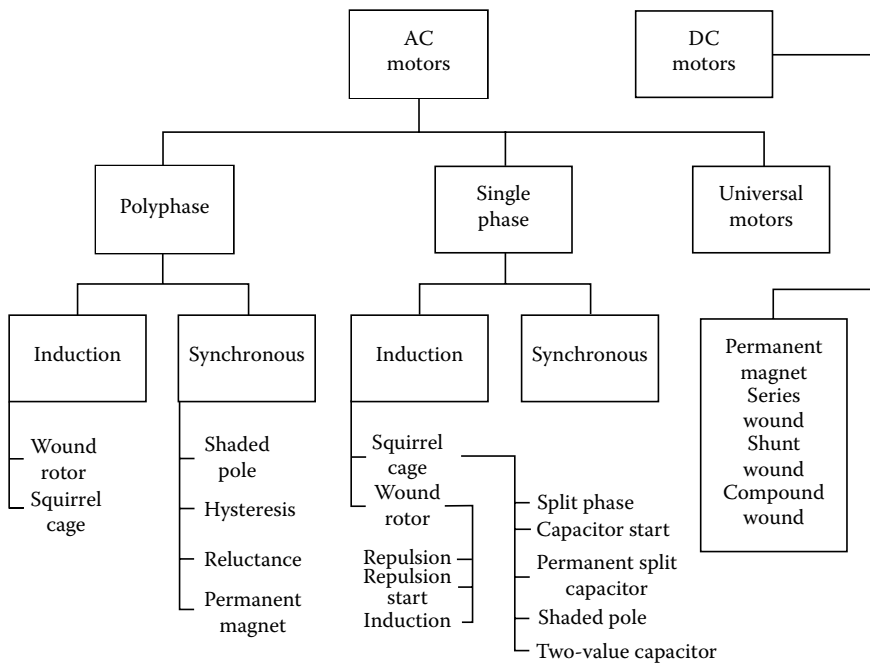

There are a wide variety of electric motors, based on the type of power supply (AC or DC) that feeds the windings, as well as on different methods and technologies to generate the magnetic fields in the rotor and in the stator. Figure 28.2 presents the most important types of motors.

Because of their low cost, high reliability, and fairly high efficiency, most of the motors used in large home appliances, industry, and commercial buildings are induction motors. Figure 28.3 shows the operating principle of a three-phase induction motor.

**FIGURE 28.1**

Torque generation in a motor. The generated torque is proportional to the strength of each magnetic field and depends on the angle between the two fields. Mathematically, torque equals  $|B_{\text{rotor}}| \times |B_{\text{stator}}| \times \sin \alpha$ , where  $B$  refers to a magnetic field. (Reprinted from Nadel, S. et al., *Energy-Efficient Motor Systems: A Handbook on Technologies, Programs, and Policy Opportunities*, 1st edn., American Council for an Energy-Efficient Economy, Washington, DC, 1992. With permission.)

**FIGURE 28.2**

Motor types. (From EPRI, *Electric motors: Markets, trends and application*, EPRI Report TR-100423, Electric Power Research Institute, Palo Alto, CA, 1992.)

**FIGURE 28.3**

Operation of a four-pole squirrel-cage induction motor. Rotating magnetic field is created in the stator by AC currents carried in the stator winding. Three-phase voltage source results in the creation of north and south magnetic poles that revolve or *move around* the stator. The changing magnetic field from the stator induces current in the rotor conductors, in turn creating the rotor magnetic field. Magnetic forces in the rotor tend to follow the stator magnetic fields, producing rotary motor action.

Synchronous motors, where the rotor spins at the same speed as the stator magnetic field, are used in applications requiring constant speed, high operating efficiency, and controllable power factor. Efficiency and power factor are particularly important above 1000 hp. Although DC motors are easy to control, both in terms of speed and torque, they are expensive to produce and have modest reliability. DC motors are used for some industrial and electric traction applications, but their importance is dwindling.

---

## 28.2 Motor Systems Efficiency

The efficiency of a motor-driven process depends upon several factors, which may include

- Motor efficiency
- Motor speed controls
- Proper sizing
- Power supply quality
- Distribution losses
- Transmission
- Maintenance
- Driven equipment (pump, fan, etc.) mechanical efficiency

It must be emphasized that the design of the process itself influences the overall efficiency (units produced/kWh or service produced/kWh) to a large extent. In fact, in many systems the largest opportunity for increased efficiency is in improved use of the mechanical energy (usually in the form of fluids or solid materials in motion) in the process. Comprehensive programs to address motor-system energy use start with the process and work back toward the power line, optimizing each element in turn, as well as the overall system. Outlining such a program is beyond the scope of this discussion; see, for example, Baldwin (1989) for the benefits that propagate all the way back to the power plant. Additionally, the U.S. Department of Energy (U.S. DOE) has published several *Energy Tips* sheets on motor system efficiency (USDOE, 2012). Topics include estimating motor efficiency, motor drives, and electrical system considerations. Additional publications detailing motor and motor system efficiency characteristics, how to identify motor system losses, and system efficiency improvement opportunities are available from the U.S. DOE (USDOE, 2014a–c).

### 28.2.1 Motor Efficiency

[Figure 28.4](#) shows the distribution of the losses of an induction motor as a function of the load. At low loads, the core magnetic losses (hysteresis and eddy currents) are dominant, whereas at higher loads, the copper resistive (“Joule” or  $I^2R$ ) losses are the most important. Mechanical losses are also present in the form of friction in the bearings and windage.

#### 28.2.1.1 Motor Efficiency: *Energy Efficient, Premium Efficient, and Beyond*

After World War II and until the early 1970s, there was a trend to design inefficient motors, which minimized the use of raw materials (copper, aluminum, and silicon steel). These induction motors had lower initial costs and were more compact than the previous generations of motors, but their running costs were higher. When electricity prices started escalating rapidly in the mid-1970s, most of the large motor manufacturers added a line of higher-efficiency motors to their selection. Such motors feature optimized design, more generous electrical and magnetic circuits, and higher quality materials (Baldwin, 1989). Incremental efficiency improvements are still possible with the use of superior materials (e.g., amorphous silicon steel) and optimized computer-aided design techniques.

**FIGURE 28.4**

Variation of losses with load for a 10 hp motor. (Reprinted from Nadel, S. et al., *Energy-Efficient Motor Systems: A Handbook on Technologies, Programs, and Policy Opportunities*, 1st edn., American Council for an Energy-Efficient Economy, Washington, DC, 1992. With permission.)

In 1997, the U.S. Energy Policy Act (EPAct) put in place mandatory efficiency standards for many general-purpose motors. Also in the 1990s, the Consortium for Energy Efficiency (CEE) developed a voluntary premium-efficiency standard, which evolved into the NEMA Premium designation (Nadel et al., 2002; NEMA, 2000). Premium efficiency motors offer an efficiency improvement over EPAct, which typically ranges from 4% for a 1 hp motor to 2% for a 150 hp motor (Figure 28.5). Due to long motor lives, many motors in use are less efficient than EPAct, and thus there is an even larger difference between them and premium efficiency motors. Premium efficiency motors normally cost around 15%–25% more than standard motors, which translates into a price premium of \$8–\$40/hp. In new applications, and for motors with a large number of operating hours, the paybacks are normally under 4 years for Premium vs. EPAct motors, and under 2 years for Premium vs. older, standard-efficiency motors.

In 2007, the U.S. Energy Independence and Security Act (EISA) raised the minimum efficiency standards set by EPAct to meet efficiency requirements equivalent to NEMA Premium effective December 2010. Additionally, EISA also expanded the number of motors covered by EPAct. In 2014, U.S. DOE passed a final rule expanding the number of motors required to meet the energy efficiency guidelines outlined in NEMA Table 12-12, which is the table used to designate a premium efficiency motor. For example, where EISA requires 1–200 hp general purpose Design B motors to meet NEMA Premium efficiency levels, the 2014 rule expands the covered size range to 500 hp (USDOE 2014c).

An important measure for the wide market acceptance of high efficiency motors is the availability of harmonized standards, dealing with motor performance testing, efficiency classification, and display of ratings (Brunner et al., 2013, De Almeida 2013). This also applies to adjustable-speed drives (ASDs; see later section). In PR China and in the EU, high-efficiency/IE2 motors are mandatory since 2011, and Premium/IE3 motors will be mandatory in 2015 in the EU (De Almeida et al., 2014). The IEC60034-30 efficiency

**FIGURE 28.5**

Planned revision (second edition) of IEC60034-30 nominal efficiency classes limits, for four-pole motors (0.12–800 kW power range). (From De Almeida, A. et al., *IEEE Indust. Appl. Mag.*, 17(1), 12, January/February 2011; De Almeida, A. et al., *IEEE Trans. Indust. Appl.*, 50(2), March/April, 1274, 2014; IEC60034-2-1, 2nd edn., 2/1687/CDV: Rotating electrical machines—Part 2-1: Standard method for determining losses and efficiency from tests [excluding machines for traction vehicles], 2013.)

classification standard (IEC60034-30, 2008) is being revised, and while the IE4\* Super-Premium efficiency class is now well established, a new IE5 Ultra-Premium efficiency class is being considered in the Second Edition<sup>†</sup> (IEC/TS60034-31, 2010). However, there is a question with regard to its achievability (De Almeida et al., 2013).

In Figure 28.5, the IE1, IE2, IE3, IE4, and IE5 classes of the revised IEC60034-30 standard are shown for four-pole, 50/60 Hz motors (IEC60034-30, 2008). The motor nominal efficiency should be determined according to IEC60034-2-1 (IEC60034-2-1, 2007; IEC6003-2-1, 2013).

### 28.2.1.2 Efficiency of Rewound Motors

When a motor fails, the user has the options of having the motor rebuilt, buying a new standard motor, or buying a NEMA Premium motor. Except for large motors with low annual operating hours, it is typically very cost-effective to replace the failed motor with a Premium motor. Although motor rebuilding is a low-cost alternative, the efficiency of a rebuilt motor can be substantially decreased by the use of improper methods for stripping the old winding. On average, the efficiency of a motor decreases by about 1% each time the motor is rewound.

\* The designation of the energy-efficiency class in the IEC60034-30 standard consists of the letters “IE” (International Energy-Efficiency), directly followed by a numeral representing the classification.

<sup>†</sup> The Second Edition will be denoted as IEC60034-30-1, for line-start motors and IEC60034-30-2 for ASD-fed motors.

The use of high temperatures (above 350°C) during the rewinding process can damage the interlaminar insulation and distort the magnetic circuit with particular impact on the air gap shape, leading to substantially higher core and stray losses. Before any motor is rewound, it should be checked for mechanical damage and the condition of the magnetic circuit should be tested with an electronic iron core loss meter. There are techniques available to remove the old windings, even the ones coated with epoxy varnish, which do not exceed 350°C (Dreisilker, 1987).

### 28.2.2 Recent Motor Developments

In the low horsepower range, the induction motor is being challenged by new developments in motor technology such as PM and reluctance motors, which are as durable as induction motors and are more efficient. These advanced motors do not have losses in the rotor and feature higher torque and power/weight ratio. In fractional-horsepower motors, such as the ones used in home appliances, the efficiency improvements can reach 10%–15%, compared with single-phase induction motors. Compared to the shaded-pole motors commonly used in small fans, improved motor types can more than double motor efficiency.

#### 28.2.2.1 Permanent-Magnet Motors

Over the last few decades, there has been substantial progress in the area of PM materials. Figure 28.6 shows the relative performance of several families of magnetic materials. High-performance PM materials such as neodymium–iron–boron alloys, with a large energy

**FIGURE 28.6**

The evolution of permanent-magnet materials, showing the increasing magnetic energy density (*energy product*). Ferrites were developed in the 1940s and AlNiCos (aluminum, nickel, and cobalt) in the 1930s. The rare-earth magnets were developed beginning in the 1960s (samarium–cobalt) and in the 1980s (neodymium–iron–boron). The higher the energy density, the more compact the motor design can be for a given power rating. (Reprinted from Nadel, S. et al., *Energy-Efficient Motor Systems: A Handbook on Technologies, Programs, and Policy Opportunities*, 1st edn., American Council for an Energy-Efficient Economy, Washington, DC, 1992. With permission.)

**FIGURE 28.7**

Control system scheme of a brushless DC motor. This motor is also known as an electronically commutated permanent-magnet (PM) motor. The motor is composed of three sets of stator windings arranged around the PM rotor. AC power is first converted to DC, and then switched to the windings by the power control unit, which responds to both an external speed command and rotor position feedback from  $H_1$ ,  $H_2$ , and  $H_3$ , which are magnetic position sensors. If a DC power supply is available, it can be used directly by the power control unit in place of the AC supply and converter. The function of the commutator and brushes in the conventional DC motor is replaced by the control unit and power switches. The PM rotor follows the rotating magnetic field created by the stator windings. The speed of the motor is easily changed by varying the frequency of switching.

density and moderate cost, offer the possibility of achieving high efficiency and compact lightweight motors.

In modern designs, the PMs are used in the rotor. The currents in the stator windings are switched by semiconductor power devices based on the position of the rotor, normally detected by Hall sensors, as shown in Figure 28.7. The rotor rotates in synchronism with the rotating magnetic field created by the stator coils, leading to the possibility of accurate speed control. Because these motors have no brushes, and with suitable control circuits they can be fed from a DC supply, they are sometimes called brushless DC motors.

### 28.2.2.2 Switched Reluctance Motors

Switched reluctance motors are also synchronous motors whose stator windings are commutated by semiconductor power switches to create a rotating field. The rotor has no windings, being made of iron with salient poles. The rotor poles are magnetized by the influence of the stator rotating field. The attraction between the magnetized poles and the rotating field creates a torque that keeps the rotor moving at synchronous speed. [Figure 28.8](#) shows the structure of a switched reluctance motor.

**FIGURE 28.8**

Schematic view of a switched reluctance motor. The configuration shown is a 6/4 pole. A rotating magnetic field is produced by switching power on and off to the stator coils in sequence, thus magnetizing poles a–a', b–b', and c–c' in sequence. Switching times are controlled by microprocessors with custom programming.

Switched reluctance motors are more efficient than induction motors, are simple to build, and are robust, and if mass produced, their price can compete with induction motors. Switched reluctance motors can also be used in high-speed applications (above the 3600 rpm possible with induction or synchronous motors operating on a 60 Hz AC supply) without the need for gears.

### 28.2.2.3 Synchronous Reluctance Motors

In synchronous reluctance motors (SynRMs), the stator has windings (similar to those used in the squirrel-cage induction motors [SCIMs]) and the rotor is cylindrical (as distinguished from Figure 28.8) but with anisotropic magnetic structure (magnetic reluctance varies with the flux direction) (ABB, 2012, 2013; Boglietti et al., 2005). In these motors, when fed by an ASD, speed and torque control is possible and large energy savings may be realized in variable-flow pump and fan applications.

Similar to permanent-magnet synchronous motors (PMSMs), it is possible to design SynRMs for (as illustrated in Figure 28.9 from left to right) the same frame size and better efficiency, an in-between solution with slight higher efficiency and slightly smaller frame size, or smaller frame size and equal efficiency.

Figure 28.10 shows the expected loss reduction when comparing the same and smaller frame sizes to a reference SCIM frame size (De Almeida et al., 2013). The new rotor has neither magnets nor windings, and thus suffers virtually no power losses—which makes it uniquely cool. For the same frame size, there is typically a 25% reduction in the overall losses with respect to IE3-Class/NEMA Premium SCIMs. Therefore, there is the possibility of a significant efficiency gain if the standard frame size is used.

It should be mentioned that the commercially available models of SynRM and drive packages are optimized for variable-speed pump and fan applications to achieve the

**FIGURE 28.9**  
Frame size vs. efficiency and power density in SynRMs.

**FIGURE 28.10**  
Same stator size, different rotor type: loss reduction (note: stator copper losses slightly increase and rotor losses are reduced to zero).

highest efficiency. Since SynRM have no rotor cage losses, their overall losses are lower and, consequently, the efficiency is higher. For the same efficiency, SynRM can be up to two frame sizes smaller than conventional SCIM. The output and efficiency performance of SynRM are comparable to a PMSM drive, but with construction techniques similar to those used in SCIMs, bringing the best of both worlds to users.

#### 28.2.2.4 Promising Industrial Motor Technologies

The Super-Premium efficiency class (NEMA Premium or IE3 mentioned earlier) motor technologies can be divided into fixed- and variable-speed applications. For fixed-speed applications, the existing SCIM and line-start (motors that can start and run directly from grid power without an ASD) permanent magnet (LSPM) technologies are already within

the IE4 class. Although not commercially available, SynRM technology is likely to evolve to a line-start solution by means of embedding an auxiliary cage in the rotor (e.g., embedded in the air spaces of the rotor), as was done for the PM technology. This type of motor would be useful in constant speed applications and would not require an ASD.

Presently for variable-speed applications, the existing ASD-fed PMSMs (with rare-earth PMs and silicon steel core or with ferrite PMs and amorphous metal core) and SynRMs are the best options. In such applications, it is important to note that the efficiency at partial speed and torque is very important since the operation cycle typically includes long periods with speeds and torques lower than nominal. Therefore (as with any variable load motor system), when analyzing the energy performance of the drive system, the efficiency maps are much more relevant than a single efficiency point for the rated speed and torque.

### 28.2.3 Motor Speed Controls

AC induction and synchronous motors are essentially constant-speed motors. Most motor applications would benefit if the speed could be adjusted to the process requirements. This is especially true for new applications where the processes can be designed to take advantage of the variable speed. The potential benefits of speed variation include increased productivity and product quality, less wear in the mechanical components, and substantial energy savings.

In many pump, fan, and compressor applications, the mechanical power grows roughly with the cube of the fluid flow; to move 80% of the nominal flow only half of the power is required. Fluid-flow applications are therefore excellent candidates for motor speed control.

Conventional methods of flow control have used inefficient throttling devices such as valves, dampers, and vanes. These devices have a low initial cost but introduce high running costs due to their inefficiency. [Figure 28.11](#) shows the relative performance of different techniques to control flow produced by a fan. In [Figure 28.11](#), it should be noted that in VAV systems static pressure typically acts as a feedback mechanism for controlling fan speed. Consequently, there will be some power consumption at 0 CFM with the result that overall savings is less than the theoretical condition.

Motor system operation can be improved through the use of several speed-control technologies, such as those covered in the following three sections.

#### 28.2.3.1 Mechanical and Eddy-Current Drives

Mechanical speed control technologies include hydraulic transmissions, adjustable sheaves, and gearboxes. Eddy-current drives work as induction clutches with controlled slip (Magnusson, 1984).

Both mechanical drives and eddy drives have relatively low importance. They suffer from low efficiency, bulkiness, limited flexibility, or limited reliability when compared with other alternatives; in the case of mechanical drives, they may require regular maintenance.

Mechanical and eddy drives are not normally used as a retrofit due to their space requirements. Their use is more and more restricted to the low horsepower range where their use may be acceptable due to the possible higher cost of ASDs.

#### 28.2.3.2 Multispeed Motors

In applications where only a few operating speeds are required, multispeed motors may provide the most cost-effective solution. These motors are available with a variety of

**FIGURE 28.11**

Comparison of several techniques for varying air flow in a variable air volume (VAV) ventilation system. The curve on the lower right represents the power required by the fan itself, not including motor losses. Electronic adjustable-speed drives are the most efficient VAV control option, offering large savings compared to outlet dampers or inlet vanes, except at high fractions of the rated fan speed. (From Greenberg, S. et al., Technology assessment: Adjustable speed motors and motor drives, Lawrence Berkeley Laboratory Report LBL-25080, Lawrence Berkeley Laboratory, University of California, Berkeley, CA, 1988.)

torque-speed characteristics (variable torque, constant torque, and constant horsepower) (Andreas, 1992), to match different types of loads. Double-winding motors can provide up to four speeds but they are normally bulkier (one frame size larger) than single-speed motors for the same horsepower rating. Pole-amplitude modulated (PAM) motors are single-winding, two-speed SCIMs that provide a wide range of speed ratios (Pastor, 1986). Because they use a single winding they have the same frame size of single-speed motors for the same horsepower and are thus easy to install as a retrofit. PAM motors are available with a broad choice of speed combinations (even ratios close to unity), being especially suited and cost-effective for those fan and pump applications that can be met by a two-speed duty cycle.

### 28.2.3.3 Electronic Adjustable-Speed Drives

Induction motors operate with a torque-speed relation as shown in Figure 28.12. The speed of the motor is very nearly proportional to the frequency of the AC power supplied to it; thus, the speed can be varied by applying a variable-frequency input to the motor. Electronic ASDs (Bose, 1986) achieve this motor input by converting the fixed frequency power supply (50 or 60 Hz), normally first to a DC supply and then to a continuously variable frequency/variable voltage (Figure 28.13). ASDs are thus able to continuously change the speed of AC motors. Electronic ASDs have no moving parts (sometimes with the

**FIGURE 28.12**

Speed–torque curves for an induction motor ( $f_1 < f_2 < f_3 < f_4 < f_5$  and  $f_5$  = normal line frequency). Normal operation of the motor is in the nearly vertical part of the curves to the right of the *knee* (known as the *breakdown* or *pullout* torque).

**FIGURE 28.13**

General inverter-based adjustable-speed drive power circuit with motor load.

exception of a cooling fan), presenting high reliability and efficiency and low maintenance requirements. Because ASDs are not bulky and have flexible positioning requirements, they are generally easy to retrofit.

Electronic ASDs are the dominant motor speed control technology at the present and for the foreseeable future. Developments in the past two decades in the areas of microelectronics and power electronics make possible the design of efficient, compact, and increasingly cost-competitive electronic ASDs. As ASDs control the currents/voltages fed to the motor through power semiconductor switches, it is possible to incorporate motor protection features, soft-start and remote control, at a modest cost. By adding additional power switches and controlling circuitry (Figure 28.14), ASDs can provide regenerative braking,

**FIGURE 28.14**

Power circuitry of a pulse-width modulation variable speed drive with regenerative capacity and power factor control. Whereas conventional adjustable-speed drives use diode rectifiers in the input stage, regenerative units use insulated gate bipolar transistors (IGBTs) at both the input and output stages to enable bidirectional power flow.

**FIGURE 28.15**

Pulse-width modulation for synthesizing a sinusoidal output. Output voltage, the average of which resembles the current waveform  $i(t)$ , is varied by changing the width of the voltage pulses  $v(t)$ . Output frequency is varied by changing the length of the cycle.

slowing the driven load and feeding power back into the AC supply. Such regenerative braking capability can increase the energy efficiency of applications such as elevators, downhill conveyors, and electric transportation.

Across the range of motor applications, no single ASD technology emerges as a clear winner when compared with other ASD types. Pulse-width modulation (PWM) voltage-source inverters ASDs dominate in the low to medium horsepower range (up to several hundred horsepower) due to their lower cost and good overall performance. Figure 28.15 shows how the variable-frequency/variable-voltage waveform is synthesized by a PWM ASD.

In the range above several hundred horsepower, the choice of ASD technology depends on several factors including the type of motor, horsepower, speed range, and control requirements (Greenberg et al., 1988). [Table 28.1](#) presents a general classification of the most widely used adjustable-speed motor drive technologies.

It should be noted that electronic ASDs have internal power losses, and they also adversely affect the efficiency of the motors they control. The losses within the drive are due to the AC to DC conversion losses, internal resistance in the DC bus filter, and switching losses in the DC to AC inverter section. As a function of rated output power, they are typically 94%–97% efficient at full load, 91%–95% at 50% load, and 86%–94% at 25% load, over the power range of 3–100 hp, respectively, though there is significant variation in reported losses (Krukowski and Wray, 2013). There is no standard for how the losses are determined, so there is likely even more uncertainty than the reports suggest. Since ASDs provide a nonsinusoidal waveform to the motor, the motor efficiency is adversely affected, with typical degradation (relative to across-the-line operation) of 1% at full load, 3% at 50% load, and 1% at 25% load, with large variations depending on the specific motor used (Burt et al., 2008). The industry has recognized a need to address these effects, and there is now a standard for how losses are determined (ANSI/AHRI, 2013). This standard only applies to ASD and motor combinations and is the overall ASD and motor efficiency (i.e., the efficiency is the shaft power output from the motor divided by the electrical power input to the ASD); the standard does not attempt to segregate the losses within the system.

#### 28.2.4 Motor Oversizing

Motors are often oversized as a result of the compounding of successive safety factors in the design of a system (Smeaton, 1988). The magnetic losses, friction, and windage losses are practically constant as a function of the load. Therefore, motors that are oversized

**TABLE 28.1**

Adjustable-Speed Motor Drive Technologies

Technology	Applicability (R = Retrofit; N = New)	Cost <sup>b</sup>	Comments
<i>Motors</i>			
Multispeed (incl. PAM <sup>a</sup> ) motors	Fractional—500 hp PAM; fractional—2,000 + hp R, N	1.5–2 times the price of single-speed motors	Larger and less efficient than one-speed motors. PAM is more promising than multiwinding. Limited number of available speeds.
Direct-current motors	Fractional—10,000 hp N Shaft-applied drives (on motor output)	Higher than AC induction motors	Easy speed control. More maintenance required.
<i>Mechanical</i>			
Hydraulic drive	5–10,000 hp N	Large variation	5:1 speed range. Low efficiency below 50% speed.
Eddy-current drive	Fractional ~2,000 + hp N Wiring-applied drives (on motor input)	\$900–\$60/hp (for 1–150 hp)	Reliable in clean areas, Relatively long life. Low efficiency below 50% speed.
<i>Electronic ASDs</i>			
Voltage-source inverter	Fractional—1500 hp R, N	\$300–\$80/hp (for 1–300 hp)	Multimotor capability. Can generally use existing motor. PWM <sup>c</sup> appears most promising.
Current-source inverter	100–100,000 hp R, N	\$120–\$50/hp (for 100–20,000 hp)	Larger and heavier than VSI Industrial applications, including large synchronous motors.
Others	Fractional—100,000 hp R, N	Large variation	Includes cycloconverters, wound rotor, and variable voltage. Generally for special industrial applications.

<sup>a</sup> PAM means pole amplitude modulated.

<sup>b</sup> The prices are listed from high to low to correspond with the power rating, which is listed from low to high. Thus, the lower the power rating, the higher the cost per horsepower.

<sup>c</sup> PWM means pulse width modulation.

(working all the time below 50% of capacity) present not only lower efficiency (as shown in Figure 28.16) but also poor power factor (NEMA, 1999). The efficiency drops significantly when a motor operates lightly loaded (below 40% for a standard motor). The power factor drops continuously from full load. The decrease in performance is especially noticeable in small motors and standard-efficiency motors.

It is therefore essential to size new motors correctly and to identify motors that run grossly underloaded all the time. In the last case, the economics of replacement by a correctly sized motor should be considered. Considerations include the load at which the motor is most efficient, difference in efficiency between current and correctly sized motor, and practicality of mounting smaller sized motor. In medium or large industrial plants, where a stock of motors is normally available, oversized motors may be exchanged for the correct size versions.

### 28.2.5 Power Quality

Electric motors, and in particular induction motors, are designed to operate with optimal performance when fed by symmetrical three-phase sinusoidal waveforms with the

**FIGURE 28.16**

Typical efficiency vs. load curves for 1800 rpm, three-phase 60 Hz Design B squirrel-cage induction motors. (Reprinted from Nadel, S. et al., *Energy-Efficient Motor Systems: A Handbook on Technologies, Programs, and Policy Opportunities*, 2nd edn., American Council for an Energy-Efficient Economy, Washington, DC, 2002. With permission.)

nominal voltage value. Deviations from these ideal conditions may cause significant deterioration of the motor efficiency and lifetime. Possible power quality problems include voltage unbalance, undervoltage or overvoltage, and harmonics and interference. Harmonics and interference can be caused by, as well as affect, motor systems.

### 28.2.5.1 Voltage Unbalance

Induction motors are designed to operate at their best with three-phase balanced sinusoidal voltages. When the three-phase voltages are not equal, the losses increase substantially. Phase unbalance is normally caused by an unequal distribution of the single-phase loads (such as lighting) on the three phases or by faulty conditions. An unbalanced supply can be mathematically represented by two balanced systems rotating in opposite directions. The system rotating in the opposite direction to the motor induces currents in the rotor that heat the motor and decrease the torque. Even a modest phase unbalance of 2% can increase the losses by 25% (Cummings et al., 1985).

When a phase unbalance is present, the motor must be derated according to [Figure 28.17](#).

### 28.2.5.2 Voltage Level

When an induction motor is operated above or below its rated voltage, its efficiency and power factor change. If the motor is underloaded, a voltage reduction may be beneficial, but for a properly sized motor, the best overall performance is achieved at the rated voltage. The voltage fluctuations are normally associated with ohmic (IR) voltage drops or with reactive power (poor power factor) flow in the distribution network (see Section 28.2.6).

### 28.2.5.3 Harmonics and Electromagnetic Interference

When harmonics are present in the motor supply, they heat the motor and do not produce useful torque. This in turn affects the motor lifetime and causes a derating of the motor

**FIGURE 28.17**

Derating factor due to unbalanced voltage for integral-horsepower motors. (Reprinted from Nadel, S. et al., *Energy-Efficient Motor Systems: A Handbook on Technologies, Programs, and Policy Opportunities*, 1st edn., American Council for an Energy-Efficient Economy, Washington, DC, 1992. With permission.)

capacity. This is also true when motors are supplied by ASDs that generate the harmonics themselves. The use of premium-efficiency motors can alleviate these problems due to their higher efficiency and thermal capacity; there are also motors specially designed for use with ASDs known as inverter-duty motors.

Reduction of harmonics is also important for the benefit of other consumer and utility equipment. Harmonics, caused by nonlinear loads such as the semiconductor switches in ASDs, should be reduced to an acceptable level as close as possible to the source. The most common technique uses inductive/capacitive filters at the ASD input circuit to provide a shunt path for the harmonics and to perform power factor compensation.

IEEE Standard No. 519 (IEEE, 1992) contains guidelines for harmonic control and reactive power compensation of power converters. The cost of the harmonic filter to meet this standard is typically around 5% of the cost of the ASD.

ASD power semiconductor switches operate with fast switching speeds to decrease energy losses. The fast transitions in the waveforms contain high-frequency harmonics, including those in the radio-frequency range. These high-frequency components can produce electromagnetic interference (EMI) through both conduction and radiation. The best way to deal with EMI is to suppress it at the source. Radiated EMI is suppressed through shielding and grounding of the ASD enclosure. Proper ASD design, the use of a dedicated feeder, and the use of a low-pass input filter (an inductor; often called a *line reactor*), will normally suppress conducted EMI.

## 28.2.6 Distribution Losses

### 28.2.6.1 Cable Sizing

The currents supplied to the motors in any given installation will produce Joule ( $I^2R$ ) losses in the distribution cables and transformers of the consumer. Correct sizing of the cables will not only allow a cost-effective minimization of those losses but also help decrease the

voltage drop between the transformer and the motor. The use of the National Electrical Code for sizing conductors leads to cable sizes that prevent overheating and allow adequate starting current to the motors, but can be far from an energy-efficient design. For example, when feeding a 100 hp motor located at 150 m from the transformer with a cable sized using NEC, about 4% of the power will be lost in heating the cable (Howe et al., 1999). Considering a 2-year payback, it is normally economical to use a cable one wire size larger than the one required by the NEC.

#### **28.2.6.2 Reactive Power Compensation**

In most industrial consumers, the main reason for a poor power factor is the widespread application of oversized induction motors. Correcting oversizing can thus contribute in many cases to a significant improvement of the power factor.

Reactive power compensation, through the application of correction capacitors, not only reduces the losses in the network but also allows full use of the power capacity of the power system components (cables, transformers, circuit breakers, etc.). In addition, voltage fluctuations are reduced, thus helping the motor to operate closer to its design voltage.

#### **28.2.7 Mechanical Transmissions**

The transmission subsystem transfers the mechanical power from the motor to the motor-driven equipment. To achieve overall high efficiency, it is necessary to use simple, properly maintained transmissions with low losses. The choice of transmission is dependent upon many factors including speed ratio desired, horsepower, layout of the shafts, and type of mechanical load.

Transmission types available include direct shaft couplings, gearboxes, chains, and belts. Belt transmissions offer significant potential for savings. About one-third of motor transmissions use belts (Howe et al., 1999). Several types of belts can be used such as V-belts, cogged V-belts, and synchronous belts.

V-belts have efficiencies in the 90%–96% range. V-belt losses are associated with flexing, slippage, and a small percentage due to windage. With wear, the V-belt stretches and needs retensioning, otherwise the slippage increases and the efficiency drops. Cogged V-belts have lower flexing losses and have better gripping on the pulleys, leading to 2%–3% efficiency improvement when compared with standard V-belts.

Synchronous belts can be 98%–99% efficient as they have no slippage and have low flexing losses; they typically last over twice as long as V-belts, leading to savings in avoided replacements that more than offset their extra cost. [Figure 28.18](#) shows the relative performance of V-belts and synchronous belts. The efficiency gains increase with light loads.

#### **28.2.8 Maintenance**

Regular maintenance (such as inspection, adjustment, cleaning, filter replacement, lubrication, and tool sharpening) is essential to maintain peak performance of the mechanical parts and to extend their operating lifetime. Both under- and overlubrication can cause higher friction losses in the bearings and shorten the bearing lifetime. Additionally, overgreasing can cause the accumulation of grease and dirt on the motor windings, leading to overheating and premature failure.

The mechanical efficiency of the driven equipment (pump, fan, cutter, etc.) directly affects the overall system efficiency. Monitoring wear and erosion in this equipment is

**FIGURE 28.18**

Efficiency vs. torque for V-belts and synchronous belts in a typical application. (Reprinted from Nadel, S. et al., *Energy-Efficient Motor Systems: A Handbook on Technologies, Programs, and Policy Opportunities*, 1st edn., American Council for an Energy-Efficient Economy, Washington, DC, 1992. With permission.)

especially important as its efficiency can be dramatically affected. For example, in chemical process industries, the erosion of the pump impeller will cause the pump efficiency to drop sharply; a dull cutter will do the same to a machine tool.

Cleaning the motor casing is also relevant because its operating temperature increases as dust and dirt accumulates on the case. The same can be said about providing a cool environment for the motor. A temperature increase leads to an increase of the windings' resistivity and therefore to larger losses. An increase of 25°C (45°F) in the motor temperature increases the Joule losses by 10%.

## 28.3 Energy-Saving Applications of ASDs

Typical loads that may benefit from the use of ASDs include those covered in the following four sections.

### 28.3.1 Pumps and Fans

In many pumps and fans where there are significant variable-flow requirements (i.e., where a significant portion of the system operating hours occurs at various partial loads), substantial savings can be achieved, as the power is roughly proportional to the cube of the flow (and thus speed of the motor). The use of ASDs instead of throttling valves with pumps shows similar behavior to that for fans in [Figure 28.11](#). In applications where the majority of the system operation occurs at a single partial load, other techniques, such as pump impeller trimming and changing fan speed, may lead to

greater savings than installation of an ASD. The use of ASDs can in many cases allow fans to be driven directly from the motor, eliminating the belt drive with its losses and maintenance requirements.

### 28.3.2 Centrifugal Compressors and Chillers

Most industrial compressed air systems have significant savings potential. Well-engineered efficiency improvements yield verified savings in the range of 15%–30% of system energy consumption (Fraunhofer Institute, 2000). Furthermore, in the United States, it is estimated that 21% of the overall compressed air system energy use from 15 industrial sectors could be saved through the implementation of cost-effective energy-saving measures (McKane and Hasanbeigi, 2010).

Centrifugal compressors and chillers can take advantage of motor controls in the same way as other centrifugal loads (pumps and fans). The use of wasteful throttling devices or the on–off cycling of the equipment can be largely avoided, resulting in both energy savings and extended equipment lifetime. Since motors driven by ASDs can operate at higher speeds than those operating at line frequency, speed-up gearboxes can be eliminated, saving energy, first cost, and maintenance cost.

Savings from compressed air measures are mostly coincident with electric system peak periods. Plant air systems normally have a large duty factor, typically operating 5000–8000 h/year. Thus, energy and demand reductions are very likely to occur at system peaks and contribute to system reliability. Compressed air system efficiency improvements are highly cost-effective and additionally lead to reduced plant downtime. Many projects have been identified with significant energy and demand reduction potential and paybacks less than 2 years (XENERGY, 2001).

### 28.3.3 Conveyors

The use of speed controls, in both horizontal and inclined conveyors, allows the matching of speed to material flow. As the conveyor friction torque is constant, energy savings are obtained when the conveyor is operated at reduced speed. In long conveyors, such as those found in power plants and in the mining industry, the benefits of soft-start without the need for complex auxiliary equipment are also significant (De Almeida et al., 2005).

For horizontal conveyors (Figure 28.19), the torque is approximately independent of the transported load (it is only friction dependent). Typically, the materials handling output of a conveyor is controlled through regulating the material input, and the torque and speed are roughly constant. But if the materials input to the conveyor is changed, it is possible to

**FIGURE 28.19**

Power required by a conveyor.

**FIGURE 28.20**

Energy savings in a conveyor using speed control, in relation to the typical constant speed.

reduce the speed (the torque is the same), and, as can be seen in Figure 28.20, significant energy savings can be achieved, proportional to the speed reduction.

### 28.3.4 High-Performance Applications

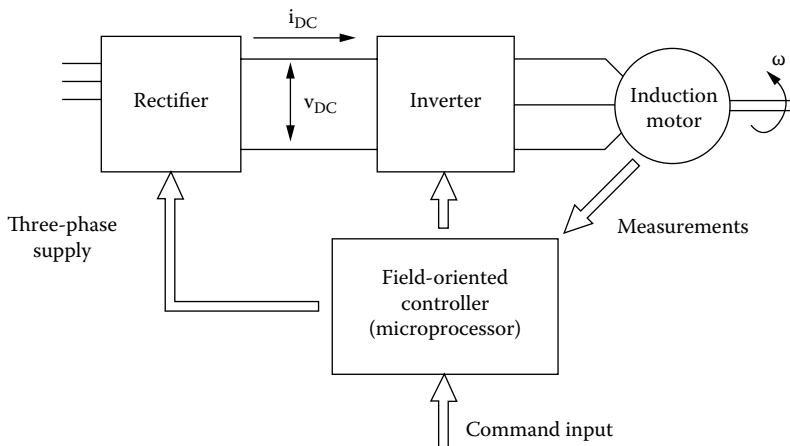

AC motors have received much attention in recent years as a proposed replacement for DC motors in high-performance speed control applications, where torque and speed must be independently controlled. Induction motors are much more reliable, more compact, more efficient, and less expensive to buy and maintain than DC motors. As induction motors have no carbon brush commutation, they are especially suitable for corrosive and explosive environments. In the past, induction motors have been difficult to control as they behave as complex nonlinear systems. However, the appearance on the market of powerful and inexpensive microprocessors has made it possible to implement in real time the complex algorithms required for induction motor control.

Field-oriented control, also called vector control, allows accurate control of the speed and torque of induction motors, in a way similar to DC motor control (Leonhard, 1984). The motor current and voltage waveforms, together with motor position feedback, are processed in real time, allowing the motor current to be decomposed into speed producing component and into a torque producing component. Vector control operation principle is represented in Figure 28.21 and is being applied to a wide variety of high-performance applications described next.

Rolling mills were one of the strongholds of DC motors, due to the accurate speed and torque requirements. With present ASD technology, AC drives can outperform DC drives in all technical aspects (reliability, torque/speed performance, maximum power, efficiency) and are capable of accurate control down to zero speed.

The availability of large diameter, high torque, and low speed AC drives makes them suitable for use in applications like ball mills and rotary kilns without the need for gear-boxes. This area was also a stronghold of DC drives. Again, AC drives have the capability to offer superior performance in terms of reliability, power density, overload capability, efficiency, and dynamic characteristics.

AC traction drives can also feature regenerative braking. AC traction drives are already being used in trains, rapid transit systems, and ship propulsion and are the proper choice for the electric automobile.

**FIGURE 28.21**

Schematic of a vector-control drive (also known as a field-oriented control). (Reprinted from Nadel, S. et al., *Energy-Efficient Motor Systems: A Handbook on Technologies, Programs, and Policy Opportunities*, 1st edn., American Council for an Energy-Efficient Economy, Washington, DC, 1992. With permission.)

DC drives have traditionally been used with winders in the paper and steel industry in order to achieve the constant tension requirements as the winding is performed. Sometimes the constant tension is obtained by imposing friction, which wastes energy. AC drives can also be used to replace DC drives, saving energy, and achieving better overall performance.

The use of field-oriented AC drives in machine tools and robotics allows the stringent requirements regarding dynamic performance to be met. Positioning drives can produce a peak torque up to 10 times the rated torque and make it possible to adjust the speed to very low values.

In machine tools, AC drives can provide accurate higher spindle speeds than DC drives without the need for gearboxes and their associated losses. The ASDs can also adjust the voltage level when the spindle drive is lightly loaded, providing further savings. In robotics, the higher power density and superior dynamics of AC drives are important advantages.

## 28.4 Energy and Power Savings Potential; Cost-Effectiveness

The energy and peak power savings potential for any motor-related technology depends on a number of factors, including the characteristics of the motor, the motor drive, the driven equipment, and the load (Nadel et al., 2002). Since all of this information is seldom available, it is difficult to determine the effect of even a single application; it is far more difficult to determine the savings potential for diverse applications, across all sectors, for an entire nation.

A 2010 UNIDO study made an initial effort to categorize the energy saving potential—both technical and cost effective—of measures frequently undertaken to improve the energy efficiency of industrial compressed air, pumping, and fan systems in several countries/regions (the United States, Canada, the European Union, Thailand, Vietnam, and Brazil) through combining available data and expert opinion. For example, the study finds

that 25% of 2008 motor system energy used in the United States could be saved through implementing cost-effective measures. However, the study highlighted the lack of current installed motor system efficiency data as a substantial barrier to the analysis. The full report is available online (McKane and Hasanbeigi, 2010).

A 2013 study by the U.S. DOE estimated that the technical annual energy savings potential from upgrading motors and implementing ASDs in the residential sector is approximately 0.54 quads of the 4.73 quads of motor driven energy consumption (includes electricity generation, transmission, and distribution losses) in the sector. Similarly, the report estimated that the technical annual energy savings from upgrading motors in the commercial sector is 0.46 quads of the total 4.87 quads (includes electricity generation, transmission, and distribution losses) of motor driven energy consumption in the sector and 0.53 quads could be saved through implementing ASDs. The report states that total savings potential in the commercial sector from upgrading motors and implementing ASDs would be less than the sum of the individual saving estimates.

This section estimates the energy and power savings that could be realized nationwide in the United States through the application of certain efficiency technologies in the residential, commercial, industrial, and utility sectors. Table 28.2 lists the major motor-driven end-uses, estimates of their energy use as a percentage of total national electricity use (based on Howe et al., 1999; Nadel et al., 2002), and the potential energy savings from ASDs expressed as a fraction of existing use.

**TABLE 28.2**

Electric Motor Usage and Potential Adjustable-Speed Drive Savings by Sector and End Use

Sector	End Use	Usage (% of Total U.S. Usage)	Potential ASD Savings (% of Usage for Each End Use)
Residential	Refrigeration	3.0	10
	Space heating	2.1	20
	Air-conditioning	3.4	15
	HVAC dist. fan	1.8	25
	Others	1.6	5
	Residential total	11.9	15
Commercial	Refrigeration	2.2	10
	HVAC compressors	3.3	15
	HVAC distribution	4.2	25
	Others	0.7	20
	Commercial total	10.4	18
Industrial	Refrigeration	1.5	10
	Pumps	5.7	20
	Fans	3.2	20
	Compressed air	3.6	15
	Material handling	2.8	15
	Material process	5.2	15
	Others	1.0	0
	Industrial total	23.1	16
Utilities	Pumps and fans	4.9	15
	Material handling and processing	2.2	15
	Utilities total	7.1	19

### 28.4.1 Potential Savings in the Residential Sector

About 38% of residential electricity is used in motor systems. The primary motor technology for realizing energy and power savings in the residential sector is the electronic ASD. Heat pumps, air conditioners, forced-air furnaces, and washing machines with ASDs have already been introduced into the market. Other appliances, such as refrigerators, freezers, heat-pump water heaters, and evaporative coolers, are also potential candidates for adjustable-speed controls. Most of the energy-saving potential of ASDs in the home is associated with the use of refrigerant compressors for cooling or heating (as in heat pumps, air conditioners, refrigerators, and freezers). In all of these applications, ASDs can reduce energy consumption by matching the speed of the compressor to the instantaneous thermal load. Given the assumed savings potential for each end use, the overall savings is about 15% of the sector's motor electricity.

Several improvements in home appliance technology that are likely to become common over the next few years will complement the use of ASDs:

- *High-efficiency compressor and fan motors:* The use of PM and reluctance motors can increase the efficiency of the motor by 5%–15%, when compared with conventional squirrel-cage single-phase induction motors; as noted earlier, even larger savings are possible with many small fan motors. PM AC motors are used in the latest ASD-equipped furnace and heat pump.
- *Rotary and scroll compressors:* The use of rotary (in small applications) or scroll compressors in place of reciprocating compressors can take full advantage of the speed variation potential of ASDs.
- *Larger heat exchangers with improved design:* Improved heat exchangers increase the efficiency by decreasing the temperature difference of the compressor thermal cycle.

### 28.4.2 Potential Savings in the Commercial Sector

An estimated 37% of commercial electricity use is for motor-driven end uses (Howe et al., 1999); the percentage for peak power is higher. The savings potential of ASDs in air-conditioning and ventilation applications was estimated by running DOE-2 computer simulations on two representative building types in five U.S. cities (Eto and de Almeida, 1988). Comparisons were made between the cooling and ventilation systems with and without ASDs. The results indicate ventilation savings of approximately 25% for energy and 6% for peak power, and cooling savings of about 15% and 0%, respectively. In [Table 28.2](#), it is assumed that these energy results can be applied nationwide.

The estimated 10% energy savings for refrigeration are shown in [Table 28.2](#); an estimated 5% savings in peak power should also be attainable. Other motor efficiency measures (discussed in [Section 28.2](#)) combined can capture approximately 10% more energy and demand savings, with an overall potential savings of about 18% of the sector's motor system electricity.

### 28.4.3 Potential Savings in the Industrial and Utility Sectors

About 70% of industrial and 89% of the utility sector electricity use is for motor systems. In [Table 28.2](#), the fluid moving end-use savings are estimated at 20%, except for utilities, where the system requirements of municipal water works limit the savings. Compressed air and materials applications are assumed to have 15% potential.

As most industries are nonseasonal, with flat load profiles during operating hours, the peak savings are similar to energy savings. When other motor efficiency measures (see Section 28.2) are combined, approximately 10% more energy and demand savings can be obtained, resulting in a total of 18% combined savings for the motor systems in these sectors.

#### 28.4.4 Cost-Effectiveness of ASDs

The price of ASD equipment, in terms of cost/horsepower, is a function of the horsepower range, the type of AC motor used, and the additional control and protection facilities offered by the electronic ASD. ASD installation costs vary tremendously depending on whether the application is new or retrofit, available space, weather protection considerations, labor rates, etc. Thus, there is a huge range of installed costs possible for any given ASD size, and the costs listed in Table 28.3 necessarily have large uncertainties. These numbers are presented in their original units of Euros and kW.

To determine whether an ASD is cost-effective for any given application, the following need to be taken into account:

- First cost (acquisition and installation)
- System operating load profile (number of hours per year at each level of load)
- Motor and drive performance curves as a function of load
- Cost of electricity
- Maintenance requirements
- Reliability
- Secondary benefits (less wear on equipment, less operating noise, regeneration capability, improved control, soft-start, and automatic protection features)
- Secondary problems (power factor, harmonics, and interference)

A careful analysis should weigh the value of the benefits offered by each option against the secondary problems, such as power quality, that may impose extra costs for filters and power factor correction capacitors.

Comparing the cost of conserved energy to the cost of electricity is a crude way to assess the cost-effectiveness of energy efficiency measures. More accurate calculations would account for the time at which conservation measures save energy relative to the utility system peak demand, and relate these *load shape characteristics* to baseload, intermediate, and peaking supply resources. See Koomey et al. (1990a,b) for more details.

**TABLE 28.3**

Typical ASD Unit and Installation Costs for Various Sizes

Power (kW)	Unit Price (€)	Installation Costs (€)
0.12–0.75	200	50%–300%
0.75–2.1	280	50%–250%
7.5–45	1,130	50%–200%
76–110	5,320	50%–175%
375–1000	41,790	50%–150%

## 29.1 Introduction

The industrial sector in the United States is highly diverse—consisting of manufacturing, mining, agriculture, and construction activities—and consumes one-third of the nation's primary energy use, at an annual cost of around \$200 billion.<sup>1</sup> The industrial sector encompasses more than three million establishments engaged in manufacturing, agriculture, forestry, construction, and mining. These industries require energy to light, heat, cool, and ventilate facilities (end uses characterized as energy needed for comfort). They also use energy to harvest crops, process livestock, drill and extract minerals, power various manufacturing processes, move equipment and material, raise steam, and generate electricity. Some industries require additional energy fuels for use as raw materials—or feedstocks—in their production processes. Many industries use by-product fuels to satisfy part or most of their energy requirements. In the more energy-intensive manufacturing and nonmanufacturing industries, energy used by processes dwarfs the energy demand for comfort.

The U.S. sector energy use for 2014 is shown in Figure 29.1, industrial energy use is shown in Figure 29.2, and industrial electricity use is shown in Figure 29.3.

Manufacturing companies, which use mechanical or chemical processes to transform materials or substances to new products, account for about 69% of the total industrial sector use. The “big three” in energy use are petroleum, chemicals, and paper; these manufacturers together consume almost one-half of all industrial energy. The “big six,” which adds the primary metals group, the food and kindred products group, as well as the stone, clay, and glass group, together accounts for 88% of manufacturing energy use, and over 60% of all industrial sector energy consumption.<sup>1</sup>

**FIGURE 29.1**

The U.S. energy use by sector, 2014. (From U.S. DOE, Energy Information Agency, Monthly Energy Review, Washington, DC, March 27, 2014; U.S. Department of Energy, Office of Industrial Technologies, Industrial Technology Program, Washington, DC, 2005.)

**FIGURE 29.2**

Manufacturing energy use 2006 (end-use basis). (From U.S. Department of Energy, Energy Information Agency, Manufacturing Energy Consumption Survey, Washington, DC, September 2012.)

**FIGURE 29.3**

Manufacturing electrical energy use 2006 (end-use basis) (From U.S. Department of Energy, Energy Information Agency, Manufacturing Energy Consumption Survey, 2006, Washington, DC, 2002.)

According to the U.S. Energy Information Administration, energy efficiency in the manufacturing sector improved by 25% over the period 1980–1985.<sup>2</sup> During that time, manufacturing energy use declined 19%, and output increased 8%. These changes resulted in an overall improvement in energy efficiency of 25%. However, the “big five” did not match this overall improvement; although their energy use declined 2%, their output decreased by 5%, resulting in only a 17% improvement in energy efficiency during 1980–1985.

This 5-year record of improvement in energy efficiency of the manufacturing sector came to an end, with total energy use in the sector growing by 10% from 1986 to 1988, and overall manufacturing energy intensity stagnated during 1985–1994 due to falling and low energy prices, economic recession during part of this period, and a recovery in some of the more energy-intensive groups such as steel and aluminum production. However, industrial energy intensity again declined significantly during the late 1990s due to high capital investment, rapid industrial modernization, and explosive growth of “high-tech” industries that are not energy-intensive.

Since 1980, the overall value of industrial output increased through 2003, while the total energy consumed by the industrial sector has fallen overall throughout 2003.<sup>3</sup> This relationship is shown in Figure 29.4, where the consumption index for both primary and site energy is greater than the output index before 1980, and less afterward, with the gap consistently widening in the late 1980s. New energy-efficient technology and the changing production mix from the manufacture of energy-intensive products to less intensive products are responsible for this change.

Continuing this overall record of energy efficiency improvements in industry will require emphasis on energy management activities, as well as making capital investments in new plant processes and facilities improvements. Reducing the energy costs per unit of manufactured product is one way that the United States can become more competitive in the global industrial market. The U.S. Department of Energy has formally recognized these multiple benefits to the country by including the following statement in its 2004 Industrial Technology Program Report: “By developing and adopting more energy efficiency technologies, U.S. industry can boost its productivity and competitiveness while strengthening national energy security, improving the environment, and reducing emissions linked to global climate change.”<sup>4</sup> Additionally, it is interesting to note that

**FIGURE 29.4**

Industrial energy intensity 1980–2003. (From NAM, *Efficiency and Innovation in U.S. Manufacturing Energy Use*, National Association of Manufacturers, Washington, DC, 2005. With permission.)

Japan—one of the United States' major industrial competitors—has a law that says every industrial plant must have a full-time energy manager.<sup>5</sup>

Manufacturing energy intensity continued its gradual drop, as documented by the National Renewable Energy Laboratory report in 2009 showing the industrial use of Btu per dollar of gross domestic product fell by 20% from 1998 to 2007 (Ref. #7).

Several studies of industrial energy efficiency have been performed in recent years, and the results from the studies show that there is a readily achievable, cost-effective, 20% reduction in industrial consumption using good energy management practices and energy-efficient equipment. One highly credible study that has been done of the potential for industrial energy efficiency improvement in the United States is the "Energy Use, Loss and Opportunities Analysis: U.S. Manufacturing and Mining" report issued by the U.S. Department of Energy, Office of Industrial Technologies (OIT), in December 2004.<sup>1</sup> This report, together with the report on "Efficiency and Innovation in U.S. Manufacturing Energy Use" from the National Association of Manufacturers (NAM), conducted with the Alliance to Save Energy, makes a strong and very credible case for the achievement of a 20% savings in energy for the industrial sector.<sup>3</sup>

Earlier studies by the national laboratories in the United States produced a composite report, "Scenarios for a Clean Energy Future," in 2000 that also supported the achievement of a 20% reduction in industrial energy use. One element of this study was to examine data from the Industrial Assessment Center (IAC) Program (discussed in more detail later in this chapter) from 12,000 plant energy audits making 82,000 recommendations for actions to increase energy efficiency in the facilities audited.<sup>6</sup> Results from these real-world energy audits also supported the 20% reduction estimate.

Other groups, such as Lawrence Berkeley Laboratory, have performed studies of industrial energy efficiency, and their results from their studies show improvements of 20% or greater in industrial energy efficiency.<sup>7</sup> A recent study from the American Council for an Energy-Efficient Economy (ACEEE) showed the potential for a 40% reduction in electricity use for fan and pumping applications in industry.<sup>8</sup> Specific details and recommendations from these studies are presented in Section 29.5.

The most recent projections of the energy efficiency gains available in the manufacturing sector comes from the ACEEE, which in their January 2012 report (Ref. #29), "The Long Term Energy Efficiency Potential: What the Evidence Suggests," provided three different scenarios for energy consumption in the United States, and in the industrial sector, of between 40% and 58% reduction in energy use relative to their 2050 base case. The executive summary of their report is as follows:

In 2010 the U.S. used just under 100 quads of total energy resources to power our economy. Using the Energy Information Administration's (EIA) Annual Energy Outlook we project that our total energy needs might rise to about 122 quads of energy by the year 2050. In this report we explore a set of energy efficiency scenarios that emphasizes a more productive investment pattern, one that can enable the U.S. economy to substantially lower overall energy expenditures should we choose to invest in and develop that larger opportunity. Building on the historical record of energy efficiency investments and their contribution to the nation's economic well being, we highlight three economy wide, long term scenarios to explore the potential contributions that more energy efficient behaviors and investments might play in reducing overall energy use by the year 2050. These three are

1. *Reference case*: A continuation of trends projected by EIA for the 2030–2035 period
2. *Advanced scenario*: It includes penetration of known advanced technologies

3. *Phoenix scenario*: In addition to advanced technologies also includes greater infrastructure improvements and some displacement of existing stock to make way for newer and more productive energy efficiency technologies, as well as configurations of the built environment that reduce energy requirements for mobility

For the industrial sector, energy intensity is projected to improve in the Reference Case by about 1%/year through 2050, but leading companies have been achieving continued improvements at more than double this rate. In our Advanced Scenario we project a 2%/year improvement rate for overall industrial energy intensity, which increases to 2.75% in our Phoenix Scenario. Future energy efficiency opportunities will come less from seeking out individual sources of waste and more from optimization of complex systems enabled by advances in information, communication and computational infrastructure. Most of the energy use in industry is in processes, not individual equipment, so improved processes represent the largest opportunity for energy intensity improvements. Current focus has been on process optimization, but we anticipate that even greater opportunities exist in the optimization of entire supply chains that may span many companies and supply chain integration that allows for efficient use of feedstocks and elimination of wasted production.

The really good news in the ACEEE study is that there is a tremendous potential for saving energy in the industrial sector, which is mainly the manufacturing sector. For their Advanced Scenario, which projects a 2%/year reduction in industrial energy intensity, this means that energy use in the industrial sector would fall to half its value in 2010 by 2045, a 35-year period.

## 29.2 Industrial Energy Management and Efficiency Improvement

### 29.2.1 Setting Up an Energy Management Program

The effectiveness of energy utilization varies with specific industrial operations because of the diversity of the products and the processes required to manufacture them. The organization of personnel and operations involved also varies. Consequently, an effective energy management program should be tailored for each company and its plant operations. There are some generalized guidelines, however, for initiating and implementing an energy management program. Many large companies have already instituted energy management programs and have realized substantial savings in fuel and electric costs. Smaller industries and plants, however, often lack the technical personnel and equipment to institute and carry out effective programs. In these situations, reliance on external consultants may be appropriate to initiate the program. Internal participation, however, is essential for success. A well planned, organized, and executed energy management program requires a strong commitment by top management.

Assistance also can be obtained from local utilities. Utility participation would include help in getting the customer started on an energy management program, technical guidance, or making information available. Most electric and gas utilities today have active programs that include training of customer personnel or provision of technical assistance. [Table 29.1](#) summarizes the elements of an effective energy management program. These are discussed further in more detail.

**TABLE 29.1****Elements of an Energy Management Program***Phase 1: Management Commitment*

- 1.1 Commitment by management to an energy management program
- 1.2 Assignment of an energy management coordinator
- 1.3 Creation of an energy management committee of major plant and department representatives

*Phase 2: Audit and Analysis*

- 2.1 Review of historical patterns of fuel and energy use
- 2.2 Facility walk-through survey
- 2.3 Preliminary analyses, review of drawings, data sheets, equipment specifications
- 2.4 Development of energy audit plans
- 2.5 Conduct facility energy audit, covering
  - a. Processes
  - b. Facilities and equipment
- 2.6 Calculation of annual energy use based on audit results
- 2.7 Comparison with historical records
- 2.8 Analysis and simulation step (engineering calculations, heat and mass balances, theoretical efficiency calculations, computer analysis, and simulation) to evaluate energy management options
- 2.9 Economic analysis of selected energy management options (life cycle costs, rate of return, benefit–cost ratio)

*Phase 3: Implementation and Submitters*

- 3.1 Establish energy effectiveness goals for the organization and individual plants
- 3.2 Determine capital investment requirements and priorities
- 3.3 Establish measurement and reporting procedures, install monitoring and recording instruments as required
- 3.4 Institute routine reporting procedures (“energy tracking” charts) for managers and publicize results
